out-of-order data. For instance, CEDR suggests a solution based on stream-relational algebra using several timestamps per tuple (Barga et al. 2007). One challenge that is particular to SQL-like languages is how to extend them with user-defined operators without losing the well-definedness of the restricted algebra. For instance, StreamInsight addresses this issue with an extensibility framework (Ali et al. 2011). Finally, the semantics of SQL are defined by reevaluating relational operators on windows whenever the window contents change. Nobody suggests that this reevaluation is the most efficient approach, but developing better solutions is an interesting research challenge. For instance, the DABA algorithm performs associative sliding-window aggregation on FIFO windows in worst-case constant time (Tangwongsan et al. 2017). All three of the abovementioned research topics (out-of-order processing, extensibility, and incremental streaming algorithms) are still ripe with open issues.

Continuous Query Optimization

► Stream Query Optimization

Coordination Avoidance

Faisal Nawab

University of California, Santa Cruz, CA, USA

Definitions

Coordination avoidance denotes a class of distributed system methods that minimize the amount of coordination between nodes while maintaining the integrity of the application.

Overview

In many data management systems, data and processing are replicated or distributed across nodes (Kemme et al. 2010; Bernstein and Goodman 1981). This replication and distribution increase the levels of fault tolerance and availability. However, they introduce a coordination cost to maintain the integrity of applications. Since nodes are processing data for the same application simultaneously, there is the possibility of conflicting operations that may overwrite the work of other nodes. To overcome this problem, coordination and synchronization protocols have been developed to ensure the integrity of data. Typically, the coordination protocols strive to ensure a guarantee of correctness, such as serializability (Bernstein et al. 1987) and linearizability (Herlihy and Wing 1990). These are strong notions of correctness that model the correctness of a distributed system by whether the data management system can mask the underlying concurrency from the upper layers. Serializability, for example, guarantees that the outcome of the execution of distributed transactions (i.e., bundles of operations) is equivalent to some serial execution.

Thus, the application developer has the illusion of the existence of a single machine that executes transactions serially.

A strong guarantee of correctness is extremely useful for application developers because it frees them from thinking about concurrency and replication issues. Additionally, relying on the application level to deal with concurrency anomalies is error-prone and may lead to many wasted efforts in applications reinventing the wheel. Rather, the data management approach separates concerns and relies on a data management layer to manage concurrency and replication to guarantee the consistency of the application. However, these approaches are expensive, requiring extensive coordination between nodes, as any two operations touching the same data item need to be synchronized. Data management systems tackled this problem by building better coordination and synchronization designs and protocols to optimize performance. Unfortunately, this continues to be a challenging task as distributed systems are becoming bigger with large-scale many-node and many-core deployments that increase the coordination and communication demands. Also, distributed systems are increasingly being deployed across wide geographical locations, increasing the latency of communication. These two trends continue to be adopted and are made accessible through cloud technology. To reduce the cost of coordination, there have been approaches that relax the consistency guarantees and trade them off with better performance. This approach, however, does not retain the easy-to-use data management abstractions that can be provided with strong consistency guarantees.

Coordination avoidance aims to reduce the cost of coordination while maintaining the integrity of data and the easy-to-use data management abstractions. The approach of coordination avoidance exploits knowledge of the application layer to extract the set of consistency guarantees that are sufficient for its application-level correctness. Therefore, the cost of coordination is only incurred when there is a potential that it will lead to an anomaly. Extensions to coordination avoidance approaches build execution

models and abstractions that facilitate and enable avoiding coordination.

Key Research Findings

The goal of coordination avoidance techniques and protocols is to minimize the cost of coordination while retaining the application integrity. There have been a plethora of work that investigates such approaches. What these works have in common is attempting to leverage application-level semantics to deduce the set of guarantees that are sufficient for a consistent execution. They may take various forms that are presented in this section. Coordination avoidance techniques combine a subset of different approaches. Generally, a coordination avoidance protocol tackle two tasks: extracting or modeling a set of consistency semantics for a particular application and executing operations while minimizing coordination to the cases when only the set of extracted consistency semantics are threatened.

There are various approaches for extracting consistency semantics that vary in their ease of use, generality, and optimality, where coordination avoidance protocols typically face the trade-off between these three properties. One approach extracts consistency semantics from existing code via the use of static analysis or other similar methods. This approach requires the least intervention from application developers. However, it introduces the challenge of extracting features from general code which can be limited in its scope. Some other approaches rely on the application developers to annotate or model their code to enable extracting the consistency semantics. This approach requires additional intervention from the application developer, although allowing the use of existing general code. Alternatively, some works explore an approach where specialized frameworks and abstractions are introduced to facilitate and enable the extraction of consistency semantics. With the extracted features, there are various approaches to execute distributed applications that also vary in their ease of use, generality, and optimality. One approach is to selectively coordinate between nodes according

to the extracted consistency semantics. Another approach is to provide specialized protocols and execution mechanisms that guarantee the consistency semantics. The following are examples of coordination avoidance methods and work that combine and explore different extraction and execution approaches.

Commutativity and Convergence

A large number of coordination avoidance protocols leverage the commutativity of operations. Commutative operations are ones that can be reordered arbitrarily while reaching the same final state. Therefore, commutative operations can execute at different nodes in different orders without synchronously coordinating with other nodes. The operations are asynchronously propagated to other nodes that execute them without the need of any ordering. Commutative operations are especially useful for hot spots that are frequently being updated, such as counters. Many attempts have been made to generalize the notion of commutativity in the context of data management (Badrinath and Ramamritham 1992; Korth 1983). Recoverability (Badrinath and Ramamritham 1992) generalizes commutativity to include more operations by explicitly ordering commit points. For example, two operations pushing to a stack simultaneously are not commutative. However, with recoverability, they can execute concurrently while maintaining serializability with the condition that they commit in the order they are invoked. Korth (1983) generalizes locking to account for the existence of commutative operations and thus allow more concurrency when commutative operations are being used. Commutative operations can also be used in conjunction with other consistency guarantees. Walter (Sovran et al. 2011), for example, is a system that employs a consistency notion based on snapshot isolation. Walter allows commutative operations to be performed without coordination.

Convergent and commutative replicated data types (CRDTs) (Shapiro et al. 2011) are an approach to make the use of commutativity more powerful by designing access abstractions and data structures that are more general than

traditional commutative operations while still maintaining commutativity. This has led to the development of nontrivial data structures that perform complex operations while being commutative, thus requiring no coordination (Preguica et al. 2009). CRDTs are also used in the context of eventual consistency by providing a means to converge operations to the same, eventually consistent state. Also, it is used in coordination-free protocols to converge operations that do not need to be synchronously coordinated (Bailis et al. 2014).

CALM (Alvaro et al. 2011) is a principle that shows that a distributed program can be executed without coordination if the program's logic is monotone. This enables avoiding coordination by building programs that ensure logical monotonicity in addition to using analysis techniques to assist whether a given program is logically monotonic. Bloom is a domain-specific declarative language that facilitates leveraging the CALM principle to build coordination-free programs. In this approach, the whole program does not have to be monotonic, rather, it is possible to detect potential anomalies that need to be addressed by the developer.

Application-Level Correctness Semantics

Many data management system works utilize application-level invariants and correctness semantics to avoid coordination (Lamport 1976; Agrawal et al. 1993, 1994; Garcia-Molina 1983; Li et al. 2012; Roy et al. 2015; Bailis et al. 2014). In this approach, operations are allowed to execute and commit without coordination if the application-level correctness semantics are not violated. Lamport (1976) (as described in Agrawal et al. 1993) is the first to show that application-level semantics can be used to avoid coordination between certain types of transactions. Garcia-Molina (1983) introduced a design of a concurrency control protocol that leverages application-level correctness semantics. The protocol receives application-level semantics from users and then uses them to allow nonserializable schedules that do not violate the application's correctness semantics. To achieve this, the protocol divides

the transaction into steps and derives what steps can interleave with each other. Other works adopt a similar approach of dividing the transaction to find interleaving between the parts of the transaction. A set of work has shown that performing this division hierarchically may lead better results (Lynch 1983; Weikum 1985; Farrag and Özsu 1989). A formalization of the correctness of application-level consistency definitions is provided in Korth and Speegle (1988).

Defining how the application-level consistency semantics are expressed is important for the practicality of the solution (i.e., how accessible is the interface to developers) and the performance gains of the solution (i.e., how the interface can maximize the amount of captured knowledge). Agrawal et al. (1993) propose the use of special operations, called consistency assertions, that captures a user's view of the database and the criterion for correct concurrency execution. Two correctness criteria are developed to leverage the special operations by making the database allow concurrent execution of two transactions if the consistency assertions are not violated. Relative serializability (Agrawal et al. 1994) extends the transaction model by allowing users to define the atomicity requirements of transactions relative to each other. Then, it is possible to interleave parts of transactions that do not violate the defined atomicity requirements.

The use of application-level correctness invariants is especially important for large-scale and geo-scale deployments where the coordination cost is high. This has motivated the development of more solutions that use application-level correctness invariants for these new architectures (Li et al. 2012; Roy et al. 2015; Bailis et al. 2014; Zhang et al. 2013). Gemini (Li et al. 2012) enables the coexistence of fast, eventually consistent operations with strongly consistent, slow operations. Therefore, operations are executed with high performance, and the cost of enforcing consistency is only paid when necessary. To facilitate this, a consistency model, called RedBlue consistency, is proposed. Using the consistency formulation and application-level consistency invariants, operations are assigned to

be either fast or consistent. The assignment is made with the guarantee that executing fast operations without synchronous coordination would not lead to violations of the application-level consistency semantics. Specifically, fast operations execute locally at one of the data centers and then lazily propagate to other data centers. Fast operations are only guaranteed to be causally ordered. Consistent operations, on the other hand, are synchronously synchronized, potentially with other data centers, leading to high latency. To be either the Homeostasis protocol (Roy et al. 2015) aims at automating the process of generating application-level correctness invariants. A program analysis technique is used to extract the application-level consistency invariants from code. In the Homeostasis protocol, the target consistency level is serializability, and the code is analyzed to extract the invariants that will lead to a serializable execution as observed by users. Application developers can then refine the extracted application-level correctness invariants. The Homeostasis protocol may enable and inspire future work on the use of automatic extraction of correctness invariants that improve their accuracy. However, it is also useful as a tool to bootstrap the process of specifying application-level correctness invariants.

Transaction chains (Zhang et al. 2013) leverage transaction chopping (Shasha et al. 1995) to commit transactions in a geo-scale deployment locally without waiting for other data centers. Transaction chopping (Shasha et al. 1995) is a theoretical framework that enables decomposing transactions to smaller pieces. The original goal of transaction chopping is to allow more concurrency. Transaction chains (Zhang et al. 2013) use the concepts of transaction chopping to decompose transaction. Then, it introduces constraints on the execution of transactions. Transaction parts are executed in the same order at the different nodes (potentially at different data centers). Also, instances of the same transaction are ordered at the first node that handles that type of transactions. It turns out that these two constraints, in addition to transaction chopping, allow guaranteeing the success of the execution of the transaction after the success in the first

node. Thus, rather than waiting for the response from multiple nodes at multiple data centers, transaction can execute and be guaranteed to succeed after execution at the first node only. Transaction chains incorporate many annotation and commutative techniques to enable more flexibility in the schedules and constraints that are enforced on transactions.

Weak and Relaxed Consistency

Another method to avoid coordination is to weaken or relax the consistency guarantees. Eventual consistency (Cooper et al. 2008; DeCandia et al. 2007; Bailis and Ghodsi 2013) only guarantees that the data copies are eventually consistent in the absence of updates. Therefore, coordination can be performed asynchronously, and convergence can be achieved via commutative and converging operators. Causality (Lamport 1978) is a stronger guarantee that ensures that events at one node are totally ordered and events at one node are ordered after everything that have been received by the point they are generated. Causality does not require synchronous coordination, which made it a candidate for many environments with high coordination costs (Lloyd et al. 2011, 2013; Bailis et al. 2013; Nawab et al. 2015; Du et al. 2013). Extensions of causality that consider causal transactions rather than operations or events are also shown to require no synchronous coordination (Lloyd et al. 2011, 2013; Nawab et al. 2015). Parallel snapshot isolation (PSI) (Sovran et al. 2011) extends snapshot isolation (Berenson et al. 1995) for geo-scale environments. This extension allows many types of transactions to execute without the need for synchronous coordination between data centers. Transactions with write-write conflicts, however, are still required to synchronously coordinate.

Versioning and Snapshots

Serializability is a guarantee that the outcome of transactions mimics an outcome of a serial execution. This makes read-only transactions have the opportunity to execute without coordination by reading from a consistent snapshot of data.

The outcome of such read-only transaction might be stale but consistent. However, the challenge in read-only transactions is in the development of methods that minimize the interference with read-write transactions. This is especially the case for analytics queries that translate to large, long-lived read-only transactions. Schlageter (1981) showed that read-only transactions can be executed without interfering with read-write transactions. Specifically, in an optimistic concurrency control protocol, read-only transactions do not need to be validated as long as they reflect the consistent state of the database. However, read-write transactions wait for read-only transactions to finish. This may lead to long delays with large read-only transactions. To overcome this limitation, multi-versioning techniques were proposed to execute read-only transactions on a recent, possibly stale snapshot of the database (Agrawal et al. 1987). In a replicated system, it was shown that a read-only transaction can avoid coordination with other replicas by reading a local, consistent copy (Satyanarayanan and Agrawal 1993). This entails modifying the coordination of read-write transactions and additional overhead to enable creating a consistent snapshot locally at every replica. Recently, Spanner (Corbett et al. 2012) shows the use of accurate time synchronization to serve consistent read-only transactions with improved freshness.

Conclusion

Coordination is continuing to be a major challenge in data management systems due to large-scale and geo-scale deployments. Coordination avoidance techniques enable reducing the overhead of coordination, thus improving performance, while maintaining the ease of use and intuition of data management abstractions and strong consistency guarantees. There have been many ways that can be used individually or together to avoid coordination such as leveraging commutativity and convergence, application-level consistency semantics, relaxed consistency guarantees, and specialized transaction types.

These solutions provide different levels of ease of use, generality, and optimality, making them suitable for different classes of applications and use cases.

C

Examples of Application

Coordination avoidance is used in traditional and cloud data management systems.

Future Directions for Research

The emergence of many new technologies, system architectures, and applications invites the investigation of new coordination avoidance techniques and adaptations of existing coordination avoidance technique.

Co-resident Attack in Cloud Computing: An Overview

Sampa Sahoo, Sambit Kumar Mishra,
Bibhudatta Sahoo, and Ashok Kumar Turuk
National Institute of Technology Rourkela,
Rourkela, India

Introduction

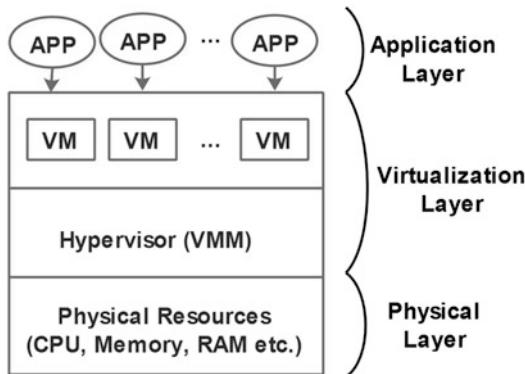

Cloud computing is a novel computing model that leverages on-demand provisioning of computational and storage resources. It uses pay-as-you-go economic model, which helps to reduce CAPEX and OPEX. Cloud computing essence and scope can be best described by the “5-3-2 principle,” where 5 stands for its essential characteristics (on-demand service, ubiquitous network access, resource pooling, rapid elasticity, and measured service) (Puthal et al. 2015). Three stands for service delivery models (SaaS, PaaS, and IaaS). Two points to basic deployment models (private and public) of the cloud (Sahoo et al. 2015).

Figure 1 shows the layered architecture of cloud. Various layers of a cloud are as follows:

application, virtualization, and physical. Application layer consists of user applications. The virtualization layer’s main components are a hypervisor or Virtual Machine Manager (VMM) and VM. A hypervisor acts as an administrator for the virtualized data center that permits the user to configure and manage cloud resources to create and deploy virtual machines and services in a cloud. A VM is an emulation of a physical machine. The virtualization technology allows creating several VMs on a single physical machine (Mishra et al. 2018a). The physical layer is a container of various physical resources like memory, RAM, etc. (Sahoo et al. 2016).

The rise of multimedia data and ever-growing requests for multimedia applications has tendered multimedia as the biggest contributor of big data. Applications on entertainment demand low security as compared to personalized videos like business meetings, telemedicine, etc. A secured video transmission ensures authorized entrance and prevents information leakage by any unapproved eavesdroppers. Various cryptographic algorithms (AES, DES, etc.) can be used to guarantee security to the multimedia application. Few examples of big data are credit card transactions, Walmart customer transactions, and data generated by Facebook users. A security breach in big data will cause severe legal consequences and reputational damage than at present. The use of big data in business also gives rise to privacy issues (Inukollu et al. 2014). Big data applications demand scalable and cost-efficient technology for huge data storage, computation, and communication. One of the solutions to address these issues is the use of cloud computing which is both scalable and cost-efficient. Since cloud computing is an umbrella term used by many technologies like networks, databases, virtualization, operating system, resource scheduling, transmission management, load balancing, etc., security issues related to these systems are also applicable to cloud computing.

Cloud computing facilitates business models and allows renting of IT resources on a utility like a basis through the Internet. Security is one of the most challenging issues to deal with in cloud computing due to numerous forms of

Co-resident Attack in Cloud Computing: An Overview, Fig. 1 Layered architecture of cloud

attacks on the application side as well as the hardware components. Various reasons for difficulties correlated with cloud computing are the loss of control, lack of trust, and multi-tenancy (Bhargava 2010). A cloud user outsourced its content to a remote server, losing direct control over the data, which becomes one of the reasons for cloud security issues. An attacker can target the communication link between cloud provider and clients. Multi-tenants of cloud use a shared pool of resources having conflicting goals. This gives opportunities to an attacker to steal useful information from the legitimate user on the same physical machine.

The virtualization method allows sharing of computing resources among many tenants, which may be business partners, suppliers, competitors, or attackers (Mishra et al. 2018b). Even though there is substantial logical isolation between VMs, shared hardware creates vulnerabilities to side channel attacks, i.e., data leakage through implicit channels (Zhang et al. 2011). The following sections discuss security issues in the cloud, co-resident attack, and its defense methods, followed by the conclusion.

Security Issues in Cloud

Security is a dominant barrier to the development and widespread use of cloud computing. Big data computing in cloud environment fur-

ther intensified security and privacy issues. The cheaper compute environment, networked application environment, and shared cloud system environment generate security, compression, encryption, and access control challenges, which must be addressed in a systematic way (Cloud-Security-Alliance 2012). Cloud provider security implementation mainly focused on the assumption that outsiders of the cloud are evil, whereas insiders are good. An outside attacker performs the following actions to get unauthorized access: listen to network traffic, insert malicious traffic, and launch DoS. An inside attacker can log on to user communication, peek into VMs or make copies of VMs, and monitor application pattern for unapproved access. The deficit security features in local devices also provide a way for malicious services on the cloud, as an attacker can use these devices to attack local networks.

Various terms representing the security or privacy attributes are confidentiality, integrity, availability, accountability, and privacy preservability (Xiao and Xiao 2013). Confidentiality ensures that user's data and computation are kept confidential from both the cloud provider and other users. Primary threats to confidentiality are co-resident VM attack and malicious system admin. Cloud integrity implies that data are stored honestly on data storage, computation is performed without any distortion, and integrity is affected by data loss or manipulation and dishonest computation. Availability ensures that cloud services are available most of the time and meet the SLA. It is influenced by flooding attack (denial of service (DoS)) and fraudulent resource consumption (FRC) attack. Accountability implies capability of identifying a party responsible for the specific event. Several threats to cloud accountability are SLA violation, inaccurate billing, etc. Since cloud user's data and business logic reside among distributed cloud servers, there are potential risks that confidential and personal information will be disclosed to public or business competitors. Privacy preservation is one of the critical attributes of privacy, which prevents disclosure of private data. Confidentiality is indispensable, whereas integrity guarantees

data, or computation is corruption-free, which somehow preserves privacy.

The following challenges are faced by cloud providers to build secure and trustworthy cloud system.

- *Outsourcing*: A cloud user outsourced its content to the cloud provider's data center and lost the direct physical control over the data. The computing and data storage are done at the cloud provider's end, causing the main reason for cloud insecurity. Outsourcing may also incur privacy violations.
- *Multi-tenancy*: Since multiple customers share the cloud resources, it gives rise to co-residency issues. Cross-VM or co-resident VM attack exploits the multi-tenancy nature.
- *Massive data and intense computation*: Traditional security methods may not suffice for massive data storage and computation.

Various Attacks on VM

VMs are the principal computing unit in the cloud computing environment that facilitate efficient utilization of hardware resources and reduce maintenance overhead of computing resources. VMs provide the additional layer of hardware abstraction and isolation but require quality methods to prevent attackers to access information from other VMs and the host. Vulnerabilities in VMs pose an immediate threat to the privacy and security of the cloud services. The shared and distributed nature of cloud resources makes it difficult to develop a security standard that ensures data security and privacy. Vulnerabilities in the cloud are the security loopholes, which allow unauthorized access to the network and infrastructure resources. Vulnerabilities in virtualization or hypervisor will enable an attacker to perform a cross-VM side-channel attack, and DoS attack provides access to legitimate user's VM. Solution directives for VM attacks include alert message for any breach of VMs isolation, integrity and security assurance of VM images, vulnerability-free virtual machine manager (VMM) or hypervisor, etc. (Modi et al.

2013). Different classes of attacks (Hyde 2009) that affect VMs are:

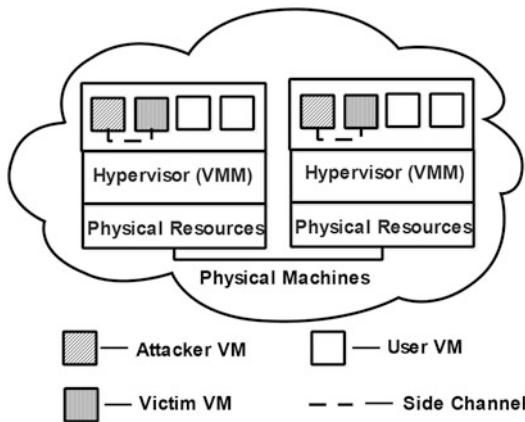

- *Co-resident attack*: Attacker adversary VM to communicate with other colocated VMs on the same host, thus violating isolation feature of VMs.
- *Attack on hypervisor*: The attack on a hypervisor allows the attacker to access VM, host operating system, and hardware.
- *DoS attack*: DoS attacks are endeavors by an unapproved user to degrade or deny resources to a genuine user. DoS attack consumes resources from all VMs on the host.

C

Co-resident Attack

Colocated VMs are logically separated from each other. Users are migrating to the cloud that was exposed to an additional threat caused by neighbors due to the sharing of resources. This exposure raises questions about neighbors' trustworthiness and integrity as a malicious user can build side channel to circumvent logical isolation and extract sensitive information from co-resident VMs (Han et al. 2017). Like traditional web services, VMs are exposed to various security threats, and co-resident attack is one of them. Other names of co-resident attack are co-residence, co-residency, and colocation attack. Figure 2 shows co-resident VM attack in cloud. It shows that attacker VM and target VM are placed on the same physical machine, where attacker extracts target VM information through the side channel.

In co-resident attack, malicious users extract information from colocated virtual machines on the same physical machine by building side channels. The various side-channel attack includes cache attack, timing attack, power monitoring attack, software-initiated fault attack, etc. In cache attack, attackers take action based on cache access of the victim in a virtualized environment like a cloud, whereas timing attack is based on computation time of various activities (e.g., the comparison between attacker's password with

Co-resident Attack in Cloud Computing: An Overview, Fig. 2 Co-resident attack

victim's unknown one). The power monitoring attack makes use of power consumption variation by the hardware during computation. Software-initiated fault attack is a rare one, where off-limits memory is changed by accessing adjacent memory too often.

The co-resident attack is a two-step process. First, the attacker sets target VMs and collocates their VMs with these VMs on the corresponding physical servers. The second process builds the side channels to extract valuable information from the victim. The following steps are performed by an attacker for co-resident attack (Han et al. 2016):

1. An attacker first targets some VMs.
2. Attacker starts some VMs either from a single account or multiple accounts.
3. Check whether new VM is colocated with target VM on the same physical machine or not.
4. Repeat steps 2–3 until co-residency is achieved.
5. If co-residency is achieved, non-colocated VMs are turned off. Now, the attacker gains access and steals information from the target VM.

Defense Methods

Cloud security providers mainly aim to prevent the attacker from achieving co-residence. Co-

residence may lead to cross-VM information leakage. The attacker analyzes the cloud infrastructure and identifies the residency of target VM. After several attempts, an attacker may succeed to instantiate new VMs, co-resident with target VM. Now, the attacker can leak all kinds of information which are known as the side-channel attack. This is because both target and attacker VM share the same resource. Various methods used to defend co-resident attack in cloud are listed below:

- *Elimination of side channels:* One of the solutions to handle co-resident attack is the elimination of side channels. But, this method needs modifications to the current cloud platform.
- *VM-allocation policy:* Another answer is VM allocation policy, which can influence the probability of colocation. The bigger the probability of non-co-residency, the better the policy is.
- *Increasing difficulty level of co-residence verification:* Usually the IP address of a VM Dom0 is a privileged VM responsible for management of all VMs on a host. For co-resident VMs, Dom0 IP addresses must be same. So, the disclosure of Dom0 IP address must be restricted.
- *Detection of co-resident attacks trademark:* Any attack can be identified by unusual behavior of a cloud system. Various indicators of co-resident attack include abnormalities in the CPU and RAM behavior, cache miss, system calls, etc.
- *Periodic VM migration:* Periodic migration of VMs helps to counter co-resident attack. Like every coin has two sides, this method comes with additional drawbacks like extra power consumption, performance degradation, SLA violation, etc.
- *Encrypted VM images:* Encrypted VM images can guarantee the security of a VM, which can be accessible by only an authorized user who knows the security keys of permitted access.

Case Study

Multiple VMs of various organizations run on Amazon's EC2 infrastructures with virtual boundaries, and each VM can operate within a single physical server. VMs located on the same physical server have IP addresses approaching each other. An attacker can set up lots of his own virtual machines to get a glance at their IP addresses and figure out VMs that share the same resources as a meditated target. Once the adversary VM is located along with target VM on the same server, an attacker can deduce sensitive information about the victim, and this action can cause resource usage fluctuations.

Conclusion

This chapter manifests various security and privacy issues of cloud running big data applications. Virtualization technology and VM are the two most essential components of a cloud. Our aim in this paper is to give an overview of various security issues in the cloud (specific to VM) and its solutions. Here, we present details about co-resident VM attack that includes steps performed by an attacker, various defense methods, and the explanation with an example.

CRUD Benchmarks

Steffen Friedrich and Norbert Ritter
Department of Informatics, University of Hamburg, Hamburg, Germany

Synonyms

[NoSQL benchmarks](#)

Definitions

A CRUD benchmark is a generic experimental framework for characterizing and comparing the performance of database systems by executing

workloads using only a simple CRUD (create, read, update, and delete) interface.

Since each database system provides at least this minimal subset of operations, CRUD benchmarks allow a general performance comparison of a variety of non-relational *NoSQL database systems*.

Overview

For many decades, relational database management systems (RDBMSs) have been the first choice for business applications. A high degree of standardization, especially the standard query language SQL, made it possible to develop domain-specific benchmarks for RDBMSs.

The DebitCredit benchmark by Jim Gray laid down the foundation for standardized database benchmarks (Anon et al. 1985). It introduced most of the key ideas that were later taken up by the Transaction Processing Performance Council (TPC) for the specification of the TPC-A benchmark and its famous successor, TPC-C (2010). The TPC was founded in 1988 as an industry-consensus body to fulfill the need for benchmark certification. Previously, many RDBMS vendors had conducted benchmarks based on their own interpretation of DebitCredit. Since its foundation, the TPC has developed numerous benchmarks for various kinds of online transactional processing (OLTP) and also online analytical processing (OLAP) workloads.

However, the amount of useful data in some applications has become so vast that it cannot be stored or processed by traditional relational database solutions (Hu et al. 2014). At the beginning of the twenty-first century, this led to the development of non-relational database systems able to cope with such Big Data. These systems are subsumed under the term *NoSQL database systems*. They offer horizontal scalability and high availability by sacrificing querying capabilities, the strict ACID guarantees, and the transactional support as known from RDBMSs.

Since most TPC benchmark specifications assume ACID compliant transactions, they cannot be applied to mostly non-transactional NoSQL

databases. Defining similar domain-specific standards for those systems is even more complicated due to the sheer heterogeneity in their data models and APIs.

Therefore, many NoSQL vendors and open source communities implemented their own database-specific performance measurement tools, just as the RDBMS vendors did before TPC. These include, for example, the Cassandra-stress tool, Mongoperf for MongoDB, the Redis-benchmark utility, or Basho_bench for Riak. In the end, the results of these tools are often difficult to understand, cannot be extended to other scenarios, and do not allow comparisons between different databases.

Eventually, the *Yahoo! Cloud Serving Benchmark* (YCSB) was proposed (Cooper et al. 2010). YCSB is limited to a simple CRUD interface and has become the de facto standard for NoSQL database performance comparison, which is why the term *NoSQL Benchmark* is often used interchangeably for CRUD benchmark. Due to the fact that YCSB is open source and extensible, the developer community has added support for almost every NoSQL database system since the release in 2010.

Scientific Fundamentals

The Benchmark Handbook for Database and Transaction Systems edited by Jim Gray (1993) can be regarded as the first reference work of database benchmarking. It identifies four requirements that a domain-specific benchmark must meet:

1. **Relevance** means that the benchmarks should be based on a realistic workload such that the results reflect something important to their readers.
2. **Simplicity** describes that the workload should be understandable.
3. **Portability** means that it should be easy to run the benchmark against a large number of systems.

4. **Scalability** says that it should be possible to scale the benchmark up to larger systems as performance and architectures evolve.

These requirements have been refined over time to reflect the current developments of database systems (Huppler 2009; Folkerts et al. 2013). The book *Cloud Service Benchmarking* by Bermbach et al. (2017) is an excellent modern reference work in which these design objectives are also discussed in detail with regard to cloud computing and Big Data requirements. Regarding the mentioned four requirements, CRUD benchmarks significantly weaken the relevance aspect in order to achieve the greatest possible portability, simplicity, and scalability. They do not model a real domain-specific application workload like the TPC standard specifications but a simpler one in which the choice of CRUD operations is selected according to a given probability distribution of real web application workloads (*workload generation*). The typical *metrics* measured during the benchmark run are throughput (operations per second) and latency (response time in milliseconds). CRUD benchmarks also define hardly any restrictions on the *system under test* in favor of portability. The actual data values consist of simple synthetically generated random character strings (*data generation*). Overall, this makes them less relevant for concrete applications but allows to measure the performance of highly scalable NoSQL systems in the first place.

Hence, CRUD benchmarks are also often used and extended in research to measure additional performance aspects of distributed NoSQL database systems. An overview of these research efforts can be found in Friedrich et al. (2014), and the book by Bermbach et al. (2017) can also be recommended as a reference for the current state of measurement methods for nonfunctional properties such as scalability, elasticity, and consistency of NoSQL data management solutions.

It should be noted that the basics of scalability and elasticity benchmarking were already determined by the Wisconsin benchmark, an early performance evaluation framework for RDBMS (DeWitt 1993). It was by no means as popular as

DebitCredit and the TPC benchmarks for comparative studies by RDBMS vendors, but it was widely used in research for measuring the performance of parallel database system prototypes designed for shared nothing hardware architectures. As these database prototypes should already meet horizontal scalability and elasticity requirements, the benchmark defined the key metrics scale-up and speedup to measure them.

Current research work is further developing domain-specific benchmarks for certain classes of NoSQL database systems such as document stores that go beyond pure CRUD benchmarks. This allows to compare the performance of more sophisticated query capabilities in the context of a particular application. Reniers et al. (2017) give an up-to-date overview of these domain-specific NoSQL benchmarks and CRUD benchmarks.

Key Applications

In addition to the four requirements that a benchmark must meet, Gray (1993) also describes four motivations for database benchmarking which can be extended to NoSQL database performance evaluation:

1. **Different proprietary software and hardware systems:** The classical competitive situation between two relational database vendors running their solution on their own dedicated specialized hardware can, nowadays, for example, be transferred to proprietary NoSQL database as a service solutions (DBaaS) as provided by cloud service providers.
2. **Different software products on the same hardware:** This is the most common form in which NoSQL database system vendors compare their systems with others. The different databases are set up in a cluster of the same hardware or cloud infrastructure, and their performance is usually measured with a selection of different workloads.
3. **The same software product on different hardware systems:** The database workload serves as a reference application for comparing different underlying hardware platforms.

Nowadays, this can mean that users benchmark their NoSQL database system on different infrastructure as a service (IaaS) solutions to select the most performant or cost-effective cloud provider.

4. **Different releases of a software product on the same hardware:** The benchmarking of newer versions of a database system is an integral part of the modern agile software development process. This is one of the major reasons why NoSQL developers often implement database-specific performance measurement tools.

Comparative studies are primarily promoted by database vendors themselves for marketing and advertising purposes. Since there is no instance like TPC for the verification of benchmark results in the NoSQL area, these results should always be looked at critically, because the workload parameters, the hardware, and the presentation of the results are selected in such a way that the own product performs particularly well. This kind of *benchmarketing* already existed for RDBMSs in the early 1980s.

In addition to comparative studies, one of the main motivations for benchmarking is systems research, i.e., understanding the performance behavior of certain system designs or understanding quality trade-offs like the consistency/latency trade-off of different data replication techniques.

Future Directions

The research in the field of benchmarking nonfunctional properties of distributed NoSQL database systems is still in an early stage. For example, a number of methods for measuring the consistency of replicated databases have already been proposed. Apart from further studies on scalability and elasticity, there is only little work on the topic of availability benchmarking of NoSQL database systems, especially not under different failure conditions. Therefore, further research in this area is still needed to develop

standard methodologies for measuring these requirements.

Furthermore, there is a variety of possible benchmark designs between simple CRUD benchmarks and application-oriented benchmarks for one specific NoSQL data model that still need to be explored. One can imagine domain-specific workloads that are still general enough to allow specific implementations for all the different data models.

[Data cleansing](#)

Definitions

Data cleaning is used to refer to all kinds of tasks and activities to detect and repair errors in the data.

Overview

Enterprises have been acquiring large amounts of data from a variety of sources to build their own “data lakes,” with the goal of enriching their data asset and enabling richer and more informed analytics. Data collection and acquisition often introduce errors in data, for example, missing values, typos, mixed formats, replicated entries for the same real-world entity, outliers, and violations of business rules.

A Kaggle’s 2017 survey about the state of data science and machine learning reveals that dirty data is the most common barrier faced by workers dealing with data (Kaggle 2017). Not surprisingly, developing effective and efficient data cleaning solutions is a challenging venue and is rich with deep theoretical and engineering problems.

There are various surveys and books on different aspects of data quality and data cleaning. Rahm and Do (2000) give a classification of different types of errors that can happen in an extract-transform-load (ETL) process and survey the tools available for cleaning data in an ETL process; Bertossi (2011) provides complexity results for repairing inconsistent data and performing consistent query answering on inconsistent data; Hellerstein (2008) focuses on cleaning quantitative data, such as integers and floating points, using mainly statistical outlier detection techniques; Fan and Geerts (2012) discuss the use of data quality rules in data consistency, data currency, and data completeness and how different

aspects of data quality issues might interact; Dasu and Johnson (2003) summarize how techniques in exploratory data mining can be integrated with data quality management; Ilyas and Chu (2015) provide taxonomies and example algorithms of qualitative error detection and repairing techniques; and Ganti and Das Sarma (2013) focus on an operator-centric approach for developing a data cleaning solution, which involves the development of customizable operators that could be used as building blocks for developing common solutions.

This chapter covers four commonly encountered data cleaning tasks, namely, outlier detection, rule-based data cleaning, data transformation, and data deduplication. Since there is a very large body of work on these tasks, this chapter only intends to provide an introduction to each data cleaning task and categorize various techniques proposed in the literature to tackle each task. There are also many complementary research efforts to data cleaning that are not covered in this chapter, such as data profiling, provenance, and metadata management, data discovery, consistent query answering, metadata management, schema mapping, and data exchange.

Key Research Findings

Outlier Detection

Outlier detection refers to the activity of detecting outlying values and is a quantitative error detection task. While an exact definition of an outlier depends on the application, there are some commonly used definitions, such as “an outlier is an observation which deviates so much from other observations as to arouse suspicions that it was generated by a different mechanism” (Hawkins 1980). For example, for a company whose employees’ salaries are mostly around 100 K, an employee with a salary of 10 K can be considered to be an outlying record.

Multiple surveys and tutorials have been published to summarize different definitions of outliers and algorithms for detecting them (Hodge and Austin 2004; Chawla and Sun 2006; Aggarwal 2013). In general, outlier

detection techniques fall into three categories: statistics-based, distance-based, and model-based. Statistics-based outlier detection techniques assume that the normal data points would appear in high-probability regions of a stochastic model, while outliers would occur in the low-probability regions of a stochastic model (Grubbs 1969). They can often provide a statistical interpretation for discovered outliers, or a score/confidence interval for a data point being an outlier, rather than making a binary decision. Distance-based outlier detection techniques often define a distance between data points, which is used for defining a normal behavior, for example, normal data point should be close to a lot of other data points, and data points that deviate from such normal behavior are declared outliers (Knorr and Ng 1998). A major advantage of distance-based techniques is that they are unsupervised in nature and do not make any assumptions regarding the generative distribution for the data. Instead, they are purely data driven. Model-based outlier detection techniques first learn a classifier model from a set of labeled data points and then apply the trained classifier to a test data point to determine whether it is an outlier (De Stefano et al. 2000). Model-based approaches assume that a classifier can be trained to distinguish between the normal data points and the anomalous data points using the given feature space. They label data points as outliers if none of the learned models classify them as normal points.

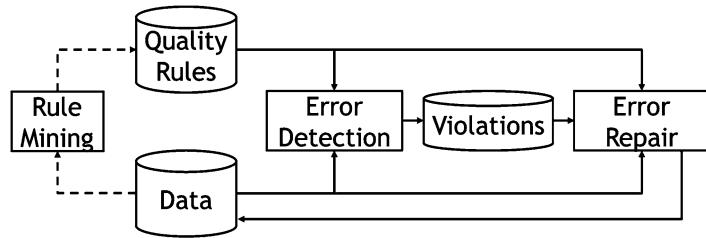

Enforcing Data Quality Rules

One common way to detect and rectify errors in databases is through the enforcement of data quality rules, often expressed as integrity constraints (ICs) (Chu et al. 2013; Fan and Geerts 2012). In this context, (qualitative) error detection is the process of identifying *violations of ICs*, namely, subsets of records that cannot co-exist together; and error repair is the exercise of modifying the database, such that the violations are resolved and the new data conforms to the given ICs.

Figure 1 shows a typical workflow of qualitative data cleaning. In order to clean a dirty dataset using qualitative data cleaning techniques, there

Data Cleaning, Fig. 1

Rule-based data cleaning workflow with an optional rule mining step, the error detection step, and the error repair step

D

need to be data quality rules that reflect the semantics of the data. One way to obtain data quality rules is by consulting domain experts, which requires a lot of domain expertise and is usually a time-consuming processing. An alternative approach is to design an algorithm to automatically discover data quality rules. Given a dirty dataset and the associated data quality rules, the error detection step detects violations of the specified rules in the data. A violation is *minimal set of cells in a dataset that cannot coexist together*. Finally, given the violations and the rules that generate those violations, the error repair step produces data updates, which are applied to the dirty dataset. The error detection and the error repair loop go on until the data conforms to the data quality rules, namely, there is no violations in the data.

Example 1 Consider Table 1 that contains employee records in a company. Every tuple specifies a person in a company with her id (GID), name (FN, LN), level (LVL), zip code (ZIP), state (ST), and salary (SAL). Suppose two data quality rules hold for this table. The first rule states that, if two employees have the same zip code, they must have the same state. The second rule states that among employees working in the same state, a higher-level employee cannot earn less salary than a lower-level employee.

Given these two data quality rules, the error detection step detects two violations. The first violation consists of four cells $\{t_1[\text{ZIP}], t_1[\text{ST}], t_3[\text{ZIP}], t_3[\text{ST}]\}$, which together violate the first data quality rules. The second violation consists of six cells $\{t_1[\text{ROLE}], t_1[\text{ST}], t_1[\text{SAL}], t_2[\text{ROLE}], t_2[\text{ST}], t_2[\text{SAL}]\}$, which together violate the second data quality rule. The data repair step takes the violations and produces an

Data Cleaning, Table 1 An example employee table

TID	FN	LN	LVL	ZIP	ST	SAL
t_1	Anne	Nash	5	10001	NM	110,000
t_2	Mark	White	6	87101	NM	80,000
t_3	Jane	Lee	4	10001	NY	75,000

update that changes $t_1[\text{ST}]$ from “NM” to “NY,” and the new data now has no violation with respect to the two rules.

Data Transformation

Data transformation refers to the task of transforming data from one format to another. Data transformation tasks can be classified into two types in general: *syntactic data transformations* and *semantic transformations*. Syntactic transformations aim at transforming a table from one syntactic format to another, often without requiring external knowledge or reference data. On the other hand, semantic transformations usually involve understanding the meaning/semantics, instead of simply as a sequence of characters; hence, they usually require referencing external data sources.

Example 2 Figure 2a shows a syntactic transformation, where a tabular data containing person names, telephone numbers, and fax numbers, originally arranged in a tabular format with phone and fax numbers stored in the same column as a complex data type, are flattened into a normal relational table representation to enable efficient querying of this data. In addition, the telephone numbers and the fax numbers are also transformed by adding two dashes between the nine digits. Both cases do not require external knowledge to perform these transformations.

Data Cleaning, Fig. 2 Example transformations. (a) Syntactic transformation. (b) Semantic transformation

Figure 2b shows a semantic transformation, where country codes are transformed into country names; obviously, it requires external knowledge, such as an external knowledge base that contains both full and abbreviated country names.

There are generally three major components/dimensions of a syntactic data transformation system: *language*, *authoring*, and *execution*. Since there are many ways to transform a dataset, syntactic data transformation solutions usually adopt a *transformation language* that limits the space of possible transformations. The language could consist of a finite set of operations allowed on a table (Raman and Hellerstein 2001; Kandel et al. 2011), such as splitting a column and merging two columns, or it could consist of a set functions for string manipulations (Gulwani 2011), such as extracting substring and concatenating two substrings. There is a balance that needs to be achieved when choosing a particular language: it needs to be expressive enough so that it captures many real-world transformation tasks and, at the same time, restricted enough to allow for effective and easy authoring of the transformations. For a specific transformation task, syntactic transformation tools have different interaction models with the users to *author a transformation program* using the adopted language. The interaction models could be generally classified as declarative, example-driven, or proactive. In the declarative model,

users specify the transformations directly, usually through a visual interface. In the example-driven model, users are required to give a few input-output examples, based on which the tool automatically infers likely transformations that match the provided examples. In the proactive interaction model, the transformation tool provides hints or highlights for which data needs transformation and sometimes even suggests possible transformations so that users simply need to accept or reject the suggestions. Finally, *transformation execution* applies the specified transformations to the dataset. Since there might be multiple specified transformations from the previous step, transformation tools usually offer assistance to the users in selecting the desired transformation, for example, by displaying the effect of the specified transformation immediately on a sample data or by providing interpretable statements of the specified transformations. Different transformation tools offer different capabilities along these three dimensions.

Semantic transformations usually involve understanding the meaning/semantics, or the typical use of the data, instead of simply as a sequence of characters. In contrast to syntactic transformations, semantic transformations cannot be computed by solely looking at input values; rather, they usually require external data sources to look up the values that need to be transformed. Example-driven techniques have been mostly used for semantic transformations (Singh and Gulwani 2012; Abedjan et al. 2016). Users

are usually asked to provide a few input-output examples, and semantic transformation tools then will search the available external data sources to find a “query” that matches the examples. The query can then be used to transform new unseen data.

Data Deduplication

Data deduplication, also known as duplicate detection, record linkage, record matching, or entity resolution, refers to the process of identifying tuples in one or more relations that refer to the same real-world entity (Elmagarmid et al. 2007). A data deduplication process usually involves many steps and choices, including designing similarity metrics to evaluate the similarity for a pair of records, training classifiers to determine whether a pair of records are duplicates or not, clustering all records to obtain clusters of records that represent the same real-world entity, consolidating clusters of records to unique representations, designing blocking or distributed strategies to scale up the deduplication process, and involving humans to decide whether a record pair are duplicates when machines are uncertain.

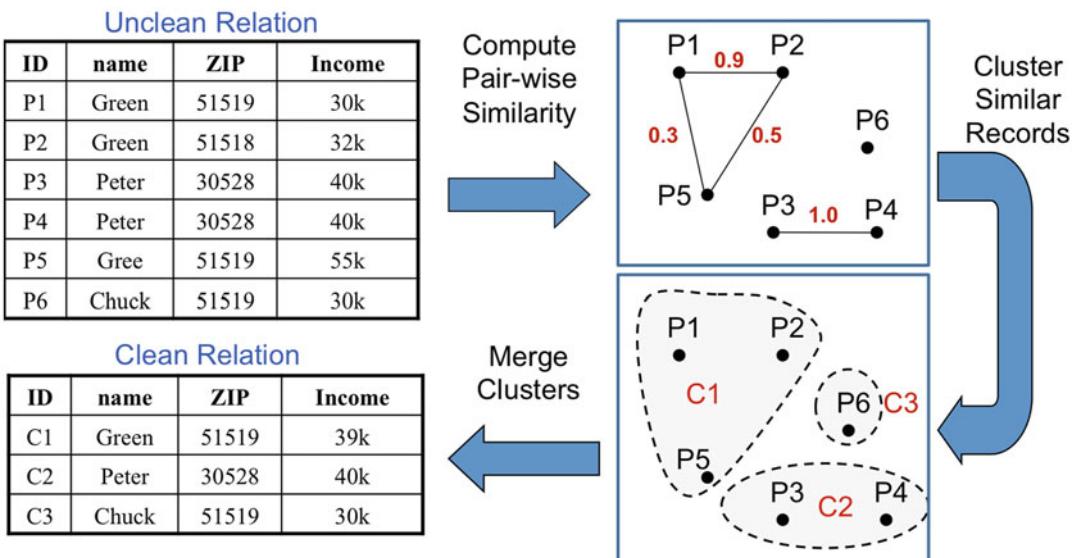

D

Example 3 Figure 3 illustrates a typical example of data deduplication. The similarities between pairs of records are computed and are shown in the similarity graph (upper right graph in Fig. 3). The missing edges between any two records indicate that they are non-duplicates. Records are then clustered together based on the similarity graph. Suppose the user sets the threshold to be 0.5, namely, any record pairs having similarity greater than 0.5 are considered duplicates. Although Records P_1 and P_5 have similarity less than 0.5, they are clustered together due to transitivity; that is, they are both considered duplicates to Record P_2 . All records in the same cluster are consolidated into one record in the final clean relation.

Applications of Data Cleaning

Data cleaning is a necessary step in many data-driven analytics. Different data cleaning tasks target different types of errors.

Applications of outlier detection include network intrusion detection, financial fraud detection, and abnormal medical condition

Data Cleaning, Fig. 3 A typical deduplication task

detection. For example, in the context of computer networks, different kinds of data, such as operating system calls and network traffic, are collected in large volumes. Outlier detection can help with detecting possible intrusions and malicious activities in the collected data.

Rule-based data cleaning can help clean any relational databases where data quality rules can be defined. The richer the semantics of the data is, the better rule-based data cleaning techniques are at detecting and repairing violations.

Data transformations are used in a variety of tasks and at different stages of the ETL life cycle. For example, before running a data integration project, transformations are often used to standardize data formats, to enforce standard patterns, or to trim long strings. Transformations are also used at the end of the ETL process, for example, to merge clusters of duplicate records, to find a unique representation for a cluster of records (aka golden record), or to prepare data to be consumed by analytics tools. Data transformations can also be seen as a tool for data repair in rule-based data cleaning, since it can be used to “transform” erroneous data.

Duplicate records can occur due to many reasons. For example, a customer might be recorded multiple times in a customer database if the customer used different names at the time of purchase; a single item might be represented multiple times in an online shopping website; and a record might appear multiple times after a data integration project because that record had different representations in original data sources. Data deduplication targets specifically duplicate records and resolves them.

Future Directions for Research

Data cleaning is a complicated process, and an end-to-end data cleaning solution usually involves many different cleaning sub-tasks. We have discussed techniques for tackling four common data cleaning tasks. There are still many challenges and opportunities in building practical data cleaning systems: (1) the scale of data renders many data cleaning techniques

insufficient. New cleaning solutions must adapt to growing datasets of the Big Data era, for example, by leveraging sampling techniques or distributed computation. (2) Although there are existing research about involving humans to perform data deduplication, for example, through active learning (Tejada et al. 2001; Sarawagi and Bhamidipaty 2002; Arasu et al. 2010), involving humans in other data cleaning tasks, such as repairing IC violations and taking user feedback in discovering of data quality rules, is yet to be explored; (3) a significant portion of data is residing in semi-structured formats (e.g., JSON) and unstructured formats (e.g., text documents). Data quality problems for semi-structured and unstructured data remain largely unexplored; and (4) there is significant concerns about data privacy as increasingly more individual data are collected by governments and enterprises. Data cleaning is by nature a task that requires examining and searching through raw data, which may be restricted in some domains including finance and medicine. How to perform most data cleaning tasks, while preserving data privacy, remains an open challenge.

Introduction and Key Concepts of Information Fusion: Data, Models, and Context

Information fusion (IF) is a multi-domain-growing field aiming to provide data processes for situation understanding (Liggins et al. 2008). Globally, fusion systems aim to integrate sensor data and information/knowledge databases, contextual information, mission goals, etc., to describe dynamically changing situations. In a sense, the goal of information fusion is to obtain continuous refinements of estimates and assessments of a subset of the world based on partial observations and the evaluation of the need for additional sources or modification of the process itself, to achieve improved results.

The capability to fuse digital data and generate useful information is conditioned by the quality of inputs, whether device-derived or text-based. Data are generated in different formats, some of them unstructured and may be inaccurate, incomplete, ambiguous, or contradictory. The key aspect in modern DF applications (Gómez et al. 2011) is the appropriate integration of diverse types of information and knowledge (see Fig. 1): observational data, knowledge models (a priori or inductively learned), and contextual information. Each of these categories has a distinctive nature and potential support to the result of the fusion process.

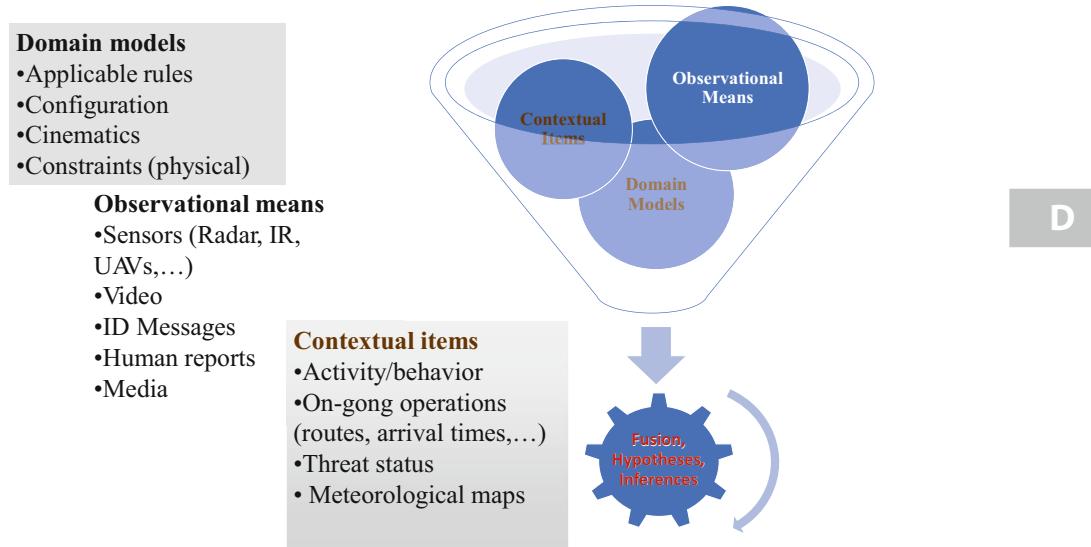

- **Observational data:** Observational data are the fundamental data about the dynamic scenario and entities of interest, as collected from the available observation means, including both physical devices (“hard” data)

and human observers (“soft” data) (Biermann et al. 2016).

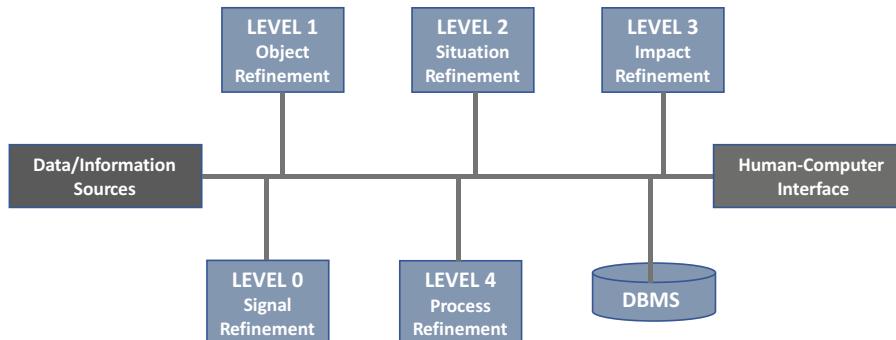

- **A priori and learned domain models:** Information fusion provides inferences about certain entities or hidden states (e.g., detection and tracking of certain objects, presence of a certain type of criminal activity, etc.). This involves combining data to update estimates, exploiting dynamic models of the expected behaviors of entities (physical models like kinematics or logical models with expected behaviors depending on context). Accurate models allow good predictions, being uncertainty modelling the key aspect to develop appropriate estimates, combining predictions and data observations. In those cases when a priori detailed models cannot be formed, one possibility is to try and excise the knowledge through online machine learning processes operating on the observational and other data. These are procedural and algorithmic methods for discovering relationships among and behaviors of entities of interest (Bishop 2004).
- **Context:** Contextual information has become fundamental to develop models in complex scenarios. Among other possible alternatives, context can be defined as “the set of circumstances surrounding a task that are potentially of relevance to its completion” (Bettini et al. 2010). Because of its task relevance, fusion or estimating/inferring task implies the development of a best possible estimate, considering this lateral knowledge (Snidaro et al. 2014, 2016). We can see the context as background, i.e., not the specific entity, event, or behavior of prime interest but that information which is influential to the formation of a best estimate of these items.

Levels of Abstraction: The JDL Model

Among different alternatives to classify IF functions and problems, the model developed by Joint Directors of Laboratories Data Fusion Subpanel has gained the greatest recognition. The “JDL model” differentiates functions into fusion “levels” that relate to the refinement of estimates

Data Fusion, Fig. 1 Information fusion. Observations, models, and context

Data Fusion, Fig. 2 JDL model

for parameters of interest related to “objects,” “situations,” “threats,” and “processes.” As illustrated in Fig. 2, taking into account recent revisions (Steinberg and Bowman 2009), the levels can be defined as follows:

- Level 0 – Sub-Object Data Assessment: estimation and prediction of signal/object observable states based on pixel/signal level data association and characterization
- Level 1 – Object Assessment: estimation and prediction of entity states based on inferences from observations

- Level 2 – Situation Assessment: estimation and prediction of entity states based on inferred relations among entities
- Level 3 – Impact Assessment: estimation and prediction of effects on situations of planned or estimated/predicted actions by the participants
- Level 4 – Process Refinement (an element of Resource Management): adaptive data acquisition and processing to support mission objectives

Low levels of JDL, namely, Levels 0 and 1, are focused in detection and tracking of in-

dividual entities, a problem usually named as multi-target tracking, while higher levels, namely, Levels 2 and 3, are related with what is happening around the entities to understand how information, events, and own actions will impact goals and objectives. Situation assessment (L2) is related with the capacity to obtain a global view of the environment, to describe the relationship between the entities tracking in the environment and to infer or describe a joint behavior. Impact assessment (L3) is related with the estimation of the impact of a special situation to the application of interest, processing and evaluating situations that are of special relevance to the scenario because they relate to some type of threatening, critical situation, or any other special world state.

Computational Resources for Big Data Fusion: Cloud Computing

Ubiquitous electronic sources such as sensors and video cast a steady stream of dynamic data, while text-based data from databases, Internet, email, social media, chat and VOIP, etc. is growing exponentially. Therefore, the high data flows, both from devices or text sources, may make systems unable to process them in real time and lead to time delays, extra costs, and even inappropriate decisions due to missing or incomplete information. Therefore, IF systems should maximize throughput while allowing complex fusion analytics to discover critical information in a huge amount of data. Hence, there is an immediate need to leverage efficient and dynamically scalable data processing infrastructure to analyze big data streams from multiple sources in a timely and scalable manner to establish accurate situation awareness (Szuster et al. 2017).

A complete ICT (information and communications Technologies) paradigm shift supports the development and delivery of IF applications depending on high-volume data streams, for instance, emergency management, to avoid getting overwhelmed by incoming data volumes, data sources, or data types. An appropriate trade-off between time and accuracy requires big data analytic architectures to support both batch data an-

alytic processes (for latent but quality solutions) and streaming data analytics (for near real-time situation awareness). This exponential explosion has a tremendous effect to the information fusion community that constantly deals with big data streams.

The deployment and provision of IF systems based on big data, like emergency management, will greatly benefit from a cloud-like middleware infrastructure, which could be formulated to create a hybrid environment consisting of multiple private (municipalities, enterprises, research organizations) and public (Amazon 2017; Microsoft 2017) infrastructure providers to deliver on-demand access to emergency management applications. Cloud computing assembles large networks of virtualized ICT services such as hardware resources (such as CPU, storage, and network), software resources (such as databases, application servers, and web servers), and applications. In industry these services are referred to as Infrastructure as a Service (IaaS), Platform as a Service (PaaS), and Software as a Service (SaaS). Cloud computing services are hosted in large data centers, often referred to as data farms, operated by companies such as Amazon (A), Google Microsoft, etc. The special features of cloud, like elasticity, thin-client user interface, as well as resource pools for both data and computing, denote that the cloud technique is adequate for collecting, hosting, and processing emergency data.

However, the creation of a middleware infrastructure and an associated dynamic deployment model enabling hybrid cloud-based applications faces technical obstacles and research challenges. Cloud-based delivery of dynamic IF applications has fundamental differences from existing cloud application models (e.g., web applications, content delivery networks (CDNs), and large-scale scientific simulations), usually operated on static data in response to queries such as provision a video file (CDNs) or commit a credit card transaction (e.g., e-commerce). That is, these applications are designed to maintain efficient and fault-tolerant collection of data that is accessed and aggregated only when a query or transaction request is issued by a user. Such data manipu-

lation application model incurs high overheads when applied to IF applications that demand for high processing capacity over heterogeneous and streaming data from multiple sources with strict QoS guarantees on processing latency.

Hence, there is need to innovate a dynamically deployable, multi-cloud middleware infrastructure to establish these applications on-demand, scalable interactions with cloud resources (such as CPU, storage disks, networks, and software frameworks) to optimize quality of service (QoS) targets in terms of data analysis delay, decision-making delay, storage cost, availability, reliability, and the like. The main challenge exists in the design of intelligent technologies with integrated control criteria and mechanisms for fast access to distributed, streaming data, services, and network equipment and dynamic adaptation of the device capacities and services to traffic loads, user requirements, and scenarios of application.

Application Examples

Three representative examples have been selected to illustrate the open problems and expected IF outputs for situation assessment based on electronic devices and information sources.

(A) *Emergencies.* Natural and man-made disasters, such as tsunamis, earthquakes, floods, or epidemics, pose a significant threat to human societies. The lessons learned from the growing number of recent emergencies, such as Colorado flood (2013), Japan's earthquake (2011), Queensland flooding in Australia (2010), Haiti earthquake (2010), etc. have put impetus on the development of emergency evacuation systems. Well-coordinated emergency management activities that involves guiding of citizens out of danger areas, placement of medical team to the most appropriate locations, and real-time planning of evacuation routes before and after a disaster play a significant role in saving lives, protecting critical infrastructures, and minimizing causalities. The management of emergency activities such as guiding people

out of dangerous areas and coordinating rescue teams is dependent on the availability of historical data as well as on the effective real-time integration and utilization of data streaming from multiple sources including on-site sensors, social media feeds, and messaging on mobile devices. The ability to make sense of data by fusing it into new knowledge would provide clear advantages in emergency situations. Inadequate SA in disasters has been identified as one of the primary factors in human errors, with grave consequences such as deaths and loss of infrastructure. As an example, during the 2010 Haiti earthquake (Caragea et al. 2011), text messaging via mobile phones and Twitter made headlines as being crucial for disaster response, but only some 100,000 messages were actually processed by government agencies due to lack of automated and scalable data processing infrastructure. As large numbers of people opted for social media (and, even worse, many people re-tweeted inaccurate information), it led to a tsunami of data for agencies and rescue staff, who were not able to analyze it fast enough to respond.

(B) *Threats.* Integrating low- and high-level information may lead to significant new capabilities in the counterterrorism field (Biermann et al. 2014). In this critical area, work is currently partitioned into two main subareas: analyzing terrorism and detecting preparations for it using high-level information (intelligence reports) and immediate response to threats using sensor information. By combining the two, it will be possible to achieve shorter response times and better direction of the immediate response, enabling better preventative measures. From sensor information it is possible to detect that something is about to happen. By combining sensor data with intelligence information, it will be possible to understand more about the terrorist event and thus more easily prevent it. There are a number of practical needs from civilian, law enforcement, and security applications

for fusing information stored in databases, ontologies, or other sources. Effective use of this information potential requires tracking and data fusion systems that provide near real-time situation pictures electronically representing a complex, dynamically evolving overall picture. For example, the ability to quickly fuse information from multiple sources on organized crime or terrorist activities from the various member states and make this available to the appropriate authorities rapidly would increase safety and protect citizens. So, contextual knowledge can aid both the formulation of an improved state estimate and also be used to aid in the interpretation of a computed estimate. However, its incorporation in the fusion process adds complexity and demands that new, hybrid techniques be developed.

(C) *Healthcare.* The problem of bridging the gaps between the relatively mature technology of device-based fusion and the increasingly important, but as yet still immature, field of high-level (network or text-based) medical data remains an open-ended problem. In spite of this interest, there are, today, many ideas but no real solutions. The ability to automate the fusion of device-based and text-based information should have a huge impact on healthcare, resulting in faster, more accurate information for authorities and citizens to base their decisions upon, better logistics in the case of medical service provision and consumption and transnational medical information sharing.

Conclusion and Future Research

The synergic fusion of sensory data, natural language information, and contextual information may bring important benefits in critical problems such as protection from criminal threats, emergency/disaster situation management, border security, or healthcare. It is clear that this type of emergency situations are chaotic in nature,

and any incident management system typically encompasses multiple and diverse sources of information such as mobile devices from affected people, social network feeds, available on-site sensors, contextual information databases, etc.

Processing these big volumes of data in real time is a grand challenge in computing, considering besides that sources are available in different formats and relative qualities, scattered in different geographical areas, reliable at different confidence levels, etc. Situation awareness in big areas such as emergency scenarios becomes a complex, distributed information fusion scenario in which innovative techniques are needed to efficiently curate information sources and build inferences and assessments in real time useful for decision and sense making. Future research is required to analyze appropriate storage and computing architectures, algorithms to merge in real time the diverse data streams to meet the required performance in challenging scenarios.

Definitions

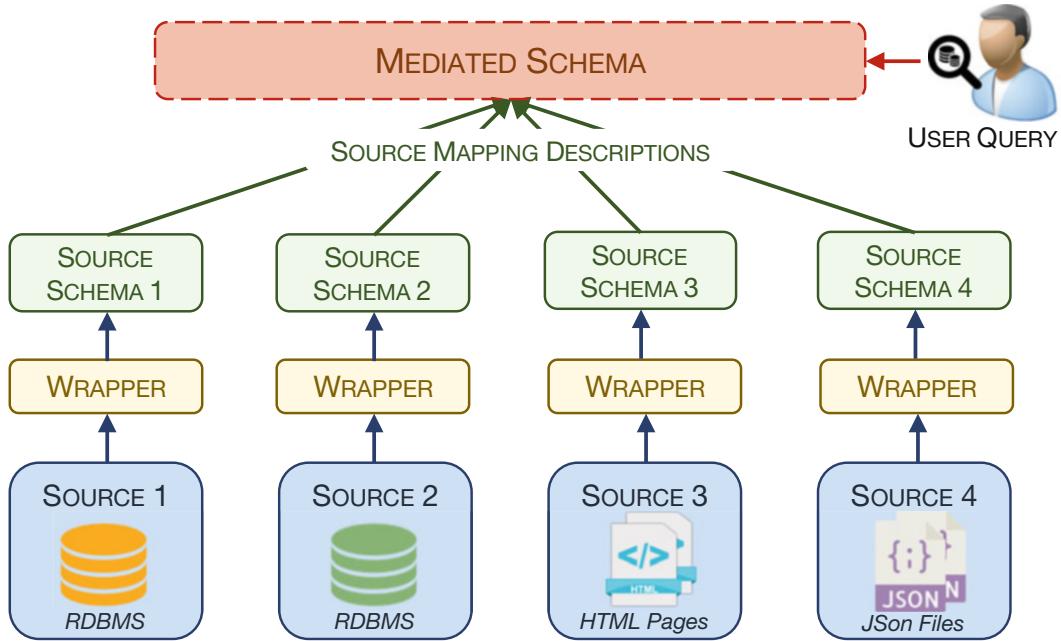

The goal of data integration systems is to provide a uniform access to a set of heterogeneous data sources. These sources can differ on the data model (relational, hierarchical, semi-structured), on the schema level, or on the query-processing capabilities. In a data integration architecture, these sources are queried by using a global schema, also called mediated schema, which provides a virtual view of the underlying sources.

Overview

Integrating data between different sources is a crucial step in many real-life applications, and the growth of structured data sources available on the Web is making this problem even more challenging. Consider as an example a Web application where users can query information about sport events planned in a particular day. In a traditional data management application, the information is stored in a database with a fixed schema (e.g., in a relational data management system) and retrieved by using a query. However, in many cases the information is stored on multiple, independent databases, which can have heterogeneous schemas and different logical organization. A data integration system solves this problem by adopting a virtual approach (Liu and Zsu 2009; Doan et al. 2012), as outlined in Fig. 1.

At the bottom of the figure, there are data sources that provide the data. Examples of these sources are HTML pages of a website, relational databases, XML or JSON files, and so on. Each source has a different schema and requires a different query. Moreover, once the results are collected from the sources, they must be merged to produce a unique answer for a given query. All these steps are not trivial and can lead to a large amount of work for users with an increasing number of sources and queries. However, with a data integration system, users do not have to execute queries directly on these sources but rather on a unified representation by using a virtual mediating schema. This schema, at the top of the figure, is defined to support the query workload and contains only the aspects of the domain that are relevant to the final application. The approach is defined *virtual* because the mediated schema does not store any data: the queries posed on the mediated schema are converted into queries on the base data sources and their results combined by the system.

To ease the extraction from the data sources, a set of wrappers are needed. The goal of each wrapper is to convert the query result of a data source into an easy to process form. For example, a wrapper for a Web form converts an input query into a set of HTTP transactions to collect results

Data Integration, Fig. 1 A typical data integration architecture

in terms of HTML pages. Finally, these pages are converted in a structured format, for example, relational tuples. To create wrappers, one can use a manual approach or rely on automatic and semi-automatic techniques to infer them (Crescenzi et al. 2001).

In order to connect the sources to the mediated schema, a set of source descriptions are defined. Essentially, these descriptions represent a semantic mapping between every source schema and the mediated schema (but not across source schemas). These mappings define correspondences between source and target attributes and take care of different structural representation across the schemas. For example, if two attributes appear in the same relation in a source and in two relations in the target schema, and the two target relations have a foreign key defined across them, then the mapping explicitly represents the semantic relationship in the source with a join between the two target relations.

A different approach for integrating data from heterogeneous sources is data warehousing. In these systems, the underlying data sources are translated and materialized into a single phys-

ical database, called warehouse. While in the virtual approach, the queries posed on the mediated schema are then translated into queries on the base sources, in a warehouse system, the queries are directly answered on the materialized database. The query execution phase is usually faster on data warehouses, but they require an additional materialization step that is expensive in terms of resources and needs to be executed periodically in order to handle new data (e.g., every night). This materialization step is usually performed by using an extract, transform, load (ETL) tool that extracts data from the sources and loads them into the warehouse. Unlike wrappers, ETL tools execute more complex transformations to the data but are procedural in nature and require IT experts to write and maintain them over time.

A data integration system I is formally defined as a triple $\langle G, S, M \rangle$ (Lenzerini 2002), where:

- G is the global (or mediated) schema;
- S is the source schema;
- M is the mapping between G and S .

Both G and S are expressed in a language over an alphabet formed by symbols for each of the relations. The definition of M is one of the crucial aspects in the design of a data integration system. In the literature two different languages have been proposed, called *local-as-view* (*LAV*) and *global-as-view* (*GAV*).

In a system based on the GAV approach, M associates each element of G with a query over S . The main idea is that each element of the global schema should be characterized in terms of a view over the sources. This approach is conceptually very easy, and it is usually used when the source schemas are stable, since adding a new source may require to refine existing mappings.

On the other hand, in a LAV-based system, the source database is modeled as a set of views over G . This approach makes the introduction of new sources easier, since defining a LAV mapping does not require knowing other data sources, but it is sufficient to enrich the mapping with new constraints, without other changes.

Example 1 Consider a data integration scenario with a schema G and four different data sources, $S1$, $S2$, $S3$, and $S4$, as follows:

G

$SportEvent(date, desc, sport, venue_id)$
 $Venue(venue_id, name, city)$

S1

$SoccerEvent(date, desc, stadium_id)$
 $Stadium(id, name, zip)$

S2

$Sport(id, name)$
 $Event(date, desc, sport_id)$

GAV Mappings

$m_1 : SportEvent(date, desc, sport, venue_id) \subseteq SoccerEvent(date, desc, venue_id)$
 $m_2 : SportEvent(date, desc, sport, venue_id) \subseteq Event(date, desc, sport_id), Sport(id, sport)$
 $m_3 : Venue(id, name, city) \subseteq Stadium(id, name, zip), ZipCodes(zip, city)$

LAV Mappings

$m_4 : FB_Event(date, desc, type, location, city) \subseteq SportEvent(date, desc, type, venue_id),$
 $Venue(venue_id, location, city)$

Data Integration, Fig. 2 LAV and GAV mappings for Example 1

S3

$FB_Event(date, desc, type, location, city)$

S4

$ZipCodes(zip, city)$

The mappings for the scenario are shown in Fig. 2. Data sources $S1$ and $S2$ can be connected to the mediated schema by using three GAV mappings. Note how the mediated relation *SportEvent* is defined as the union of two conjunctive queries, m_1 and m_2 : the first one is used to map data from a single relation *SoccerEvent*, while the second one requires a join between *Event* and *Sport*. Another important consideration is that mappings in some cases may leave some information incomplete. For example, source relation *Event* does not have data for the venue of the event, so m_2 will generate some null values. Finally m_4 is an example of a vertical partition, where a source record is divided into two sets of records in the target and is expressed as a LAV mapping. The symbol \subseteq defines the open-world assumption. In essence, the data sources are assumed to be incomplete and may not describe all the data in the domain.

Once the data integration scenario is defined, users can start asking queries over the mediated schema. Since, as discussed, this mediated schema is virtual, in order to answer user queries, the system needs to convert them into queries over the base data sources using mappings M . This process is known as *query reformulation* and generates as result of a logical query plan that needs to be optimized and executed to produce the final result. The query reformulation

D

algorithm is different in case of GAV or LAV mappings. In the former case, since the mediated schema is defined as a set of views over base relations, the reformulation algorithm is based on a simple unfolding strategy. In essence, given a query q posed over G , every relation element is substituted with the corresponding query over the sources. In case of LAV mappings, the problem of processing a query is called view-based query processing, and it is based on techniques for answering queries using views (Pottinger and Halevy 2001).

Key Research Findings

Mapping Generation

It is evident that there is no data integration without precise and complete descriptions of the semantic relationships between sources and mediated schema. Creating such *schema mappings* is an expensive process that can be achieved only by people with expertise in computer science, as mappings need to be expressed formally, and in the application domain, to understand precisely the semantics of the schemas involved.

Several systems have been proposed to assist humans in the task of generating schema mappings from high-level specifications, such as a GUI. The ultimate goal is to automate as much as possible the mapping creation, thus reducing the time and cost in this process. To support this task, several modules must be put together. Given a source and the mediated schema, the initial step is to profile them to identify possible semantic correspondences across their attributes. This task is called *schema matching* and can be done by exploiting metadata (such as attribute labels and types), overlapping data values, previous manually created matchings stored in a corpus, or combinations of such methods (Bernstein et al. 2011). After the users have validated the correspondences, the following task is to create the mappings according to the desired language. The schema mapping creation takes the correspondences and returns (possibly) complex logical formulas that can support the data integration (Popa et al. 2002).

Query Processing

As discussed in the previous sections, a query posed over the mediated schema is reformulated to produce a logical query plan that is then executed by the system over the base data sources. In order to produce an efficient query plan, a data integration system relies on optimization techniques. This step is conceptually similar to the optimization process adopted by traditional data management systems, and many techniques may be adopted from the literature. However, since a data integration system is usually virtual, dynamic, and distributed, it needs some special treatments. In general, executing a query in an integration context requires to deal with several challenges that would not arise in a traditional DBMS system. For example, in order to choose an efficient query plan, the optimization module needs to estimate the cost of the I/O operations. In a DBMS this estimation can be very accurate, while it is usually more involved in a data integration scenario. In fact, a data source may be a relational DBMS but also a REST Web Service, an HTML page, and so on. In these settings, the optimizer may have not enough information to choose the right query plan.

In addition, there are several factors that may change the performance of a query plan over time, such as varying network connectivities or new workloads for any of the sources. As a result, a plan may be good at optimization time but significantly bad in a second moment. To solve these problems, an adaptive query processing architecture has been proposed (Ives et al. 1999, 2004). The main idea is that, in a data integration context, the traditional separation between the query execution engine and the query optimizer is not longer appropriate, but there is the need of a continuous interaction between them. In particular an adaptive query processing starts with a preliminary plan, and during the query execution, this plan is updated and reevaluated, with the result that the engine may even decide to change the query plan during execution (Ives et al. 2004).

P2P Data Management

The standard data integration architecture is based on the concept of a global unified schema.

In some cases this approach will require an important effort in order to abstract the model of the underlying data sources and a collaboration between the owners of the data sources. There are contexts in which organizations want to share data, but a mediated schema approach is not feasible or too expensive. An important contribution to solve these problems is the peer-to-peer data management architecture (Halevy et al. 2003, 2006; Tatarinov et al. 2003). The main difference with a classical data integration solution is that the mediated schema is not used anymore, but rather each source (or peer) provides mappings to a subset of other peers. In the resulting P2P architecture, users pose queries with respect to a specific peer's schema. A query is then recursively reformulated and forwarded to connected peers.

Examples of Application

Data integration has several possible applications. Traditionally, it has been developed in the context of managing enterprise or institutional data repositories. The need of querying across several internal data source happens naturally in several settings, such as large projects where multiple parties interact, or large organizations with several units or departments. More recently, data integration has become more visible as a commodity with websites. Several services offer the access to multiple data sources in a unified querying interface, for example, online search for accommodation or flights.

Future Directions for Research

In the last years, the amount of data available on the Web is growing in an exponential way. For example, recent work has shown that hundreds of millions of structured Web tables can be harvested and used in applications (Balakrishnan et al. 2015; Chakrabarti et al. 2016). The traditional approach of building a uniform global schema is affordable only with a reasonable number of data sources and does not scale to these new opportunities. Instead of integrating all the

data, the challenge here is to build a system that provides a uniform search services over these data sources as automatically as possible. This is the approach proposed with dataspaces (Franklin et al. 2005), which provide base functionality over all data sources, regardless of how integrated they are. New methods and systems are needed to enable pay-as-you-go approaches to data integration, where even structured and unstructured data can be integrated and become available with little setup time (Golshan et al. 2017).

Data Lake

Christoph Quix¹ and Rihan Hai²

¹Fraunhofer-Institute for Applied Information Technology FIT, Sankt Augustin, Germany

²RWTH Aachen University, Aachen, Germany

Definitions

A data lake is a data repository in which datasets from multiple sources are stored in their original structures. It should provide functions to extract data and metadata from heterogeneous sources and to ingest them into a hybrid storage system. In addition, a data lake should offer a data transformation engine, in which datasets can be transformed, cleaned, and integrated with other datasets. Finally, interfaces to explore and to query the data and metadata of a data lake should be also available in a data lake system.

Overview

The term “data lake” (DL) was first mentioned by James Dixon in 2010 in a blog post (<https://jamesdixon.wordpress.com/2010/10/14/pentaho-hadoop-and-data-lakes/>) where he put data marts on the same level as bottled water, which is cleansed, packaged, and structured for easy consumption. In contrast, a data lake manages the raw data as it is ingested from the data sources.

In the initial article (and in a later, more detailed article (<https://jamesdixon.wordpress.com/2014/09/25/data-lakes-revisited/>) in 2014), DLs are described as systems that store data from a *single* source. However, most people consider a DL today as a general enterprise-wide data repository which gets data from multiple sources. Still, it is important that there is some governance about the ingestion process for a DL; a DL is *able to* take data from any kind of data source, but in order to avoid a data swamp, the ingested data should fulfill some minimal requirements (e.g., providing metadata and a description of the raw data format). Gartner pointed this out also in their criticism (<http://www.gartner.com/newsroom/id/2809117>) of the DL concept. Especially, a proper metadata management is frequently mentioned as a basic requirement for a DL system, but details about the required metadata services (e.g., model or functions) are often missing.

Key Research Findings

Architecture

Some architecture models have been proposed, some are abstract sketches from industry (e.g., by pwc in Stein and Morrison (2014) or by podium data (<http://www.podiumdata.com/solutions/>)), and some are more concrete from research prototypes (e.g., Terrizzano et al. 2015). These proposals usually describe conceptual architectures, functional requirements, and possible product components, but they do not provide the theoretical or implementation details that would enable repeatable implementations, as these scenario-specific solutions may not apply

to a wider usage of DLs (Douglas and Curino 2015).

As Hadoop is also able to handle any kind of data in its distributed file system, many people think that “Hadoop” is the complete answer to the question on how a DL should be implemented. Of course, Hadoop is good at managing the huge amount of data with its distributed and scalable file system, but it does not provide detailed metadata functionalities which are required for a DL. For example, the DL architecture presented in Boci and Thistlethwaite (2015) shows that a DL system is a complex ecosystem of several components and that Hadoop provides only a part of the required functionality.

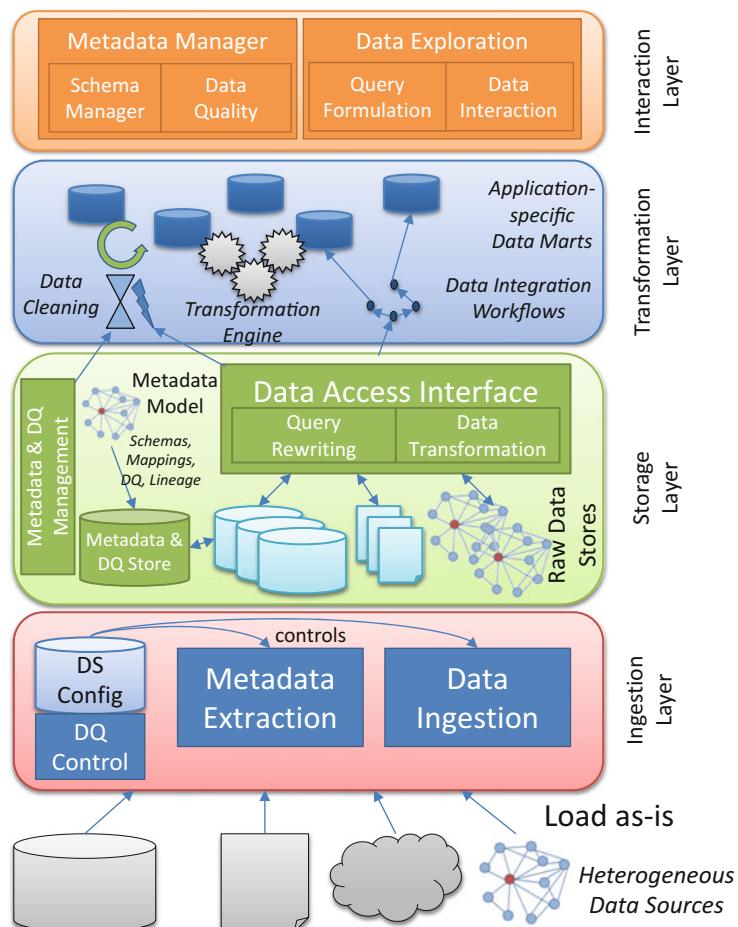

More recent articles about data lakes (e.g., Mathis 2017; LaPlante and Sharma 2016) mention common functional components of a data

lake architecture for ingesting, storing, transforming, and using data. These components are sketched in the architecture of Fig. 1 (Jarke and Quix 2017).

The architecture is separated into four layers: the *ingestion layer*, the *storage layer*, the *transformation layer*, and the *interaction layer*.

D

Data Lake, Fig. 1 Data lake architecture

information about the data sources, illustrated in the figure as *DS Config*. The metadata extractor needs to be able to detect schemas in semi-structured data (e.g., JSON or XML sources). The extracted metadata is managed by a metadata repository in the storage layer.

In addition to the metadata, the raw data also needs to be ingested into the DL. According to the idea, that the raw data is kept in its original format, this is more like a “copy” operation and thereby certainly less complex than an ETL process in data warehouses. Nevertheless, the data needs to be put into the storage layer of the DL, which might imply some syntactical transformation or loading of the data into the “raw data stores” in the storage layer. The loading process can be done in a lazy way, i.e., only if a user requests data from this particular data source (Karæz et al. 2013).

Data governance and data quality (DQ) management are important in DLs to avoid data swamps. The *DQ control* component should make sure that the ingested data has a minimal quality. For example, if a source with information about genes is considered, it should also provide an identifier of the genes in one of the common formats (e.g., from the Gene Ontology) instead of using proprietary IDs that cannot be mapped to other sources. Due to the huge volume and variety of the data, it is probably not be possible to specify all DQ rules manually; here, also automatic support is required to detect such rules and then also to evaluate these rules in a fuzzy way (Saha and Srivastava 2014). Also, data profiling techniques can help to identify patterns in the source data (Abedjan et al. 2015).

Storage Layer

The main components in the storage layer are the metadata repository and the repositories for raw data. The *metadata repository* stores all the metadata of the DL which have been partially collected automatically in the ingestion layer or will be later added manually during the curation or usage of the DL. The metadata should also include feedback from the users of the DL, e.g., which attributes have been used to join datasets, what kind of transformations (for integration or

data cleaning) have been applied to datasets, or for which analytical reports a dataset has been relevant. This information will be useful for subsequent usage of the datasets as it contains knowledge on how the dataset can be used. The main challenge for the metadata repository is the definition of a *metadata model*, which, on the one hand, is generic enough to represent the wide variety of metadata in a DL, and on the other hand, has detailed and concrete semantics for the metadata items. Furthermore, it should have a manageable complexity such that the metadata can be also exploited by the end users.

The raw data repositories are the core of the DL in terms of data volume. As the ingestion layer provides the data in its original format, different storage systems for relational, graph, XML, or JSON data have to be provided. Moreover, the storage of files using proprietary formats should be supported. Hadoop seems to be a good candidate as a basic platform for the storage layer, but it needs to be complemented with components to support the data fidelity, such as Apache Spark (<https://spark.apache.org/>). In order to provide a uniform way to query and access the data to the user, the hybrid data storage infrastructure should be hidden by a uniform *data access interface*. This data access interface should provide a query language and a data model, which have sufficient expressive power to enable complex queries and represent the complex data structures that are managed by the DL. Current systems such as Apache Spark and HBase (<https://hbase.apache.org/>) offer this kind of functionality using a variant of SQL as query language and data model. Another option is to use JSON as unifying data representation as this is supported by many NoSQL systems. Still, a problem is the lack of a standardized query language for JSON, but proposals as JSONiq (Florescu and Fourny 2013), which are based syntactically and semantically on the well-known query languages SQL and XQuery, are promising directions.

A major challenge is the rewriting of the user queries into the specific query languages of the raw data repositories. The classical query rewriting problem has been addressed in data integration for many years in which the main

focus was correctness and completeness of the rewritten query. In addition to this problem, many other aspects have to be considered for the rewriting in the DL system. For example, the costs for data transformation between the different data formats have also to be taken into account (When relational and JSON data should be joined, is it more efficient to translate the JSON data into a relational form or vice versa?) or the costs for moving the data between different nodes of the distributed storage system.

Transformation Layer

To transform the raw data into a desired target structure, the DL needs to offer a data transformation engine in which operations for data cleaning, data transformation, and data integration can be realized in a scalable way. In contrast to a data warehouse, which aims at providing one integrated schema for the all data sources, a DL should support the ability to create *application-specific* data marts, which integrate a *subset* of the raw data in the storage layer for a concrete application. From the logical point of view, these data marts are rather a part the interaction layer, as the data marts will be created by the users during the interaction with the DL. On the other hand, their data will be stored in one of the systems of the storage layer. The idea of data marts in this context is similar to the concept of personal information spaces, which were initially proposed in the context of dataspaces (Franklin et al. 2005), and support the idea of “pay-as-you-go” integration (Jeffery et al. 2008). The knowledge created during the definition of the data mart (e.g., information about how to transform, integrate, and analyze datasets) needs to be maintained at the transformation layer and should be captured in the metadata store.

In addition, data marts can be more application-independent if they contain a general-purpose dataset which has been defined by a data scientist. Such a dataset might be useful in many information requests of the users.

Interaction Layer

The top layer focuses at the interaction of the users with the DL. The users will have to access

the metadata to see what kind of data is available and can then explore the data. Thus, there needs be a close relationship between the *data exploration* and the *metadata manager* components. On the other hand, the metadata generated during data exploration (e.g., semantic annotations, discovered relationships) should be inserted into the metadata store using the *schema manager* and *enrichment* modules.

The *query formulation* component should support the user in creating formal queries that express her information requirement. As stated earlier, we cannot expect that the user is able to handle the functions offered by the data access system directly. The *data interaction* should cover all the functionalities which are required to work with the data, including visualization, annotation, selection and filtering of data, and basic analytical methods. More complex analytics involving machine learning and data mining is in our vision not part of the core of a DL system.

Lazy and Pay-as-You-Go Concepts

A basic idea of the DL concept is to consume as little upfront effort as possible and to spend additional work during the interaction with users, e.g., schemas, mappings, and indexes are created while the users are working with the DL. This has been referred to as lazy (e.g., in the context of loading database (Karæz et al. 2013)) and pay-as-you-go techniques (e.g., in data integration Sarma et al. 2008). All workflows in a DL system have to be verified, whether the deferred or incremental computation of the results is applicable in that context. For example, metadata extraction can be done first in a shallow manner by extracting only the basic metadata; only detailed data of the source is required; a more detailed extraction method will be applied.

A challenge for the application of these “pay-as-you-go” methods is to make them really “incremental,” e.g., the system must be able to detect the changes and avoid a complete recomputation of the derived elements. This challenge is also addressed in a Lambda architecture in which the speed layer should provide the incremental updates to the results computed by the batch layer.

Schema-on-Read and Evolution

DLS also provide access to un- or semi-structured data for which a schema was not explicitly given during the ingestion phase. Schema-on-read means that schemas are only created when the data is accessed, which is in-line with the “lazy” concept described in the previous section. The shallow extraction of metadata might also lead changes at the metadata level, as schemas are being refined if more details of the data sources are known. Also, if a new data source is added to the DL system, or an existing one is updated, some integrated schemas might have to be updated as well, which leads to the problem of schema evolution (Curino et al. 2013).

Another challenge to be addressed for schema evolution is the heterogeneity of the schemas and the frequency of the changes. While data warehouses have a relational schema which is usually not updated very often, DLs are more agile systems in which data and metadata can be updated very frequently. The existing methods for schema evolution have to be adapted to deal with the frequency and heterogeneity of schema changes in a big data environment (Hartung et al. 2011).

Mapping Management

Mapping management is closely related to the schema evolution challenge. Mappings state how data should be processed on the transformation layer, i.e., to transform the data from its raw format as provided by the storage layer to a target data structure for a specific information requirement. The definition of mapping languages and operations on mappings (e.g., composition) has been studied in the field of model management (Bernstein and Melnik 2007), an earlier research area at a time in which schema-less systems were not yet relevant and models were seen as an important asset in the design of interoperable information systems. Although heterogeneity of data and models has been considered and generic languages for models and mappings have been proposed (Kensche et al. 2009), the definition and creation of mappings in a schema-less world has not received much attention, yet. There has been some work in the context

of regular path queries for graph databases; for example, (Calvanese et al. 2012) defined the term “relative containment” for queries wrt. the sources that are available. Such a query language could be also applicable for a heterogeneous DL system.

A prerequisite for the definition of formal mappings is the identification of correspondences or similarities. If schemas are given explicitly, then schema matching approaches can support this task (Hartung et al. 2011); however, in DLs the raw data is less structured, and schema information is not explicitly available. Thus, in these contexts methods for data profiling or data wrangling have to be combined with schema extraction and relatable dataset discovery (Alserafi et al. 2017).

Query Rewriting and Optimization

There is a trade-off between expressive power and complexity of the rewriting procedure as the complexity of query rewriting depends to a large degree on the choice for the mapping and query language. However, query rewriting should not only consider completeness and correctness, but also the costs for executing the rewritten query should be taken into account. Thus, the methods for query rewriting and query optimization require a tighter integration (Gottlob et al. 2014).

It is also an open question whether there is a need for an intermediate language in which data and queries are translated to do the integrated query evaluation over the heterogeneous storage system or whether it is more efficient to use some of the existing data representations. Furthermore, given the growing adoption of declarative languages in big data systems, query processing and optimization techniques from the classical database systems could be applied as well in DL systems.

Data Governance and Data Quality

Since the output of a DL should be useful knowledge for the users, it is important to prevent a DL from becoming a *data swamp*. Similar with data warehouses, incomplete, inaccurate, and ambiguous data would jeopardize the query result accuracy, even worse, lead to unusable result

(Jarke et al. 1999). There is a trade-off between data openness and quality control. It is often mentioned that data governance is required for a DL. First of all, data governance is an organizational challenge, i.e., roles have to be identified, stakeholders have to be assigned to roles and responsibilities, and business processes need to be established to organize various aspects around data governance (Otto 2011). Still, data governance needs to be also supported by appropriate techniques and tools. For data quality, as one aspect of data governance, a similar evolution has taken place; the initially abstract methodologies have been complemented in the meantime by specific techniques and tools. Preventive, process-oriented data quality management (in contrast to data cleaning, which is a reactive data quality management) also addresses responsibilities and processes in which data is created in order to achieve a long-term improvement of data quality.

Applications of Data Lakes

Although data lakes are a young concept, many organizations are investigating or investing in data lake solutions. Organizations with a good data management architecture, established data governance, and several data integration solutions already in place (e.g., data warehouses) are considering data lakes as a complementary solution to their existing systems. However, the added value of a data lake in such situations might be low as many of the benefits of data lakes might be already covered by some of the existing systems.

In cases where the data management of an organization is much less developed, a data lake might be an approach to start data governance initiatives and to think about the business processes in a data-oriented way (e.g., where is data created, where is it consumed). Many organizations have a scattered data management landscape with hundreds or even thousands of partially interconnected, partially isolated databases. Especially in the case of data silos which are difficult to access, data lakes might provide a significant benefit as it

removes the hurdles to locate and to get physical access to a data source.

This situation can be often seen in industrial companies in which data has not been considered as a valuable resource. Now, with more Industry 4.0 applications and success stories becoming available, companies are examining data lakes as a potential solution to manage the data produced by their production processes or by their products. Also in the research and development department (industrial or academic), data lakes can be successful because of the heterogeneity of the sources and required flexibility in data analysis (Quix et al. 2016). A slightly different concept is the idea of a virtual or logical data lake, i.e., only metadata will be extracted from the sources and made available in a unifying metadata repository. For example, Google implements this idea in their GOODS system (Halevy et al. 2016). Such metadata registries with an overview of the datasets that are managed by an organization are also important in the context of the data privacy laws established in Europe, e.g., organizations must be able to report about the datasets with personal information managed by them.

Future Directions for Research

The approach of a raw data store in which data is only loosely connected is appealing to solve problems in getting access to the relevant data that is available in an organization. Yet, the idea of data lakes is still relatively new and has not seen much attention in research. Commercial data integration systems have addressed the data lake idea and are marketing their systems as solutions to the challenges to be addressed in data lake systems, e.g., methods for metadata extraction and metadata management. Still, there are many opportunities for research, starting from defining more general reference architectures to identify the important components of a data lake, to developing new methods for specific problems in the data lake context (e.g., schema summarization, identifying relatable datasets, data governance, query processing on heterogeneous datasets).

Data Longevity and Compatibility

Behrooz Parhami

Department of Electrical and Computer Engineering, University of California, Santa Barbara, CA, USA

Synonyms

Data archives; Data decay; Media lifespan; Storage failure

Definition of Entry

Whether stored locally or in the cloud, data ultimately resides on physical media that are subject to electrical and physical deterioration and format obsolescence, making it necessary to augment the physical storage of data with a logical organization to protect data integrity and ensure its longevity.

Overview

Like many other attributes of computing and digital systems, the volume of data produced in the world is rising exponentially (Denning and Lewis 2016; Hilbert and Gomez 2011), with a

D

growth rate that is even higher than those of circuit density and processor performance, modeled by Moore's law (Brock and Moore 2006). A few exabytes of data generation per day in the early 2010s is slated to rise to many yottabytes in the 2020s (Cisco Systems 2017; Jacobson 2013). As data gains ever-greater value in the operation of social and business enterprises, data management, integrity, and preservation become major concerns. Any physical storage medium is subject to decay over time and has a finite lifespan. Some of these lifespans are relatively short compared with desirable data retention periods in practical settings. The format in which data is stored tends to become obsolete as well. It follows that an active strategy for ensuring the integrity and longevity of stored data is an important part of any data management plan.

Media for Long-Term Data Storage

The media used for storing data have undergone significant changes over time (Goda and Kitsuregawa 2012). Data resources are maintained in hierarchical arrangements, with hardware components in the hierarchy ranging from superfast (but expensive and, thus, low-capacity) caches near processing resources to vast (but relatively slow) data vaults with ultralow storage costs. The goal of the management scheme for such hierarchical arrangements is to make the data items of highest current value reside in faster storage, where they can be efficiently accessed, with movements between the levels orchestrated so as to be responsive to changes in data values. Devices used for storing data for immediate access are known as hot storage media, in contrast to cold media that store data archives that are not in current use.

The order-of-magnitude correspondences shown in Table 1 are helpful in putting data volumes in perspective. In rough terms, the first four rows of the table (up to TBs) are currently within the domain of personal storage (although the numbers will no doubt expand in the coming years), whereas the last four are within the

Data Longevity and Compatibility, Table 1 Developing an appreciation for data volumes

Abbr.	Name	Bytes	Example(s)
KB	Kilobyte	10^3	One page of text or a small contact list
MB	Megabyte	10^6	One photo or a short YouTube video
GB	Gigabyte	10^9	A movie
TB	Terabyte	10^{12}	Netflix's movies, 4 years worth of watching
PB	Petabyte	10^{15}	Data held by an e-commerce site or bank
EB	Exabyte	10^{18}	Google's data centers
ZB	Zettabyte	10^{21}	WWW size or capacity of all hard drives
YB	Yottabyte	10^{24}	Worldwide daily data production by the 2020s

purview of large organizations, municipalities, or nation-states. At the rate data production is growing, it won't be long before we will have to decide whether to adopt proposed prefixes for 10^{27} and 10^{30} (Googology Wiki 2018).

Data lifetimes range from seconds (for temporary results kept in scratchpad or working memory, as database transactions run to completion) to centuries or more (for historical archives). Each combination of data lifetime duration and data access requirement dictates the use of certain storage device types. Setting volatile semiconductor memories aside because of their nonpermanence, the most common storage technologies used in the recent past are listed in Table 2.

Data Decay and Device Lifespans

All storage media decay over time, although the degradation mechanism, and thus methods for dealing with it, is technology-dependent. Degradations that are small-scale and/or local can be compensated for through error-correcting codes. However, once a certain number of data errors have been corrected automatically, the storage medium must be discarded and a fresh copy of the data created in a different place, because continued deterioration will eventually exceed the codes' error-correcting capacity, leading to data loss.

Magnetic storage media, the most commonly used current technology for large-scale and long-term data repositories (hot or cold), degrade through weakening or loss of magnetization, a process that is accelerated by external magnetic

fields, heat, vibration, and a number of other environmental factors. Generally, the result of such deterioration is partial data erasure, rather than arbitrary changes to the stored information. Thus, when codes are used, they can be of the erasure variety (Plank 2013; Rizzo 1997), which imply lower redundancy compared with codes for correcting arbitrary errors. Archival magnetic media, such as reel tapes, must be stored under carefully regulated environmental conditions to maximize their lifespans.

Optical storage media can decay due to the breakdown of material onto which data is stored. Here too storing the media under proper environmental conditions can reduce data decay and increase the media's lifespan. When longer lifespans are desired, storage media of higher quality must be procured. In particular, M-discs and other specially developed archival media can prolong lifespans to many centuries (Jacobi 2018; Lunt et al. 2013). Such long lifespans can be validated only via accelerated testing (Svrcek 2009), a process whose results are not as trustworthy as those obtained through direct testing in actual field use.

Solid-state media use electrical charges to store data. Imperfect insulation can lead to charges leaking out and thus data being lost. Given that the device itself degrades much more slowly, refreshing data before total decay is one possible strategy for avoiding data loss. This process is in effect very similar to refreshing in DRAM chips (Bhati et al. 2016), except that the refreshing occurs at much slower rates and, thus, its performance hit and power waste are not serious issues.

Data Longevity and Compatibility, Table 2 Attributes of storage devices in use over the past few decades

Type	Capacity	Cost	Speed	Life (years)	Archival	Additional information
Floppy disk	MB	Low	Low	5–7	No	Obsolete technology/format
CD/DVD	GB	Low	Medium	3–10	Yes	Are becoming less prominent
Blu-ray	GB+	Low	Medium	50	Yes	Still used for small-scale archives
M-disc	GB+	Low	Medium	1000	Yes	Lifespan unverified
Memory card	GB	High	High	5–10	No	Temporary personal storage
Cassette tape	GB	Low	Low	10–20	No	Obsolete technology/format
Cartridge	GB+	Low	Low	10–20	Yes	Used in mechanically accessed vaults
Hard disk	TB	Medium	Medium	3–5	No	Increasingly being replaced by SSDs
SSD (flash)	TB	High	High	5–10	No	Lifespan varies with write frequency
Reel tape	TB+	Low	Low	20–30	Yes	Lifespan with proper storage, low use
Disk array	PB	Medium	Medium	10–20	Yes	Lifespan improved by fault tolerance

Sources differ widely on the useful lifespans of data storage media. This is in part due to the fact that manufacturing quality associated with various suppliers and environmental conditions under which the media operate varies widely. Some typical figures for the most common media are included in Table 2. These figures should be used with caution, as there is no guarantee that even the lower ends of the cited ranges will hold in practice.

Preventing, and Recovering from, Data Decay

Countermeasures for avoiding data decay are very similar in nature to those used to deal with data corruption, loss, or annihilation, discussed in this encyclopedia's entry “Data Replication and Encoding” and in general references on dependable and fault-tolerant computing (Parhami 2018). Low redundancy coding can counteract small-scale or local damages (Rao and Fujiwara 1989), while replication helps prevent widespread damage. Of course, replication comes with a high storage cost, which will be even more prohibitive in the age of big data. For this reason, data dispersion (Iyengar et al. 1998; Rabin 1989) and network coding (Dimakis et al. 2011) schemes, which in effect combine the advantages of low redundancy coding with the error correction strengths of replication, will

be the preferred methods for large collections of data.

Decades of experience with building and managing large database systems are being applied to the design of big data repositories that are nonvolatile and long life (Arulraj and Pavlo 2017). However, new challenges arising from enormous amounts of less structured and unstructured data remain to be overcome. Recovery methods (Arulraj et al. 2015) are both device- and application-dependent, so they need continual scrutiny and updating as storage devices evolve, and data is used in previously unimagined volumes and ways.

Future Directions

The importance of building large-scale, nonvolatile data archives in order to safeguard immense volumes of valuable data has been recognized, to the extent of being discussed in the mass media (Coughlin 2014). Many projects are trying to achieve this goal (Yan et al. 2017). Some of the components needed for such system are already available and others are being invented.

On the storage technology side, disk arrays (Chen et al. 1994), which have played an important role in satisfying our data storage capacity and reliability needs for many years, must be adapted to the challenges presented by big data. We currently don't view semiconductor memories as suitable for data archives, but this

assessment may change in light of technology advances (Qian et al. 2015).

On the data structuring, management, and maintenance side, data centers and their interconnection networks will play a key role in the development of robust permanent data archives (Chen et al. 2016). Improved understanding of storage device failure mechanisms and data decay (Petyscale Data Storage Institute 2012; Schroeder and Gibson 2007) is another line that should be pursued.

Finally, development of new technologies for data storage, discussed in this encyclopedia under “Storage Technologies for Big Data” and “Emerging Hardware Technologies,” will no doubt be accelerated as the storage and longevity needs to expand. Examples abound, but two promising avenues currently being pursued are storing vast amounts of data on DNA (Bornholt et al. 2016; Goldman et al. 2013) and building memories based on emerging nanotechnologies involving memristors and other new device types (Menon and Gupta 1999; Strukov et al. 2008).

Definitions

According to Naumann (2013), Abedjan et al. (2015), data profiling is the set of activities and processes to determine the metadata about a given dataset. Metadata can range from simple statistics, such as the number of null values and distinct values in a column, its data type, or the most frequent patterns of its data values, to complex inter-value and intercolumn dependencies. Metadata that are more difficult to compute involve multiple columns, such as inclusion dependencies or functional dependencies. Collectively, a set of results of these tasks is called the *data profile* or *database profile*. In the *Encyclopedia of Database Systems*, Johnson considers data profiling as the activity of creating small but informative summaries of a database (Johnson 2009). In contrast to data mining, the focus of data profiling is typically the structure of a dataset. Thus data profiling generates knowledge about columns of a dataset, while data mining focusses on the actual records.

Overview

Data profiling encompasses a vast array of methods to examine datasets and produce metadata. Like many data management tasks, data profiling faces three challenges: (i) managing the input, (ii) efficiently performing the computation, and (iii) managing the output. Apart from typical data formatting issues, the first challenge addresses the problem of specifying the expected outcome, i.e., determining which profiling tasks to execute on which parts of the data. In fact, many tools require a precise specification of what to inspect. Other approaches are more open and perform a wider range of tasks, discovering all metadata automatically.

Research and industry have tackled the second challenge in different ways, relying on the capabilities of the underlying DBMS and formulating profiling tasks as SQL queries, using indexing schemes, parallel processing, and reusing intermediate results. Additionally, several methods have been proposed that deliver only approximate

Data Profiling, Fig. 1 A classification of traditional data profiling tasks

results for various profiling tasks in order to handle Big Data. Figure 1 shows the classification of profiling tasks according to Abedjan et al. (2015), which includes single-column tasks, multicolumn tasks, and dependency detection. While dependency detection falls under multicolumn profiling, it is assigned a separate profiling class to emphasize this large and complex set of tasks.

The third challenge has not yet been the focus of broader research. Typically an aggregation of the huge amounts of meta-data in form of histograms or graphs is desirable (Kandel et al. 2012; Abedjan et al. 2014a; Papenbrock et al. 2015a).

Key Research Findings

There are different directions of research that address the three general categories of data pro-

filing. Research on single column profiling is mostly concerned with the reduction of complexity in the number of rows, trying to avoid full scans or superlinear operations on the entire column. Research on multicolumn profiling and dependency discovery is mostly concerned with the reduction of the exponential complexity with regard to the number of attribute and value combinations, trying to discover new practical pruning techniques.

Single-column profiling addresses the generation of counts, such as the number of values, the number of unique values, and the number of non-null values. These metadata are often part of the basic statistics gathered by the DBMS. In addition, the maximum and minimum values are discovered, and the data type is derived (usually restricted to string vs. numeric vs. date). More advanced techniques create histograms of

value distributions and identify typical patterns in the data values in the form of regular expressions (Raman and Hellerstein 2001). Among specializations of these techniques are methods to determine the frequency distribution of soundex code, n-grams, and others; the inverse frequency distribution, i.e., the distribution of the frequency distribution; or the entropy of the frequency distribution of the values in a column (Kang and Naughton 2003). A particularly interesting distribution is the first digit distribution for numeric values. Benford's law states that in naturally occurring numbers, the distribution of the first digit d of a number approximately follows $P(d) = \log_{10}(1 + \frac{1}{d})$ (Benford 1938).

Multicolumn profiling generalizes profiling tasks on single columns to multiple columns and also identifies inter-value dependencies and column similarities. There has been work on computing multidimensional histograms for query optimization (Poosala and Ioannidis 1997; Deshpande et al. 2001). Multicolumn profiling also plays an important role in data cleansing, e.g., in assessing and explaining data glitches, which can be exposed considering column combinations instead of single columns (Dasu et al. 2014). Another task is to identify correlations between values through frequent patterns or association rules (Hipp et al. 2000). Furthermore, clustering approaches that consume values of multiple columns as features allow for the discovery of coherent subsets of data records and outliers (Berti-Equille et al. 2011; Dasu and Loh 2012). Similarly, generating summaries and sketches of large datasets relates to profiling values across columns (Garofalakis et al. 2013; Ntarmos et al. 2009; Dasu et al. 2006).

Dependencies are metadata that describe relationships among columns. The difficulties of automatically detecting such dependencies in a given dataset are twofold: First, pairs of columns or larger column sets must be examined, and second, the existence of a dependency in the data at hand does not imply that this dependency is meaningful. While much research has been invested in addressing the first challenge, there is less work on semantically interpreting the profiling results. There has been a series of new algorithms that apply hybrid pruning techniques

that reduce the runtime of validating a dependency by using inverse indexing structures (Heise et al. 2013; Papenbrock et al. 2015b; Abedjan et al. 2014b). Additionally, new algorithms apply advanced search strategies to efficiently prune the exponential solution space, using random walk techniques or user-defined heuristics (Heise et al. 2013; Papenbrock and Naumann 2016). There is also a huge body of work on the so-called relaxed dependencies (Caruccio et al. 2016), which focus on dependencies that only hold (1) partially, i.e., for a subset of the data; (2) conditionally, i.e., for a subset of the data co-occurring with a condition; or (3) for similarity-based relationships, i.e., dependencies are not invalid if depending values are unequal as long as they are at least similar.

Examples of Application

Data profiling has many traditional use cases, including the data exploration, data cleansing, and data integration scenarios. Statistics about data are also useful in query optimization.

Data exploration. Users are often confronted with new unknown datasets. Examples include data files downloaded from the Web, old database dumps, or newly gained access to some DBMS. In many cases, such data have no known schema, no or old documentation, etc. Even if a formal schema is specified, it might be incomplete, for instance, specifying only the primary keys but no foreign keys. A natural first step is to identify the basic structure and high-level content of a dataset. Data profiling techniques can support such manual exploration. Simple, ad hoc SQL queries can reveal some insight, such as the number of distinct values, but more sophisticated methods are needed to efficiently and systematically discover metadata.

Database management. Typically, the generated metadata include various counts, such as the number of values, the number of unique values, and the number of non-null values. These metadata are often part of the basic statistics gathered by a DBMS. An optimizer uses them to estimate the selectivity of operators and perform

other optimization steps. Mannino et al. give a survey of statistics collection and its relationship to database optimization (Mannino et al. 1988). More advanced techniques use histograms of value distributions, functional dependencies, and unique column combinations to optimize range queries (Poosala et al. 1996) or for dynamic reoptimization (Kache et al. 2006).

Database reverse engineering. Given a “bare” database instance, the task of schema and database reverse engineering is to identify its relations and attributes, as well as domain semantics, such as foreign keys and cardinalities (Petit et al. 1994; Markowitz and Makowsky 1990). Hainaut et al. call these metadata “implicit constructs,” i.e., those that are not explicitly specified by DDL statements (Hainaut et al. 2009). However, possible sources for reverse engineering are DDL statements, data instances, data dictionaries, etc. The result of reverse engineering might be an entity-relationship model or a logical schema to assist experts in maintaining, integrating, and querying the database.

Data integration. Before different data sources can be integrated, one has to consider the dimensions of a dataset, its data types, and formats. A concrete use case for data profiling is that of *schema matching*, i.e., finding semantically correct correspondences between elements of two schemata (Euzenat and Shvaiko 2013). Many schema matching systems perform data profiling to create attribute features, such as data type, average value length, patterns, etc., to compare feature vectors and align those attributes with the best matching ones (Madhavan et al. 2001; Naumann et al. 2002).

Scientific data management and integration have created additional motivation for efficient and effective data profiling: When importing raw data, e.g., from scientific experiments or extracted from the Web, into a DBMS, it is often necessary and useful to profile the data and then devise an adequate schema. In many

cases, scientific data is produced by non-database experts and without the intention to enable integration. Thus, they often come with no adequate schematic information, such as data types, keys, or foreign keys. Additionally, many life-science databases have been created and updated through a long period of time creating disconnected and redundant tables that require exhaustive search and exploration before they can be put into purposeful use again.

Data quality/data cleansing. A typical use case of data profiling data is the *data cleansing* process. Commercial data profiling tools are usually bundled with corresponding data quality/data cleansing software. Profiling as a data quality assessment tool reveals data errors, such as inconsistent formatting within a column, missing values, or outliers. Profiling results can also be used to measure and monitor the general quality of a dataset, for instance, by determining the number of records that do not conform to previously established constraints (Pipino et al. 2002; Kandel et al. 2012). Generated constraints and dependencies also allow for rule-based data imputation.

Big Data analytics. Many Big Data and related data science scenarios call for data mining and machine learning techniques to explore and mine data. Again, data profiling is an important preparatory task to determine which data to mine, how to import it into the various tools, and how to interpret the results (Pyle 1999). In this context, leading researchers have noted “*If we just have a bunch of datasets in a repository, it is unlikely anyone will ever be able to find, let alone reuse, any of this data. With adequate metadata, there is some hope, but even so, challenges will remain[...]*”(Agrawal et al. 2012)

Future Directions for Research

Much of the data that currently is being focused on for application purposes is of nontra-

ditional type, i.e., non-relational, non-structured (textual), and heterogeneous. Many existing profiling methods cannot adequately handle that kind of data: Either they do not exist yet or they do not scale to the existing dimensions of data. Furthermore, fast data poses a new challenge to data profiling. With fast data we are considering data that changes over time through transactions or simply streaming data. For a more elaborate overview of upcoming challenges of data profiling, we refer to (Naumann 2013).

As mentioned in the introduction, the interpretation of profiling results remains an open challenge. To facilitate interpretation of metadata, effectively visualizing any profiling results is of utmost importance. So far, there are only prototypes that rudimentary tackle visualization of metadata (Kandel et al. 2012; Abedjan et al. 2014a; Papenbrock et al. 2015a).

Definitions

Provenance is the derivative history of data (Ko et al. 2015; Ko and Will 2014). While provenance does not directly contribute to upholding and enforcing the information security requirements (confidentiality, integrity, and availability) in the context of Big Data security, provenance and its sources (e.g., metadata, lineage, data activities (create, read, update, and delete)) strongly provide verification and historical evidence to support the analysis or forecasting needs for the purpose of data security. One example is to analyze provenance to understand and prevent outages better (Ko et al. 2012), so as to achieve better availability. Provenance also contributes strongly to data forensics, especially in the study of data activity patterns triggered by software or human processes (Ko et al. 2015) (e.g., ransomware). The lineage and metadata describing provenance also provide substantial evidence for transparency and data accountability (Ko 2014). With provenance, one would essentially be able to find out or verify “what happened behind the scenes” for Big Data activities, leading to a strong case for security attribution.

Overview

In the process of Big Data leveraging the high speed (velocity), large amount (volume), and various types (variety) of data item to provide better analytics (value), there is an inherent heavily reliance on data quality (veracity). Consequently, Big Data faces challenges of data integrity, data quality, and privacy. In perhaps a cyclical way, these challenges are in turn amplified by the 4V characteristics: velocity, volume, variety, and veracity.

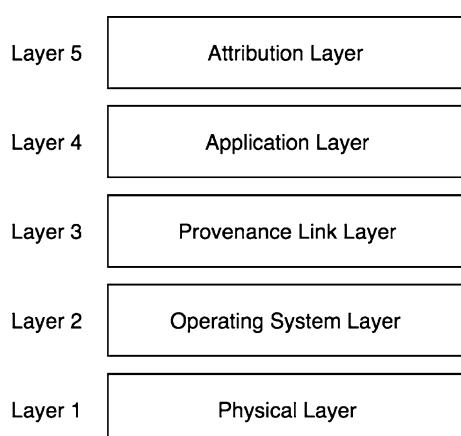

A typical Big Data workflow consists of five phases: data acquisition, extraction, integration, analysis, and interpretation. There are security risks associated with each phase, and these risks greatly affect the soundness and effectiveness of Big Data analysis. Data provenance, the deriva-

tion history of data (Ko et al. 2015; Ko and Will 2014), can improve the quality of the results by providing supporting metadata to enhance the Big Data workflow and to also serve as a tool for security, attribution, and forensics. While data provenance does not provide the security requirements of confidentiality, integrity, and availability, it serves as a security tool to provide detection, prevention, and mitigation needs – increasing the accountability of Big Data.

Provenance Abstraction Layers

Using the Full Provenance Stack (Ko and Phua 2017) shown in Fig. 1 as a guideline, a complete and meaningful Big Data provenance can be achieved. The Full Provenance Stack is an abstract model that classifies provenance into five separate layers. The higher layers encapsulate the layer below to refine the understanding of provenance from layers below them. Layer 1 is the physical layer. In this layer, provenance information found at hardware and BIOS/firmware level can be collected and analyzed. This is especially relevant in verifying the hardware integrity of the data-generating source. Data originating from a source that fails to establish its integrity can be discarded. In layer 2, data provenance in layer 1 is encapsulated to provide atomic human-readable provenance data,

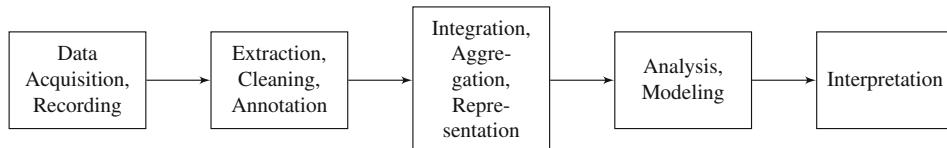

at the operating systems running on the layer 1 hardware. Activities such as data creation, reading, updating, and deleting are now captured in atomic actions such as operating system calls. Layer 3 of the provenance stack makes sense of the data flow tracking of ingress and egress of Big Data information flow between and within nodes. Nodes may be virtual machines, routers, mobile devices, or physical servers. This layer ensures there is an accurate encapsulation and representation of data provenance in between and across nodes. A compromised node can be identified by verifying the layer 3 provenance. Layer 4 provenance is what most Big Data systems record, the application provenance. This is provenance specific to a particular application or a specific phase in the Big Data workflow. Examples can be Web browsing information or database transactions. This layer of provenance provides phase-specific, semantic-rich provenance data. Layer 5, the final layer of the provenance stack, is the attribution layer; this is the encapsulation of all layers below, to provide a complete understanding of the who, what, when, where, how, and why explanation of the analysis results. At layer 5, we can attribute data creators and provide accountability and transparency for Big Data.

Data Provenance for Big Data Security and Accountability, Fig. 1 Full provenance stack (Ko and Phua 2017)

Provenance Phases in Big Data Workflows

From understanding the layers, we now move to understanding the flow and phases of provenance in relation to the Big Data workflow shown in Fig. 2. The data acquisition phase revolves around the gathering of data from various data-generating sources. This could be a heart rate monitor, emails, social network, or any Internet of things (IoT) devices. The key challenge in this phase is data quality. As the volume of data acquired may be enormous, in many cases, most of the data is discarded, either because it appears to be erroneous or of no relevance. However, it is difficult to justify which and why data should be discarded. For example, a data set may seem irrelevant at a moment but may in reality play a crucial role in the analysis process at a later

Data Provenance for Big Data Security and Accountability, Fig. 2 Big data workflow (Agrawal et al. 2012)

stage. Data provenance can record and provide the metadata required to strengthen such justifications. For example, the provenance metadata can provide information relating to how the data set was recorded, in what unit was it measured in, and further details of the data-generating source. In addition to that, data provenance can also help to eliminate inputs from untrusted data-generating sources. For example, after identifying a source that has been providing inconsistent, missing, or erroneous data, a filter may be put in place to analyze the provenance metadata and discard any data originating from this untrusted source.

Next, we discuss the extraction phase. Because data sets come in myriad forms – from sensor data to images or plain text – they may sometimes be annotated or prepared prior to analysis. The extraction phase attempts to extract information into structured form to ease analysis. An example of data extraction method is natural-language processing (NLP). This process concerns the data quality and data integrity, that is, how complete and accurate the extracted data is. Data provenance has two responsibilities here: it provides the necessary metadata to provide context and semantics to allow for better and more accurate extraction process; it also records a new provenance, to support the other phases in the pipeline. Data provenance also empowers better data integrity – aligned to typical information security requirements.

The integration phase focuses on incorporating data from other internal or external sources to expand the possibilities of Big Data analysis, for example, relating a customer's shopping habits to their online social network activities. The relationship between these data sets is not explicit and can be challenging; relevant data may be excluded resulting in missed opportunities; or

irrelevant data may be included resulting in a less accurate analytic result(s). Data provenance may reveal some non-apparent relationships between two data sets to make the integration process more coherent. Apart from relevance, the quality of the integrated data needs to be verified to prevent contamination of data. The system can gauge the trustworthiness and quality of integrated data set through their provenance.

After the analysis phase, the results are being interpreted in the interpretation phase. The interpretation phase is not a straightforward process. One must not only possess the skill but must also take into account system errors and the assumptions made. Results produced need to be verified and justified. Data provenance aids in interpreting the results by providing information on (1) how the result was derived, (2) which data contributes to the result, and (3) how a particular data set contributes to the result. Data provenance information should reveal any possibilities or at least make identifying errors and false assumptions clearer. Therefore, one can repeat the analysis process to obtain a more accurate result.

In addition, the distributed environment and actors are also of concern in Big Data security. Big Data analysis is usually carried out in a cloud environment due to their capabilities and flexibilities. However, using a third-party computing and storage resource like cloud computing poses a risk to the privacy of data, data integrity, and data quality. The security of the cloud provider needs to be taken into account, internally and externally. An external risk is that an attacker can either steal or perform malicious attack to degrade the quality of the results. An internal risk can be a malicious insider at the cloud provider. In this case, provenance information could enable the transparency required to prevent security risks in the future.

Key Provenance Research for Big Data Security

One of the earliest research applications for data provenance in distributed, large-scale Big Data was in the area of scientific workflows. Data provenance information is used by the scientific community to facilitate the reuse and sharing of experimental data. The use of data provenance has then been extended to several areas such as operating systems, database systems, and cloud computing.

Provenance-aware storage system (PASS) (Muniswamy-Reddy et al. 2006) is a storage system that automatically collects and maintains provenance. Muniswamy-Reddy et al. proposed that provenance should be treated as metadata collected and maintained by storage system. This allows storage system to generate system-level provenance automatically while easing the need for additional provenance management task. This system captures provenance data by intercepting system calls. A stackable file system was used along with a database engine to store provenance metadata.

File-Centric Logger (Flogger) (Ko et al. 2011) by Hewlett-Packard Labs was the first data-centric provenance logger for cloud data provenance tracking. This system uses the Linux Loadable Kernel Module and the Windows Device Driver to capture cloud data provenance by intercepting file and network operations. Provenance was captured at all virtual machines and physical machines. The provenance from virtual machines was securely transmitted to their physical machines via a communication channel and subsequently written to log files and then stored in a data store. Provenance from virtual machines can be correlated with the related provenance captured in the physical machines hosting the virtual machines. Ko et al. have identified that this system, like most system, runs under the assumption of kernel integrity and that provenance logs need to be tamper-proof and immutable.

Provenance logger (Progger) (Ko and Will 2014) is a tamper-evident, kernel-space cloud data provenance system. The system was de-

signed to address four critical data security and integrity problems: tamper-evidence of provenance logs, precise timestamp synchronization across machines, growth of provenance logs, and the efficient logging of root usage of the system. This work later inspired HPLogger (Fu et al. 2017), which is a provenance monitoring tool built upon Progger, tailored specific for Hadoop. HPLogger reduces the number of system calls recorded, minimized the log files by reducing the details captured, and limits the capturing scope within the Hadoop working directory. While this improves the performance of the provenance logging system, the granularity and level of details are also significantly reduced.

D

Examples Applications

Identification and exclusion of untrusted source. In Big Data, it is common for data from different sources and origins to be integrated (data fusion). However, if one or multiple combined source(s) of data is of low quality, it is hard to filter them out after it has been combined and aggregated. Data provenance is able to clearly identify each data unit and allows for removal of data from untrusted source.

Combating data poisoning attacks. Data poisoning attack is the deliberate introduction of false data to affect the Big Data analytic results. Such data can be filtered out and discarded with the help of data provenance. The origin of the data can be verified from the data provenance, and even if the origin has been spoofed, by comparing other provenance, metadata should reveal when and how was the false data introduced. For example, the false data may have missing data provenance information on extraction phase of the Big Data workflow; this can be an indicator that this is a false data, and this data is introduced after the extraction phase.

Audit trails identifying source of problems. In distributed environment, a processing node may be compromised or contains bugs, therefore

contaminating the analysis of the results. An error introduced in any phase of the Big Data workflow will render the entire process a failure. Data provenance keeps a complete audit trail, allowing for clear explanation of the source and cause of the problem, that is in which phase the error occurred, which nodes and data is affected and how are they affected.

Future Directions for Research

First-person provenance. Existing provenance logging systems can be regarded as third-person provenance, i.e., the host which is processing the data monitors the actions performed on the data and records it in a log file or database, separated from the data itself. Since Big Data analysis is performed in a distributed environment, recording the creation and modification isolated within an environment cannot provide a full picture unless the provenance data of all systems involved are aggregated. In other words, the provenance generated is only useful if it is recorded and passed down the Big Data workflow pipeline. This allows each phase to utilize the provenance recorded. Therefore, a first-person provenance approach is needed, such that data provenance is embedded along with the data itself (e.g., within the file which describes the data) and exists throughout the entire Big Data workflow.

Secure provenance. As expressed in the section above, data provenance can be used as a security tool. However, this is under the assumption that the provenance tracking and reporting system is accurate and trusted. Similar to any system, provenance system can be manipulated and compromised to record and report incorrect information or even leak sensitive information. Therefore, in order to rely on data provenance as a security tool, the provenance system must record accurate provenance, tamper-proof or tamper-evident, and enforce dynamic, fine-grained access control. Current provenance systems have yet to achieve or have only partially achieved these requirements.

Provenance storage overheads. One of the main challenges to collecting provenance is its overheads, particularly storage overheads. Provenance can grow up to 22 times the size of the original data (Xie et al. 2013). There have been proposals for provenance compression, but compression and decompression require computing effort and may shift the problem of storage overhead to performance overheads. This is especially crucial in Big Data as both storage and performance are critical.

Definitions

Data quality is commonly conceived as a multidimensional construct defined as “fitness for use.” Data quality may depend on various factors (dimensions or characteristics) such as completeness, consistency, availability, etc. Data quality assessment involves the measurement of quality dimensions or criteria that are relevant to the use case. A metric or measure is a procedure for measuring a data quality dimension with the help of a tool. These metrics are heuristics that are designed to fit a specific assessment situation.

Overview

In this chapter, we first introduce the concepts of Linked Data quality and its dimensions and metrics. Then we provide definitions for 18 quality dimensions along with a total of 69 metrics to measure the dimensions.

Thereafter, we provide an overview of tools currently available for Linked Data quality assessment followed by an introduction to the W3C Data Quality Vocabulary. Finally, we discuss some of the open research challenges along with few solutions already available.

Semantic Web Data Quality

The increasing diffusion of the Semantic Web as a standard way to share knowledge on the Web allows users and public and private organizations to fully exploit structured data from very large datasets, which were not available in the past. Over the last few years, Linked Data (LD) developed into a large number of datasets with an open access from several domains leading to the Linked Open Data cloud (Heath and Bizer 2011). This vast rich integrate data space can fuel many data-driven discoveries; however, this process is quite challenging due to the (poor) quality of Linked Data. However, assessing Linked Data quality is particularly a challenge as the underlying data stems from a set of multiple, autonomous, and evolving data sources. It is

extremely important to assess the quality of the datasets used in Linked Data applications, before using them, allowing users or applications to understand whether data is appropriate for their task at hand.

Data Quality Dimensions and Metrics

Data quality assessment involves the measurement of quality *dimensions* or *criteria* that are relevant to the consumer. The dimensions can be considered as the characteristics of a dataset. A data quality assessment *metric*, *measure*, or *indicator* is a procedure for measuring a data quality dimension (Bizer and Cyganiak 2009). These metrics are heuristics that are designed to fit a specific assessment situation (Leo Pipino and Rybold 2005). An assessment score is computed from these indicators using a scoring function. In the next section, definitions of 18 data quality dimensions are provided along with their respective 69 metrics that are studied in a survey of the quality of Linked Data (performed in Zaveri et al. 2016). These dimensions are classified into the (i) accessibility, (ii) intrinsic, (iii) contextual, and (iv) representational groups.

Accessibility Dimensions

The dimensions belonging to this category involve aspects related to the access, authenticity, and retrieval of data to obtain either the entire or some portion of the data (or from another linked dataset) for a particular use case. There are five dimensions that are part of this group, which are *availability*, *licensing*, *interlinking*, *security*, and *performance*.

Availability of a dataset is the extent to which data (or some portion of it) is present, obtainable, and ready for use.

Metrics. Availability of a dataset can be measured in terms of accessibility of the server, SPARQL endpoints, or RDF dumps and also by the dereferencability of the URIs.

Licensing is defined as the granting of permission for a consumer to reuse a dataset under defined conditions.

Metrics. Licensing can be checked by the indication of machine- and human-readable information associated with the dataset clearly indicating the permissions of data reuse.

Interlinking refers to the degree to which entities that represent the same concept are linked to each other, be it within or between two or more data sources.

Metrics. Interlinking can be measured by using network measures that calculate the interlinking degree, cluster coefficient, sameAs chains, centrality, and description richness through sameAs links.

Security is the extent to which data is protected against alteration and misuse.

Metrics. Security can be measured based on whether the data has a proprietor or requires web security techniques (e.g., SSL or SSH) for users to access, acquire, or reuse the data. The importance of security depends on whether the data needs to be protected and whether there is a cost of data becoming unintentionally available. For open data, the protection aspect of security can be often neglected, but the non-repudiation of the data is still an important issue. Digital signatures based on private-public key infrastructures can be employed to guarantee the authenticity of the data.

Performance refers to the efficiency of a system that binds to a large dataset, that is, the more performant a data source is, the more efficiently a system can process data.

Metrics. Performance is measured based on the scalability of the data source, that is, a query should be answered in a reasonable amount of time. Also, detection of the usage of prolix RDF features or usage of slash URIs can help deter-

mine the performance of a dataset. Additional metrics are low latency and high throughput of the services provided for the dataset.

Intrinsic Dimensions

Intrinsic dimensions are those that are independent of the user's context. There are five dimensions that are part of this group, which are *syntactic validity*, *semantic accuracy*, *consistency*, *conciseness*, and *completeness*. These dimensions focus on whether information correctly (syntactically and semantically), compactly, and completely represents the real world and whether information is logically consistent in itself.

Syntactic validity is defined as the degree to which an RDF document conforms to the specification of the serialization format.

Metrics. A syntax validator can be employed to assess the validity of a document, i.e., its syntactic correctness. The syntactic accuracy of entities can be measured by detecting the erroneous or inaccurate annotations, classifications, or representations. An RDF validator can be used to parse the RDF document and ensure that it is syntactically valid, that is, to check whether the document is in accordance with the RDF specification.

Semantic accuracy is defined as the degree to which data values correctly represent the real-world facts.

Metrics. Accuracy can be measured by checking the correctness of the data in a data source, that is, the detection of outliers or identification of semantically incorrect values through the violation of functional dependency rules.

Consistency means that a knowledge base is free of (logical/formal) contradictions with respect to particular knowledge representation and inference mechanisms.

Metrics. On the Linked Data Web, semantic knowledge representation techniques are employed, which come with certain inference and reasoning strategies for revealing implicit knowledge, which then might render a contradiction. Consistency is relative to a particular logic (set of inference rules) for identifying contradictions. A consequence of the definition of consistency is that a dataset can be consistent wrt. the RDF inference rules but inconsistent when taking the OWL2-QL reasoning profile into account. For assessing consistency, one can employ an inference engine or a reasoner, which supports the respective expressivity of the underlying knowledge representation formalism. Additionally, one can detect functional dependency violations such as domain/range violations. In practice, RDF Schema inference and reasoning with regard to the different OWL profiles can be used to measure consistency in a dataset.

Conciseness refers to the minimization of redundancy of entities at the schema and the data level. Conciseness is classified into (i) intensional conciseness (schema level) which refers to the case when the data does not contain redundant schema elements (properties and classes) and (ii) extensional conciseness (data level) which refers to the case when the data does not contain redundant objects (instances).

Metrics. As conciseness is classified in two categories, it can be measured as the ratio between the number of unique attributes (properties) or unique objects (instances) and the overall number of attributes or objects, respectively, present in a dataset.

Completeness refers to the degree to which all required information is present in a particular dataset. In terms of LD, completeness comprises of the following aspects:

Schema completeness the degree to which the classes and properties of an ontology are represented and thus can be called ontology completeness,

Property completeness measure of the missing values for a specific property,

Population completeness is the percentage of all real-world objects of a particular type that are represented in the datasets and

Interlinking completeness, which has to be considered especially in LD, refers to the degree to which instances in the dataset are interlinked.

Metrics. Completeness can be measured by detecting the number of classes, properties, values, and interlinks that are present in the dataset by comparing it to the original dataset (or gold standard dataset). It should be noted that in this case, users should assume a closed-world assumption where a gold standard dataset is available and can be used to compare against. Completeness can be measured by detecting the number of classes, properties, values, and interlinks that are present in the dataset by comparing it to the original dataset (or gold standard dataset). It should be noted that in this case, users should assume a closed-world assumption where a gold standard dataset is available and can be used to compare against.

Contextual Dimensions

Contextual dimensions are those that highly depend on the context of the task at hand. There are four dimensions that are part of this group, namely, *relevancy*, *trustworthiness*, *understandability*, and *timeliness*.

Relevancy refers to the provision of information which is in accordance with the task at hand and important to the users' query.

Metrics. Relevancy is highly context dependent and can be measured by using meta-information attributes for assessing whether the content is relevant for a particular task. Additionally, retrieval of relevant documents can be performed using a combination of hyperlink analysis and information retrieval methods.

Trustworthiness is defined as the degree to which the information is accepted to be correct, true, real, and credible.

Metrics. The provenance information can in turn be used to assess the trustworthiness, reliability, and credibility of a data source, an entity, publishers, or even individual RDF statements. There exists an interdependency between the data provider and the data itself. On the one hand, data is likely to be accepted as true if it is provided by a trustworthy provider. On the other hand, the data provider is trustworthy if it provides true data. Thus, both can be checked to measure the trustworthiness.

Understandability refers to the ease with which data can be comprehended without ambiguity and be used by a human information consumer.

Metrics. Understandability can be measured by detecting whether human-readable labels for classes, properties, and entities are provided. Provision of the metadata of a dataset can also contribute toward assessing its understandability. The dataset should also clearly provide exemplary URIs and SPARQL queries along with the vocabularies used so that users can understand how it can be used.

Timeliness measures how up-to-date data is relative to a specific task.

Metrics. Timeliness is measured by combining the two dimensions: currency and volatility. Additionally timeliness states the recency and frequency of data validation and does not include outdated data.

Representational Dimensions

Representational dimensions capture aspects related to the design of the data such as the *representational conciseness*, *interoperability*, *interpretability*, as well as *versatility*.

Rep. conciseness refers to the representation of the data, which is compact and well formatted on the one hand and clear and complete on the other hand.

Metrics. Representational conciseness is measured by qualitatively verifying whether the RDF model that is used to represent the data is concise enough in order to be self-descriptive and unambiguous.

Interoperability is the degree to which the format and structure of the information conform to previously returned information as well as data from other sources.

Interpretability refers to technical aspects of the data, that is, whether information is represented using an appropriate notation and whether the machine is able to process the data.

Metrics. Interpretability can be measured by the use of globally unique identifiers for objects and terms or by the use of appropriate language, symbols, units, and clear definitions.

Versatility refers to the availability of the data in different representations and in an internationalized way.

Metrics. Versatility can be measured by the availability of the dataset in different serialization formats, different languages, as well as different access methods.

Linked Data Quality Assessment Tools

There exist several approaches toward developing frameworks for assessing the data quality of LD. These frameworks can be broadly classified into: (i) automated (e.g., Guéret et al. 2011), (ii) semi-automated (e.g., Kontokostas et al. 2014), or (iii) manual (e.g., Bizer and Cyganiak 2009) methodologies. These approaches are useful at the process level wherein they introduce a methodology to assess the quality of a dataset. Additionally, a new generation of assessment tools is emerging which enable the integration of automatic tasks with human tasks in a crowdsourcing approach for LD quality assessment. Crowdsourcing is highly appropriate for any assignment involving large to huge numbers of small tasks that require human judgment. In terms of LD, crowdsourcing quality assessment may involve, for example, verifying the completeness or correctness of a fact wrt. the original dataset. Such a task does not require underlying knowledge about the structure of the data and can be done fairly quickly, without bias, and cost-effectively. In one study (Acosta et al. 2013), a comparison between assessments done by LD experts (those conversant with RDF) and Amazon Mechanical Turk workers on the DBpedia dataset was undertaken. The study showed promising results, in terms of time as well as cost-efficiency, for using a combination of crowdsourcing as well as manual (by experts) methodologies for quality assessment.

Representing Quality Metadata as Linked Data: The W3C Data Quality Vocabulary

The W3C working group on the *Data on the Web Best Practice* asserts the importance of providing quality information of a dataset (linked or not) to consumers. In an effort toward standardizing a vocabulary to represent quality metadata for data, the Data on the Web Best Practices Working Group developed the Data Quality Vocabulary

(DQV) (Albertoni et al. 2015). The idea of this vocabulary is to describe various quality aspects of the attached data in a structured, interoperable, and human - readable format. The Data Quality Vocabulary extends the Data Catalog Vocabulary (DCAT) (Maali et al. 2014) with a number of concepts (classes and properties) suitable to express quality metadata.

Open Research Challenges

Large-Scale Quality Assessment

Current tools that perform quality assessment of Web data suffer from severe deficiencies in terms of performance, once the dataset size grows beyond the capabilities of a single machine. Recently, an approach for quality assessment evaluation of large RDF datasets has been implemented using the SANSA framework (Lehmann et al. 2017), which scales over clusters of machines. The approach uses distributed in-memory for computing different quality metrics for RDF datasets using Apache Spark. However, such systems still lack inference-aware knowledge graph embeddings, distributed reasoning, and intuitive data partitioning strategies.

Data Profiling for the Web of (Big) Data

Data profiling is the set of activities and processes to produce metadata about the content of a dataset. Data profiling provides a first understanding of the data through statistics and other useful metadata. The metadata, in turn, enables reuse of existing data in useful applications. The ABSTAT tool (Spahiu et al. 2016) uses a schema-based summarization approach to profile LOD, which provides summaries that reveal quality issues that can be further analyzed. However, current datasets lack high-quality metadata, which is extremely important to enable data reuse. To tackle this problem, the recently published FAIR principles (Wilkinson et al. 2016) have been established to guide data producers to ensure that their data is maximally findable, accessible, interoperable, and reusable. These principles apply to all digital research objects (e.g., repositories, datasets, APIs, databases, publications). There is

a need to analyze the currently available digital resources with these FAIR principles.

Quality Improvement of Published Data

In addition to the assessment of quality, there need to be methods and tools for the consequent improvement of the datasets. One important step to improve the quality of data is identifying the root cause of the problem and then designing corresponding data improvement solutions. These solutions would select the most effective and efficient strategies and related set of techniques and tools to improve quality. Currently, only the RDFUnit tool Kontokostas et al. (2014) reports the exact triples which causes the quality issue. However, there need to be systems in place which close the loop, per say, from data quality assessment to improvement.

Definition of Entry

Conventional or well-established redundancy methods for preventing data loss, unavailability, or corruption can be used to protect big data, but they need to be updated in order to make them efficiently applicable to large data sets.

D

Overview

Data stored in memory devices, in storage networks, on the Web, or in the Cloud must be protected against loss, accidental contamination, or deliberate adulteration. Data are valuable assets that can be lost to negligence or theft (for illicit use or to exchange for ransom). Over the years, many methods of data protection have been devised by researchers in the field of dependable and fault-tolerant computing (Jalote 1994; Parhami 2018), all of which entail introducing redundancy to make data robust and recoverable in the event of loss or corruption. As data assumes ever-more important roles in the proper functioning of systems that affect our daily lives, greater protection, often involving higher degrees of redundancy, becomes necessary. Yet, the age of big data (Hilbert and Gomez 2011) makes naive redundancy methods costlier and less convenient, given the exponentially growing data volume, which has seen aggregate data storage capacity in the world rise from exabytes in 1986 to zettabytes at the turn of the century (Hilbert and Gomez 2011).

Data Unavailability, Corruption, and Loss

As valuable resources, data assets are subject to theft (can be worse than loss, if the entity stealing it abuses the resource), unavailability (not as bad as loss or corruption but inconvenient nonetheless), corruption, or permanent loss. Theft for illicit use can be prevented by encryption, a topic that is outside the scope of this article (Hankerson et al. 2000).

Data is lost or becomes unavailable for use if the storage device or host site holding the data crashes or is otherwise unresponsive. Data unavailability can be avoided by keeping multiple copies of the data on different devices/sites or by means of distributed encoding.

The term “error” refers to any change of bit or symbol values from the original or intended values. Errors can be classified by their type (inversion, erasure, substitution, and so on) and extent (the number and positions of the bits/symbols affected). Accordingly, error codes can be single- or multiple-error detecting/correcting. In the case of multiple errors, they can be arbitrary or correlated, important examples of the latter type being unidirectional and burst errors.

The most immediate threats to data corruption are inadvertent changes to bit or symbol values due to hardware failures (during the storage or processing of data) or transmission errors (as the data is moved from one place to another). The corruption extent ranges from one bit-flip ($0 \rightarrow 1$ or $1 \rightarrow 0$) to complete erasure via all bits being changed to 0s, say. Data corruption can be dealt with in ways similar to data loss or unavailability. Corruption that is limited in scope can be handled by error codes applied to locally stored data. We thus devote two sections to error-detecting and error-correcting codes, before describing schemes capable of dealing with more widespread data corruption.

Error codes are means of representing data so as to detect corrupting changes or to fix the corrupted values automatically (Rao and Fujiwara 1989). Of course, detection by itself is inadequate for avoiding data loss. It must be combined with a data reconstruction or recovery scheme in order to regain the original data. The recovery strategy is often based on data replication, where backup copies of data are kept in a reasonably up-to-date manner for use during recovery.

Error codes are assessed by their extent of redundancy, the total number n of bits/symbols required to represent k data bits/symbols, with $r = n - k$ being the absolute redundancy and r/k constituting the redundancy ratio, and by their detection/correction capabilities (how many and what types of errors are detected or corrected).

Error-Detecting Codes

The simplest error-detecting codes (Wakerly 1978) are based on parity, that is, the evenness or oddness of the number of 1 s in a code consisting of 0s and 1s. A simple parity code has code distance of 2, meaning that any two code words are different in at least two positions, ensuring the detection of any single-bit error. Multiple parity bits can be used in a variety of ways, leading to a wide class of codes (Garrett 2004), including Hamming error-detecting and error-correcting codes (Hamming 1950).

Information flow in coded protection of data is typically as follows:

Input → Encode → Send → Store → Send →
Decode → Output

Such a coding framework protects the middle three stages of sending to memory, residence in memory, and sending to the final destination. If data processing is also included, it corresponds to a feedback path from the decode stage back to the encode stage through a processing unit. In other words, the redundant information is stripped, and data in its original nonredundant form is subjected to processing, with the result re-encoded before being stored. Communication application of coding corresponds to the linear path from input to output depicted above, while computing applications also include the feedback path just discussed.

Protection against storage errors has a lot in common with schemes of circumventing transmission errors, so the same codes are often applicable. However, there are specific codes that can exploit the data storage pattern, say, on two-dimensional recording surfaces, to provide greater protection at the same or lower cost (e.g., Parhami and Avizienis 1973).

With codes that are closed under processing, the feedback path can be shortened to span only the middle three, rather than five, stages, thus obviating the need for stripping and reinstating the code. Processing coded information directly provides stronger protection against accidental or hardware-induced data corruption. For example, arithmetic error-detecting codes (Avizienis 1971;

Avizienis 1973; Garner 1966) allow direct addition and subtraction of coded numbers, yielding coded results. Multiplication with arithmetic-coded operands is a bit more involved but still feasible, whereas division is quite difficult, thus limiting the scope of applicability.

Popular examples of error-detecting codes include checksum codes (McAuley 1994); weight-based and Berger codes (Berger 1961; Knuth 1986); cyclic codes (Peterson and Brown 1961); linear codes (Sklar and Harris 2004), which include Hamming codes (Hamming 1950) as special cases, balanced codes (Knuth 1986); arithmetic codes (Avizienis 1971); and many other types developed for specific applications.

Error-Correcting Codes

Error-correcting codes (Arazi 1987, Peterson and Weldon 1972) are used extensively in storing data on disk memory, whose raw reliability would be dismal without the detecting and correcting capabilities of such codes (Petascale Data Storage Institute 2012; Schroeder and Gibson 2007), as well as in many other application contexts. The use of such codes within individual data blocks is often augmented by inter-block redundancy schemes that provide an extra layer of protection in what is known as RAID architecture, acronym for redundant array of independent disks (Chen et al. 1994; Feng et al. 2005), or redundant disk array, for short.

Popular examples of error-correcting codes in practical use include cyclic codes (Lin and Costello 2004), which include the widely used cyclic redundancy check or CRC codes as special cases; linear codes (Sklar and Harris 2004), which include Hamming codes (Hamming 1950) as special cases; Reed-Solomon codes (Feng et al. 2005; Reed and Solomon 1960); BCH codes (Pless 1998); and many other types developed for specific applications. Turbo codes (Benedetto and Montorsi 1996) and low-density parity-check or LDPC codes (Gallager 1962) are examples of widely studied and used modern codes that achieve very low redundancy ratios.

The theory of error-detecting and error-correcting codes is quite advanced, and progress is still being made (Guruswami and Rudra 2009). What remains missing is a methodology for choosing an optimal or near-optimal code for a given set of application requirements.

D

Replication Codes

Replication codes are the conceptually simplest codes but imply high redundancy (100% in the case of duplication, 200% for triplication). Their advantages include the fact that any unrestricted error in one copy is detectable (duplication) or correctable (triplication). Such detection and correction capabilities require that data copies be stored on distributed nodes whose failures are independent of each other (Jalote 1994).

In addition to allowing error detection or correction, replication facilitates access to data by improving availability and access latency. For example, with two copies of a particular piece of data stored on two different computers, extreme slowness or even crashing of one computer will not hinder access to the data. The prevailing nomenclature here is that we have a primary site for each piece of data and one or more backup sites (Budhiraja et al. 1993; Guerraoui and Schiper 1997; Jalote 1994). In addition to high redundancy in such primary-backup schemes, a key challenge is to keep the multiple copies up-to-date and consistent with each other (Dullmann et al. 2001).

Data Dispersion

An alternative to replication is a scheme known as data dispersion (Iyengar et al. 1998; Rabin 1989), originally devised by Michael O. Rabin, which entails much less redundancy but requires some computation to reconstruct the data.

Let us present this method through an example. Consider the three numbers a , b , and c as the data of interest to be protected. Instead of storing the three numbers, we might store the four values $f(1)$, $f(2)$, $f(3)$, and $f(4)$, where f is the polynomial function $f(x) = ax^2 + bx + c$. We

can lose any one of the four f values and still be able to derive the original data values a , b , and c from the three remaining f values by solving a system of three linear equations. This example, which entails 33% redundancy to protect against loss of any single piece of data (compared with 100% for duplication), is readily understood, but it is not a particularly efficient way of dispersing data.

Data dispersion is actually a kind of encoding (Feng et al. 2005), where k pieces of data (say, k numbers) are encoded into n pieces (with $n > k$), in such a way that any k pieces suffice to derive the original data. Besides being useful for data protection, the method has security and load-balancing applications. In security, imagine devising a scheme so that at least three officers of a bank must cooperate to gain access to a safe, whereas no two officers can gain access. Such an arrangement is sometimes referred to as “secret sharing” (Beimel 2011). In load balancing, consider that the k pieces retrieved for reconstructing the original data can come from any of the stakeholders, thus making it possible to avoid congested sites. In such a case, data dispersion can be viewed as a performance-enhancing strategy, as well as a reliability improvement method.

Future Directions

The field of dependable computing has advanced for several decades to provide more reliable processing, storage, and communication resources. It is well known that reliability is a weakest-link phenomenon, in the sense that any unprotected or weakly protected part of the system can doom the entire system. The exponential reliability law (Parhami 2018) suggests that reliability declines exponentially with an increase in the number of system parts. In the context of big data, all aspects of the system (processing, storage, and communication) will expand in complexity, challenging the system designer to seek more advanced methods of reliability assurance.

Design of computer systems and their attendant attributes in light of new application domains and technological developments in the

twenty-first century is under review by many researchers (Chen and Zhang 2014; Hu et al. 2014; Stanford University 2012). Since resources and services for big data will be provided through the Cloud, directions of cloud computing (Armburst et al. 2010) and associated hardware acceleration mechanisms become relevant to our discussion here (Caulfield et al. 2016).

A promising direction is provided by network coding (Dimakis et al. 2011). This new field essentially expands on the idea of data dispersion by considering more general data distribution schemes while also taking the impact of “repair traffic” on system performance into account.

Data preparation

Definitions

Data wrangling is the process of profiling and transforming datasets to ensure they are actionable for a set of analysis tasks. One central goal is to make data *usable*: to put data in a form that can be parsed and manipulated by analysis tools. Another goal is to ensure that data is *responsive* to the intended analyses: that the data contain the necessary information, at an acceptable level of description and correctness, to support successful modeling and decision-making.

Overview

Despite significant advances in technologies for data management and analysis, it remains time-consuming to inspect a dataset and mold it to a form that allows meaningful analysis to begin. Analysts must regularly restructure data to make it palatable to databases, statistics packages, and visualization tools. To improve data quality, analysts must also identify and address issues such as misspellings, missing data, unresolved duplicates, and outliers.

Data wrangling is the process of inspecting and transforming data to ensure it is actionable for analysis, and often consumes the lion's share of effort within data analysis efforts. Wrangling tasks range from early-stage parsing and formatting to data quality assessment and cleaning and, to data integration and distillation. While each of these topics has their own rich literatures, research on data wrangling takes a distinctly user-centered focus: how might we empower analysts to effectively orchestrate data profiling and transformation methods to ensure data is usable and responsive to analysis goals?

Interviews with data professionals reveal that a majority of their time is spent in data wrangling tasks, which can be relatively unsophisticated and repetitive, yet persistently tricky and time-consuming (Kandel et al. 2012a). The most-cited bottleneck arises in manually preparing the various sources of data required for each distinct use case. Others estimate that data cleaning is responsible for up to 80% of the development time and cost in data warehousing projects (Dasu and Johnson 2003).

This effort arises because data wrangling is an inherently *iterative* and *interactive* process. Nuanced judgments requiring domain expertise are sometimes needed, beyond the scope of analysis algorithms. For example, is an observed outlier a valid finding or an error to be discarded? Should records with missing data be kept as is, removed, or corrected via imputation (and if so, by which method)? In addition, as new questions arise and analysis goals evolve, the appropriate set of data transformations may correspondingly shift, requiring additional wrangling. Data wrangling is thus resistant to full automation. As a result, technologies for data wrangling often take the form of interactive systems, with a goal of balancing scalable, automated subroutines with human guidance and assessment.

The technical challenges of data wrangling come from the unbounded variety of inputs and outputs to the problem, which often necessitate custom work. Traditionally, data wrangling has required writing idiosyncratic scripts in programming languages such as Python and R or extensive manual editing using interactive tools such

as spreadsheets. This hurdle arguably discourages many people from working with data in the first place. The end result is that domain experts regularly spend more time manipulating data than they do exercising their speciality, while less technical audiences are needlessly excluded.

At heart, data wrangling is a domain-specific programming problem, with a strong focus on the structure, semantics, and statistical properties of data. This observation suggests that by making the specification of data transformation programs dramatically easier, we might remove drudgery for scarce technical workers and engage a far wider labor pool in time-consuming, data-centric tasks.

Key Research Findings

Data wrangling covers a range of tasks, including structuring (e.g., extracting fields from text, table reshaping), profiling (e.g., summary visual-

ization, outlier detection), standardization (e.g., entity resolution, error correction, imputation), enrichment (e.g., lookups, joins), and distillation (e.g., sampling, filtering, aggregation, windowing). Ideally, the outcome of wrangling is not simply data; it is an editable and auditable transcript of transformations coupled with a nuanced understanding of data organization and data quality issues.

D

Data Parsing and Structuring

A common first task for data wrangling is to *parse* and *structure* a new data source. As illustrated in Fig. 1, small datasets such as those found in spreadsheets may be primarily intended for manual inspection; restructuring such data allows it to be more easily visualized, modeled, or integrated with other datasets. Related challenges arise with larger datasets spanning gigabytes, terabytes, or more. For example, log files (e.g., of user interactions or system operations) often use idiosyncratic text formats or semi-structured

formats that require transformation prior to integrating with relational databases. In many cases, data resides in a text-based format that must be mapped to a corresponding tabular representation.

Data parsing involves first identifying the data format. For text-based formats one must segment the text into records and attributes. Other data may use a semi-structured format (XML, JSON) that may include nested sub-records. At this stage, one often performs *type induction* to identify the data types of individual attributes. This parsing stage can be automated for many common formats but may require interactive assistance for idiosyncratic or inconsistent encodings.

Once parsed, data must sometimes be restructured. A common goal is to ensure the data uses a *tidy* format (Wickham 2014): a tabular format in which each row corresponds to a single observation and each column represents a semantically consistent variable with a single data type. In terms of database theory, a “tidy” format is closely related to a relation in first normal form (1NF) (Codd 1971b). (Normal forms beyond first normal form (second normal form, etc.) are often less desirable for analysis purposes: one might wish to denormalize data (e.g., by joining relations with primary-foreign key relationships) in order to more conveniently perform analysis over a single table.)

Common operations for string-typed data include *splitting* columns (e.g., based on delimiters), pattern-based *extraction* of substrings into new columns, and *merging* columns together. In the case of semi-structured data, *unnesting* of sub-record attributes to flat columns is often necessary. In addition, reshaping operations may be needed to ensure a tidy organization. Consider an example table containing two columns – a string key and a numeric measure – where each unique key indicates a different type of measurement. This organization violates a tidy format, as semantically different measures are mixed within a column. This situation can be remedied via a *pivot* operation that reshapes the data into new columns, one for each unique key value (as in step 6 of Fig. 1). Conversely, spreadsheet data often

contains cross-tabulations by category or date, in which semantically similar measures are spread over multiple columns. These cross-tabulations can be mapped to a tidy format via an *unpivot* operation (also referred to as a *fold* or *melt* operation).

Data Profiling

Once data is suitably formatted, one can begin assessing the shape and structure of the data to guide further wrangling. The goal of *data profiling* is to gain a basic understanding of data content and assess potential data quality issues. Profiling typically involves consulting both summary statistics and data visualizations.

Visualization techniques are central to data profiling (Kandel et al. 2011a). Histograms are well-suited for showing the distributions of numerical data, though care must be taken regarding the choice of binning scheme. For categorical data, bar charts of occurrence counts, sorted by frequency, can depict top-K values. Other data types can benefit from specialized displays, for example, maps overlaid with symbols for geographic data and multiple plots showing various transformations for time-series data (e.g., histograms for month, day of month, day of week, etc.).

To scalably visualize relationships between variables, binned 2D histograms (a discretized version of scatterplots) can be used (Carr et al. 1987). In addition, interaction techniques such as brushing and linking (in which selections in one view are used to filter the data shown or highlighted in other views) can be applied to assess higher-dimensional relationships. Visualizations can also be augmented to aid identification of missing values, using either auxiliary visualizations (e.g., quality bars showing the proportions of valid, missing, and type-violating values, as in Kandel et al. 2011b) or by including missing values directly within a plot (Eaton et al. 2003) (e.g., including a specific category for null values).

An important goal during profiling is to account for data type violations, missing values, and outliers. Automatic identification of null values or values that do not match a column’s data

type is straightforward; once flagged they can be visually presented to a user for consideration and correction. Identification of missing records (i.e., entire table rows) is much more difficult but may be aided by looking for corresponding patterns in summary visualizations (e.g., gaps within a histogram of record timestamps).

Outliers can be identified within visualizations and using statistical routines (Hodge and Austin 2004; Hellerstein 2008). Univariate outliers can be flagged using basic summary statistics (e.g., distance from the interquartile range of numeric values), sometimes in conjunction with transformations (e.g., identifying outliers in string-typed data by analyzing the distribution of string lengths). Multivariate outlier detection is a more difficult problem, for which statistical measures such as Mahalanobis distance can be applied. Beyond numerical and categorical data, other types, including geographic and time-series data, can further benefit from specialized outlier detection techniques.

Once identified, missing or outlying values must often be interpreted in the context of other data columns (e.g., date and time of observation) and/or external knowledge (e.g., was there a power spike at that time that may have caused erroneous extreme observations?) to gauge whether the values are valid or potentially misleading. A user can then decide if corrective transformation is needed.

Data Standardization

In order to safeguard subsequent analysis, the data values within each column should be suitably *standardized*. Going beyond low-level physical types (e.g., floats, strings), many data wrangling tools support higher-level semantic types (e.g., zip codes, phone numbers) for ensuring values conform to a desired format. Data quality rules may be applied to ensure values correspond to either a strict set of legal values or satisfy a set of quality constraints. Users can perform corrective transformations to standardize values as needed. Generally speaking, any number of custom formulae may be applied, depending on the data type.

A common standardization task is *entity resolution* (or de-duplication), in which similar values representing the same entity are mapped to a single standardized value. For example, if we encounter similar names in a dataset, do they represent the same person? Entity resolution is a rich topic, with years of research into both automatic and interactive approaches (Elmagarmid et al. 2007). Common techniques include clustering to identify similar values (e.g., using string edit distance to group similar names) and blocking to aid disambiguation (consulting values in other columns to decide if similar values represent the same entity, e.g., requiring similar names to also come from the same geographic region), often followed by manual inspection (including crowdsourcing techniques to perform manual correction at scale (Stonebraker et al. 2013)).

Another standardization issue is the treatment of missing or outlier values. In the example of Fig. 1, a *fill* operation is used to copy string values into missing cells. In other cases, users may wish to remove missing data from consideration. For numerical data, interpolation (e.g., to fill in missing values over a time domain) or imputation (e.g., replacing a value with the mean value for a corresponding group) of missing values may be performed, depending on the downstream analysis needs. Similarly, outliers may be removed or replaced with an imputed value depending on the analysis goals; for example, some statistical modeling methods are highly sensitive to outliers.

Data Enrichment and Distillation

The above tasks have largely focused on wrangling a single dataset. However, in many cases a primary goal of wrangling is to combine multiple data sources in order to perform a more comprehensive analysis. This task is often referred to as *data enrichment* or *data blending* and is situated within the larger space of *data integration* tasks (Doan et al. 2012).

A basic form of enrichment is to *look up* additional details. To aid visualization and interpretation, one might use a lookup table to map from a product code to more human-friendly product name string. Such lookups are an example of data de-normalization to aid analysis. A related

operation is to perform geo-coding to retrieve the longitude-latitude coordinates for an address or zip code.

More complex operations include multi-table *join* and *union* operations. While common to database management systems, within data wrangling contexts joins and unions may involve datasets that were not originally designed to be used together. In the absence of explicit primary key and foreign key designations, key inference and schema mapping (Rahm and Bernstein 2001) may be needed to properly align tables. Moreover, additional transformation operations may be necessary to ensure compatible join keys or unionable columns.

Distillation is the task of summarizing or reducing a dataset prior to downstream analysis. For example, an analyst may wish to perform *filtering* or *sampling* to reduce the data or extract a subset appropriate for comparison (e.g., performing stratified sampling by group). *Aggregation* and *windowing* operations are means of summarizing data, often by subgroup. In some cases, aggregation is a necessary precursor to data integration, as datasets may use units of analysis with differing levels of granularity (e.g., US states versus US counties).

Organizational Deployment, Sharing, and Review

While data wrangling is an important consideration of an individual analyst's work, wrangling also plays a social role within an organization. A set of wrangling transformations may need to be applied repeatedly, scheduled to rerun at regular intervals as new data batches arrive. Once wrangled, data can be valuable to a number of various analysts or decision makers within an organization. Methods for sharing and discovery (e.g., *data cataloging*) can improve an organization's access to data and amortize wrangling effort.

The *provenance* of wrangled data is another central concern. Before using a dataset in their analyses, a user may wish to review what transformations were applied and ensure they are appropriate. An executive may wish to know what calculations were performed to derive a key per-

formance metric prior to making a dependent decision. Similarly, a compliance officer may wish to review how specific privacy-sensitive fields are subsequently used. Each of these tasks involves additionally tracking and visualizing the lineage of transformed data.

These needs imply that a critical output of the wrangling process is not simply transformed data, but rather a reusable, editable, and auditable transcript of wrangling operations. Not unlike the collaboration and management enabled by revision control tools for code, both wrangling programs and transformed data are organizational resources to be socially shared and monitored.

Examples of Application

To give a sense of the data wrangling process, Fig. 1 illustrates a scenario adapted from Guo et al. (2011), in which a user transforms spreadsheet data (step 1 within Fig. 1) into a dense relational format (step 6). This example begins with personnel data originally formatted for human reading and adapts it to a format more amenable to computational processing. The transformation process involves removing unneeded records (steps 2 and 4), splitting text fields into well-typed columns (step 3), interpolation of missing values (step 5), and finally reshaping the table via a pivot (or cross-tabulation) operation (step 6).

While involving only a small dataset, this example exhibits a number of common operations necessary for wrangling a dataset. In general, datasets of all sizes may require significant wrangling effort, whether to restructure the data for use by common tools, to identify and correct anomalies or discrepancies, or to adapt a dataset such that it can be integrated with other sources of data.

Future Directions for Research

Technologies for data wrangling aim to support one or more of the tasks described above. Wrangling tools often involve the careful integration of automatic algorithms (e.g., type inference,

transform inference, program synthesis) within interactive systems (e.g., an interactive console or graphical user interface) that enable users to inspect data and orchestrate transformations. Future work areas include (1) improved languages and runtimes for wrangling operations, (2) new user interface designs for data profiling and interactive transformation, and (3) novel inferential procedures for simplifying and scaling human guidance of the wrangling process.

Domain-Specific Languages for Data Wrangling

Data wrangling is, at its core, a programming problem: what transformations should be applied and in what order? A popular approach is thus to craft *domain-specific languages* (DSLs) that support wrangling tasks. Standard database query languages such as SQL support a number of relevant wrangling tasks (distillation, enrichment, etc.) but are less well-suited for messy data with type violations or requiring operations that transform between metadata and data (e.g., unpivot operations that map column names into data). The SchemaSQL (Lakshmanan et al. 2001) language generalizes SQL to include such second-order operations. The PADS Fisher and Walker (2011) and AJAX Galhardas et al. (2000) projects also introduce custom DSLs for data transformation. Within the R programming language for computational statistics, *dplyr* and *tidyverse* (Wickham 2014) are embedded DSLs supporting transformation and restructuring tasks. DSLs also underlie a number of interactive tools, such as Potter’s Wheel (Raman and Hellerstein 2001) and Wrangler (Kandel et al. 2011b; Guo et al. 2011). In addition to providing a succinct high-level syntax, a DSL can support compilation to alternative runtimes (e.g., computing clusters or database management systems) to enable scalable execution of transformation scripts.

Graphical Interfaces for Data Wrangling

While valuable, direct use of domain-specific languages primarily benefits programmers, as opposed to a larger swath of domain experts knowledgeable about their data but not necessarily skilled in programming. In response,

a number of graphical interfaces have been devised for supporting data wrangling. Some projects focus on new interaction techniques for a specific wrangling task, such as tools for deduplication (Sarawagi and Bhamidipaty 2002; Kang et al. 2008), schema matching (Robertson et al. 2005; Chiticariu et al. 2008), or data profiling (Dasu et al. 2002; Kandel et al. 2012b). Future research projects could develop methods for core wrangling tasks, including improved entity resolution, standardization, and analysis of data lineage.

Other projects focus on more complete environments for data wrangling. The Potter’s Wheel (Raman and Hellerstein 2001) system is an early example, providing both a spreadsheet-like table representation and menu-driven commands to perform transformations. Subsequent tools include Refine (Huynh and Mazzocchi 2010) and Wrangler (Kandel et al. 2011b; Guo et al. 2011) (later commercialized by Trifacta), which add richer support for direct manipulation and visualization.

Both the Potter’s Wheel (Raman and Hellerstein 2001) and Wrangler (Kandel et al. 2011b; Guo et al. 2011) systems map interactive operations to statements in an underlying DSL, enabling those tools to output transformation programs that can be cross-compiled to scalable runtime environments. For example, by interactively wrangling a sample of data, these tools can then generate programs that can be applied to transform terabytes (or more) of data. However, users of graphical interfaces are accustomed to directly manipulating the state of a document or dataset, not a more abstract set of (reusable) operations. Future work might explore and evaluate improved methods for representing and manipulating the *wrangling programs* created by such tools.

Inferential Methods to Accelerate Wrangling

A central feature to many successful wrangling tools is a judicious balance of user interaction and automated algorithms. Examples of useful inference methods include outlier detection, type inference (to determine column data types), join

key inference (to identify primary-foreign key relationships among multiple tables), and union inference (to determine appropriate column assignments – or lack thereof – between two or more tables). Each of these aids identification of important data characteristics and the formulation of appropriate wrangling operations (e.g., as statements in a wrangling DSL). An interactive wrangling tool must run the appropriate analysis (perhaps in response to user-initiated commands, such as selecting tables to join) and then surface the results in an actionable manner.

A number of projects have explored interactive methods, such as programming by example, to couple automatic inference with human guidance. The work of Gulwani and collaborators applies program synthesis methods to learn text extraction (Gulwani 2011) and table restructuring (Harris and Gulwani 2011) procedures from input-output examples; some of these techniques have been incorporated into Microsoft Excel.

Kandel et al.'s Wrangler (2011b) takes a different approach, performing search over the space of possible transformation operations, informed by user selections of data table rows, columns, or cell contents. Wrangler returns and visualizes potential transformations from which the user can choose (or modify). As users transform their data, the commercial Trifacta Wrangler product additionally uses automatic visualization routines to generate charts to aid data profiling. The goal of this *predictive interaction* (Heer et al. 2015) loop is recast the task of writing a DSL program into one of visually guiding and refining a transformation recommender system. Many challenges remain in perfecting mixed-initiative (Horvitz 1999) interaction techniques that use inferential methods to speed and scale wrangling, while preserving effective human assessment and guidance of the wrangling process.

Database Consistency Models

Marc Shapiro¹ and Pierre Sutra²

¹Sorbonne Université, LIP6 and INRIA, Paris, France

²Télécom Sud Paris, Évry, France

Synonyms

Consistency criterion; Consistency model; Data consistency; Isolation level

The distributed systems and database communities use the same word, consistency, with differ-

ent meanings. Within this entry, and following the usage of the distributed algorithms community, “consistency” refers to the observable behavior of a data store.

In the database community, roughly the same concept is called “isolation,” whereas the term “consistency” refers to the property that application code is sequentially safe (the C in ACID).

D

Definitions

A data store allows application processes to put and get data from a shared memory. In general, a data store cannot be modeled as a strictly sequential process. Applications observe non-sequential behaviors, called anomalies. The set of possible behaviors, and conversely of possible anomalies, constitutes the *consistency model* of the data store.

Overview

Background

A *data store*, or database system, is a persistent shared memory space, where different client application processes can store data items. To ensure scalability and dependability, a modern data store distributes and replicates its data across clusters of *servers* running in parallel. This approach supports high throughput by spreading the load, low latency by parallelizing requests, and fault tolerance by replicating demand processing; system capacity increases by simply adding more servers (scale out).

Ideally, from the application perspective, data replication and distribution should be transparent. Read and update operations on data items would appear to execute as in a single sequential thread; reading a data item would return exactly the last value written to it in real time; and each application transaction (a grouping of operations) would take effect atomically (all at once). This ideal behavior is called *strict serializability*, noted SSER (Papadimitriou 1979).

In practice, exposing some of the internal parallelism to clients enables better perfor-

mance. More fundamentally, SSER requires assumptions that are unrealistic at large scale, such as absence of network partitions (see section “[Fundamental Results](#)” hereafter). Therefore, data store design faces a *fundamental tension* between providing a strictly serializable behavior on the one hand, versus availability and performance on the other. This explains why large-scale data stores hardly ever provide the SSER model, with the notable exception of Spanner (Corbett et al. 2012).

Consistency Models

Informally, a *consistency model* defines what an application can observe about the updates and reads of its data store. When the observed values of data differ from strict serializability, this is called an *anomaly*. Examples of anomalies include *divergence*, where concurrent reads of the same item persistently return different values; *causality violation*, where updates are observed out of order; *dirty reads*, where a read observes the effect of a transaction that has not terminated; or *lost updates*, where the effect of an update is lost. The more anomalies allowed by a store, the *weaker* its consistency model. The *strongest* model is (by definition) SSER, the baseline against which other models are compared.

More formally, a consistency model is defined by the history of updates and reads that clients

can observe. A model is weaker than another if it allows more histories.

An absolute definition of “strong” and “weak consistency” is open to debate. For the purpose of this entry, we say that a consistency model is *strong* when it has consensus power, i.e., any number of failure-prone processes can reach agreement on some value by communicating through data items in the store. If this is not possible, then the consistency model is said *weak*.

In a strong model, updates are totally ordered. Some well-known strong models include SSER, serializability (SER), or snapshot isolation (SI). Weak models admit concurrent updates to the same data item and include causal consistency (CC), strong eventual consistency (SEC), and eventual consistency (EC) (see Table 1).

Key Research Findings

Basic Concepts

A *data store* is a logically shared memory space where different application processes store, update, and retrieve data *items*. An item can be very basic, such as a register with read/write operations, or a more complex structure, e.g., a table or a file system directory. An application process executes *operations* on the data store through the help of an *API*. When a process

invokes an operation, it executes a remote call to an appropriate *endpoint* of the data store. In return, it receives a *response value*. A common example of this mechanism is a POST request to an HTTP endpoint.

An application consists of *transactions*. A transaction consists of any number of reads and updates to the data store. It is terminated either by an *abort*, whereby its writes have no effect, or by a *commit*, whereby writes modify the store. In what follows, we consider only committed transactions. The transaction groups together low-level storage operations into a higher-level abstraction, with properties that help developers reason about application behavior.

The properties of transactions are often summarized as ACID: All-or-Nothing, (individual) Correctness, Isolation, and Durability.

All-or-Nothing ensures that, at any point in time, either all of a transaction's writes are in the store or none of them is. This guarantee is essential in order to support common data invariants such as equality or complementarity between two data items. *Individual Correctness* is the requirement that each of the application's transactions individually transitions the database from a safe state (i.e., where some application-specific integrity invariants hold over the data) to another safe state. *Durability* means that all later transactions will observe the effect of this transaction after it commits. A, C, and D are essential features of any transactional system and will be taken for granted in the rest of this entry.

The I property, *Isolation* characterizes the absence of interference between transactions. Transactions are isolated if one cannot interfere with the other, regardless of whether they execute in parallel or not.

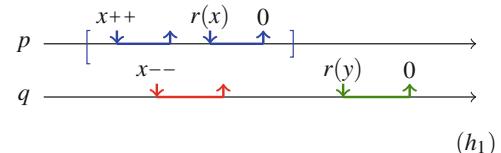

Taken together, the ACID properties provide the *serializability* model, a program semantics in which a transaction executes as if it was the only one accessing the database. This model restricts the allowable interactions among concurrent transactions, such that each one produces results indistinguishable from the same transactions running one after the other. As a consequence, the code for a transaction lives in the simple, familiar sequential programming world, and the devel-

oper can reason only about computations that start with the final results of other transactions. Serializability allows concurrent operations to access the data store and still produce predictable, reproducible results.

D

Definitions

A *history* is a sequence of invocations and responses of operations on the data items by the application processes. It is commonly represented with timelines. For instance, in history h_1 below, processes p and q access a data store that contains two counters (x and y).

(h_1)

Operations ($z++$) and ($z--$) respectively increment and decrement counter z by 1. To fetch the content of z , a process calls $r(z)$. A counter is initialized to 0. The start and the end of a transaction are marked using brackets, e.g., transaction $T_1 = (x++) . r(x)$ in history h_1 . When the transaction contains a single operation, the brackets are omitted for clarity.

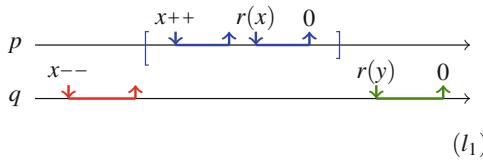

As pointed above, we assume in this entry that all the transactions are committed in a history. Thus every invocation has a matching response. More involved models exist, e.g., when considering a transactional memory (Guerraoui and Kapalka 2008).

A history induces a real-time order between transactions (denoted \prec_h). This order holds between two transactions T and T' when the response of the last operation in T precedes in h the invocation of the first operation in T' . A history also induces a per-process order that corresponds to the order in which processes invoke their transactions. For instance in h_1 , transaction $T_2 = (x--)$ precedes transaction $T_3 = r(y)$ at process q . This relation together with $(T_1 \prec_{h_1} T_3)$ fully defines the real-time order in history h_1 .

Histories have various properties according to the way invocations and responses interleave.

Two transactions are concurrent in a history h when they are not ordered by the relation \prec_h . A history h is *sequential* when no two transactions in h are concurrent. A sequential history is *legal* when it respects the sequential specification of each object. Two histories h and h' are *equivalent* when they contain the same set of events (invocations and responses).

A consistency model defines the histories that are allowed by the data store. In particular, serializability (SER) requires that every history h is equivalent to some sequential and legal history l . For instance, history h_1 is serializable, since it is equivalent to the history l_1 below.

In addition, if the equivalent sequential history preserves the real-time order between transaction, history h is said *strictly serializable* (SSER) (Papadimitriou 1979). This is the case of h_1 since in l_1 the relations $(T_2 \prec_{h_1} T_3)$ and $(T_1 \prec_{h_1} T_3)$ also hold.

When each transaction contains a single operation, SSER boils down to linearizability (LIN) (Herlihy and Wing 1990). The data store ensures sequential consistency (SC) (Lamport 1979) when each transaction contains a single operation and only the per-process order is kept in the equivalent sequential history.

The above consistency models (SER, SSER, LIN, and SC) are strong, as they allow the client application processes to reach consensus. To see this, observe that processes may agree as follows: The processes share a FIFO queue L in the data store. To reach consensus, each process enqueues some value in L which corresponds to a proposal to agree upon. Then, each process chooses the first proposal that appears in L . The equivalence with a sequential history implies that all the application processes pick the same value.

Conversely, processes cannot reach consensus if the consistency model is *weak*. A widespread

model in this category is Eventual Consistency (EC) (Vogels 2008), used, for instance, in the Simple Storage Service (Murty 2008). EC requires that, if clients cease submitting transactions, they eventually observe the same state of the data store. This eventually-stable state may include part (or all) the transactions executed by the clients. Under EC, processes may repeatedly observe updates in different orders. For example, if the above list L is EC, each process may see its update applied first on L until it decides, preventing agreement. In fact, EC is too weak to allow asynchronous failure-prone processes to reach an agreement (Attiya et al. 2017).

Fundamental Results

In the most general model of computation, replicas are asynchronous. In this model, and under the hypothesis that a majority of them are correct, it is possible to emulate a linearizable shared memory (Attiya et al. 1990). This number of correct replicas is tight. In particular, if any majority of the replicas may fail, the emulation does not work (Delporte-Gallet et al. 2004).

The above result implies that, even for a very basic distributed service, such as a register, it is not possible to be at the same time consistent, available, and tolerant to partition. This result is known as the CAP Theorem (Gilbert and Lynch 2002), which proves that it is not possible to provide all the following desirable features at the same time: (C) strong Consistency, even for a register; (A) Availability, responding to every client request; and (P) tolerate network Partition or arbitrary messages loss.

A second fundamental result, known as FLP, is the impossibility to reach consensus deterministically in presence of crash failures (Fischer et al. 1985). FLP is true even if all the processes but one are correct.

As pointed above, a majority of correct processes may emulate a shared memory. Thus, the FLP impossibility result indicates that a shared memory is not sufficient to reach consensus. In fact, solving consensus requires the additional ability to elect a leader among the correct processes (Chandra et al. 1996).

Data stores that support transactions on more than one data item are subject to additional impossibility results. For instance, an appealing property is genuine partial replication (GPR) (Schiper et al. 2010), a form of disjoint-access parallelism (Israeli and Rappoport 1994). Under GPR, transactions that access disjoint items do not contend in the data store. GPR avoids convoy effects between transactions (Blasgen et al. 1979) and ensure scalability under parallel workload. However, GPR data stores must sacrifice some form of consistency or provide little progress guarantees (Bushkov et al. 2014; Saeida Ardekani et al. 2013b; Attiya et al. 2009).

A data store API defines the shared data structures the client application processes manipulate as well as their consistency and progress guarantees. The above impossibility results inform the application developer that some APIs require synchronization among the data replicas. Process synchronization is costly; thus there is a trade-off between performance and data consistency.

Trade-Offs

In the common case, executing an operation under strong consistency requires to solve consensus among the data replicas, which costs at least one round trip among replicas (Lamport 2006). Sequential consistency allows to execute either read or write operations at a local replica (Attiya and Welch 1994; Wang et al. 2014). Weaker consistency models, e.g., eventual (Fekete et al. 1999) and strong eventual consistency (Shapiro et al. 2011), enable both read and write operations to be local.

A second category of trade-offs relates consistency models to metadata (Peluso et al. 2015; Burckhardt et al. 2014). They establish lower bounds on the space complexity to meet a certain consistency models. For instance, tracking causality accurately requires $O(m)$ bits of storage, where m is the number of replicas (Charron-Bost 1991).

Common Models

The previous sections introduce several consistency models (namely, SER, SC, LIN, SSER, and

EC). This section offers a perspective on other prominent models. Table 1 recapitulates.

D

Read Committed (RC)

Almost all existing transactional data stores ensure that clients observe only committed data (Zemke 2012; Berenson et al. 1995). More precisely, the RC consistency model enforces that if some read r observes the state \hat{x} of an item x in history h , then the transaction T_i that wrote \hat{x} commits in h . One can distinguish a *loose* and a *strict* interpretation of RC. The strict interpretation requires that $r(x)$ takes place after transaction T_i commits. Under the loose interpretation, the write operation might occur concurrently.

When RC, or a stricter consistency model holds, it is convenient to introduce the notion of *version*. A version is the state of a data item as produced by an update transaction. For instance, when T_i writes to some register x , an operation denoted hereafter $w(x_i)$, it creates a new version x_i of x . Versions allow to uniquely identify the state of the item as observed by a read operation, e.g., $r(x_i)$.

Strong Eventual Consistency (SEC)

Eventual consistency (EC) states that, for every data item x in the store, if there is no new update on x , eventually clients observe x in the same state. Strong eventual consistency (SEC) further constrains the behavior of the data replicas. In detail, a data store is SEC when it is EC, and moreover, for every item x , any two replicas of x that applied the same set of updates on item x are in the same state.

Client Monotonic (CM)

Client monotonic (CM) ensures that a client always observes the results of its own past operations (Terry et al. 1994). CM enforces the following four so-called session guarantees:

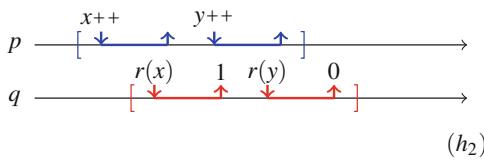

- (i) Monotonic reads (MR): if a client executes $r(x_i)$, then $r(x_{j \neq i})$ in history h , necessarily x_j follows x_i for some version order $\ll_{h,x}$ over the updates applied to x in h .

- (ii) Monotonic writes (MW): if a client executes $w(x_i)$, then $w(x_j)$, the version order $x_i \ll_{h,x} x_j$ holds;
- (iii) Read-my-writes (RMW): when a client executes $w(x_i)$ followed by $r(x_j \neq i)$, then $x_i \ll_{h,x} x_j$ holds;
- (iv) Writes-follow-reads (WFR): if a client executes $r(x_i)$ followed by $w(x_j)$ it is true that $x_i \ll_{h,x} x_j$.

Most consistency models require CM, but this guarantee is so obvious that it might be sometimes omitted – this is, for instance, the case in Gray and Reuter (1992).

Read Atomic (RA)

Under RA, a transaction sees either all of the updates made by another transaction or none of them (the All-or-Nothing guarantee). For instance, if a transaction T sees the version x_i written by T_i and transaction T_i also updates y , then T should observe at least version y_i . If history h fails to satisfy RA, a transaction in h exhibits a *fractured read* (Bailis et al. 2014). For instance, this is the case of the transaction executed by process q in history h_2 below.

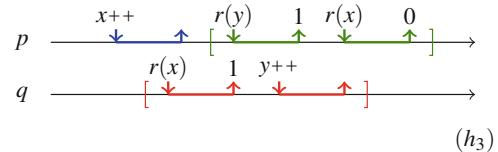

Consistent Snapshot (CS)

A transaction T_i depends on a transaction T_j when it reads a version written by T_j , or such a relation holds transitively. In other words, denoting $T_i \xrightarrow{\text{wr}} T_j$ when T_i reads from T_j , T_j is in the transitive closure of the relation $(\xrightarrow{\text{wr}})$ when starting from T_i .

When a transaction never misses the effects of some transaction it depends on, the transaction observes a *consistent snapshot* (Chan and Gray 1985). In more formal terms, a transaction T_i in a history h observes a consistent snapshot when for every object x , if (i) T_i reads version x_j , (ii) T_k writes version x_k , and (iii) T_i depends on

T_k , then version x_k is followed by version x_j in the version order $\ll_{h,x}$. A history h belongs to CS when all its transactions observe a consistent snapshot. For instance, this is not the case of history h_3 below. In this history, transaction $T_3 = r(y).r(x)$ depends on $T_2 = r(x).(y++)$, and T_2 depends on $T_1 = (y++)$, yet T_3 does not observe the effect of T_1 .

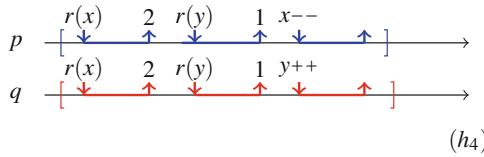

Causal Consistency (CC)

Causal consistency (CC) holds when transactions observe consistent snapshots of the system, and the client application processes are monotonic. CC is a weak consistency model, and it does not allow solving consensus. It is in fact the strongest model that is available under partition (Attiya et al. 2017). Historically, CC refers to the consistency of single operations on a shared memory (Ahamad et al. 1995). Causally consistent transactions (Causal HAT) is a consistency model that extends CC to transactional data stores (Bailis et al. 2013).

Snapshot Isolation (SI)

SI is a widely used consistency model (Berenson et al. 1995). This model is strong but allows more interleavings of concurrent read transactions than SER. Furthermore, SI is causal (i.e., $SI \subseteq CC$), whereas SER is not.

Under SI, a transaction observes a *snapshot* of the state of the data store at some point prior in time. Strong snapshot isolation (SSI) requires this snapshot to contain all the preceding transactions in real time (Daudjee and Salem 2006). Two transactions may commit under SI as long as they do not write the same item concurrent. SI avoids the anomalies listed in section “[Consistency Models](#)” but exhibits the *write-skew* anomaly, illustrated in history h_4 below.

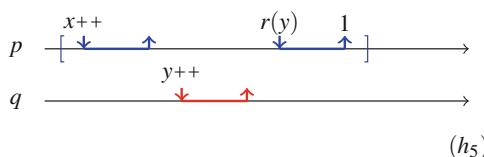

In this history, an application using data items x and y wishes to maintain the invariant $x \geq y$. The invariant holds initially and each of the two transactions T_1 and T_2 guarantees the invariant individually. As illustrated in history h_4 , running them concurrently under SI may violate the invariant.

An application is *robust* against a consistency model M when it produces serializable histories (Cerone and Gotsman 2016), despite running atop a data store providing M . It is known (Fekete et al. 2005) that an application is robust against SI when every invariant is materialized by a data item.

Parallel / Non-monotonic Snapshot Isolation (PSI/NMSI)

Parallel and non-monotonic snapshot isolation are scalable variations of SI. These models retain two core properties of SI, namely, (i) each transaction observes a consistent snapshot and (ii) no two concurrent transactions update the same data items. PSI requires to take a snapshot at the start of the transaction. NMSI relaxes this requirement, enabling the snapshot to be computed incrementally, as illustrated in history h_5 below.

A Three-Dimensional View of Data Consistency

Shapiro et al. (2016) classify consistency models along three dimensions, to better understand and compare them. Their approach divides each operation into two parts: the *generator* reads data and computes response values, and the *effector* applies side-effects to every replica. Each of

the three dimensions imposes constraints on the generators and effectors. Table 2 classifies the consistency criteria of Table 1 along these three dimensions.

D

- *Visibility dimension.* This dimension constrains the visibility of operations, i.e., how a generator sees the updates made by effectors. The strongest class of consistency models along this dimension is *external* visibility, which imposes that a generator sees the effectors of all the operations that precedes it in real time. Weakening this guarantee to the per-process order leads to *causal* visibility. A yet weaker class is *transitive* visibility, which only requires visibility to hold transitively. Finally, absence of constraints on generators, for instance, during the unstable period of an eventually consistent data store, is termed *rollback* visibility.
- *Ordering dimension.* This dimension constrains the ordering over generators and effectors. Four classes are of interest along this dimension: The strongest class is termed *total* order. For every history of a model in this class, there exists an equivalent serial history of all the operations. Weaker classes, below total order, constrain only effectors. The *gapless* order class requires effectors to be ordered online by natural numbers with no gaps; this requires consensus and is subject to the CAP impossibility result. The *capricious* class admits gaps in the ordering, allowing replicas to order their operations independently. A last-writer-wins protocol (e.g., Ladin et al. 1990) produces a consistency model in this class. This class is subject to the lost update anomaly. The weakest class along this dimension is termed *concurrent* and imposes no ordering on generators and effectors.
- *Composition dimension.* This dimension captures the fact that a transaction contains one or more operations. A model in the All-or-Nothing class preserves the A in ACID. This means that if some effector of transaction T_1 is visible to transaction T_2 , then all of T_1 's

Database Consistency Models, Table 2

Three-dimensional features of consistency models and systems

Acronym	Ordering	Visibility	Composition
EC	Capricious	Rollbacks	Single Operation
CM	Concurrent	Monotonic	Single Operation
CS	Concurrent	Transitive	All-or-Nothing + Snapshot
CC	Concurrent	Causal	Single Operation
Causal HAT	Concurrent	Causal	All-or-Nothing + Snapshot
LIN	Total	External	Single Operation
NMSI	Gapless	Transitive	All-or-Nothing + Snapshot
PSI	Gapless	Causal	All-or-Nothing + Snapshot
RC	Concurrent	Monotonic	All-or-Nothing
SC	Total	Causal	Single Operation
SER	Total	Transitive	All-or-Nothing + Snapshot
SI	Gapless	Transitive	All-or-Nothing + Snapshot
SSER	Total	External	All-or-Nothing + Snapshot
SSI	Gapless	External	All-or-Nothing + Snapshot

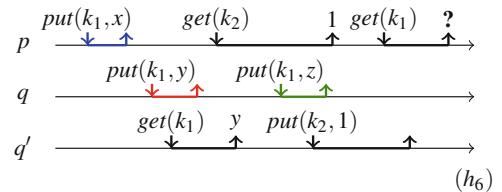

effectors are visible to T_2 . Typically, all the generators of a transaction read from the same set of effectors, i.e., its snapshot. The snapshot class extends the Visibility and Ordering guarantees to all generators of the transaction. For instance, in the case of a model both in the snapshot and total order classes, all the operations of a transaction are adjacent in the equivalent serial history.

Examples of Application

A key-value store (KVS) is a distributed data store that serves as building block of many cloud applications. This type of system belongs to the larger family of NoSQL databases and is used to store uninterpreted blobs of data (e.g., marshaled objects).

A KVS implements a map that is a mutable relation from a set of *keys* to a set of *values*. In detail, the API of a key-value store consists of two operations: Operation $put(k, v)$ adds the pair (k, v) to the mapping, updating it if necessary. Depending on the KVS, this operation may return the previous value of the key k , or simply *nil*. Operation $get(k)$ retrieves the current value stored under key k .

The notions of “current” and “previous” values depend on the consistency model of the KVS. History h_6 below illustrates this point for an operation $get(k_1)$ by process p .

When the KVS is RC, operation $get(k_1)$ returns the initial value of k_1 , or any value written concurrently or before this call. Denoting \perp the initial value of k_1 , this means that operation $get(k_1)$ may return any value in $\{\perp, x, y, z\}$.

If the KVS guarantees RMW, at least the last value written by p should be returned. As a consequence, the set of possible values reduces to $\{x, y, z\}$.

Now, let us consider that the KVS guarantees CC. Process p observes the operation $put(k_2, 1)$ by r . This operation causally follows an observation by q' of y . Therefore, p should observe either y or z .

If the KVS is linearizable, the value stored under key k_1 is the last value written before $get(k_1)$ in any sequential history equivalent to h_6 . Every such history should preserve the real-time precedence of h_6 . Clearly, the last update in h_6 sets the value of k_1 to z . Thus, if the KVS is linearizable, z is the only allowed response of operation $get(k_1)$ in h_6 .

Future Directions for Research

Consistency models are formulated in various frameworks and using different underlying assumptions. For instance, some works (ANSI 1992; Berenson et al. 1995) define a model in terms of the anomalies it forbids. Others rely on specific graphs to characterize a model (Adya 1999) or predicates over histories (Viotti and Vukolić 2016). The existence of a global time (Papadimitriou 1979) is sometimes taken for granted. This contrasts with approaches (Lamport 1986) that avoid to make such an assumption. A similar observation holds for concurrent operations which may (Guerraoui and Kapalka 2008) or not (Ozsu and Valduriez 1991) overlap in time.

This rich literature makes difficult an apples-to-apples comparison between consistency models. Works exist (Chrysanthis and Ramamritham 1994) that attempt to bridge this gap by expressing them in a common framework. However, not all the literature is covered, and it is questionable whether their definitions are equivalent to the ones given in the original publications.

The general problem of the implementability of a given model is also an interesting avenue for research. One may address this question in terms of the minimum synchrony assumptions to support a particular model. In distributed systems, this approach has led to the rich literature on failure detectors (Freiling et al. 2011). A related question is to establish lower and upper bounds on the time and space complexity of an implementation (when it is achievable). As pointed out in section “Trade-Offs”, some results already exist, yet the picture is incomplete.

From an application point of view, three questions are of particular interest. First, the robustness of an application against a particular consistency model (Fekete et al. 2005; Cerone and Gotsman 2016). Second, the relation between a model and a consistency control protocol. These two questions are related to the grand challenge of synthesizing concurrency control from the application specification (Gotsman et al. 2016). A third challenge is to compare consistency models in practice (Kemme and Alonso 1998; Wiesmann

and Schiper 2005; Saeida Ardekani et al. 2014), so as to understand their pros and cons.

Databases as a Service

Renato Luiz de Freitas Cunha
IBM Research, São Paulo, Brazil

Synonyms

[Cloud Databases](#)

Definitions

Cloud provider: A cloud infrastructure provider, such as Amazon Web Services, Microsoft Azure, or IBM Cloud.

End user: A user of cloud services, a person or company that uses services from the cloud provider.

Database server: A database management system that uses the client-server model.

Database as a service: Cloud computing service model that abstracts the setup of hardware, software, or tuning for providing access to a database.

Acronyms

IAAS Infrastructure as a service

PAAS Platform as a service

SAAS Software as a service

DBAAS Database as a service

IT Information technology

DBA Database administrator

API Application programming interface

Overview

Configuring and maintaining database systems is a complicated endeavor, which includes planning the hardware that will be used, configuring disks and file systems, installing and tuning

database management systems, determining whether and how replication will be done, and managing backups. In traditional Information technology (**IT**) environments, the setup of database systems requires the work of different professionals, such as Database administrators (**DBAs**), systems administrators, and storage administrators. In fact, tuning databases requires broad knowledge and a principled approach for measuring performance (Shasha and Bonnet 2002), and a well-tuned database system can perform faster than an improperly tuned system by a factor of two or more (Stonebraker and Cattell 2011).

In a Database as a service (**DBaaS**) setting, a service provider hosts databases providing mechanisms to create, store, and access databases at the provider. The means of interacting with the service are usually via web interfaces and Application programming interfaces (**APIs**). Although popularized in recent years by cloud computing and big data, this is not a new concept and, in fact, has been available for more than a decade (Hacigumus et al. 2002).

More recently, cloud providers have made **DBaaS** offerings available. In a **DBaaS** model, application developers neither have to maintain machines nor have to install and maintain database management systems themselves. Instead, the database service provider is responsible for installing and maintaining database systems, and users are charged according to their usage of the service.

To better place the **DBaaS** model in the cloud computing service models, a quick review of the cloud computing definition will be presented. Interested readers are directed to other sources (Mell and Grance 2011; Armbrust et al. 2010) for a more detailed definition. Readers familiar with cloud computing concepts can safely skip the next section.

Defining Characteristics of Cloud Computing

The essential characteristics of the cloud computing model is that it has *broad network access*, with *resource pooling*, *rapid elasticity*, and *measured services*, and provides *on-demand*

self-service (Mell and Grance 2011). Broad network access is a necessity in clouds, for cloud providers can be geographically distant from end users, and even in this case, end users rely on cloud services. In clouds, resources are pooled, meaning that resources are already available in the provider and, upon request, are assigned to users. These resource pools enable the rapid elasticity in clouds, enabling the addition and removal of resources in a short amount of time.

Services in clouds can be provided in three main models:

*Software as a service (**SaaS**)* In this model, applications execute on a cloud infrastructure, and users normally access them from a web browser. Usually, consumers are end users, who will not do development on top of such applications.

*Platform as a service (**Paas**)* In this model, application developers and service providers are able to deploy onto the cloud infrastructure applications created using programming languages, libraries, tools, and services supported by the cloud provider.

*Infrastructure as a service (**IaaS**)* In this model, customers have access to computing, storage, network, and similar services where the customer can execute arbitrary operating systems and software.

In this entry, there is no distinction between private and public clouds, for the discussion will be made considering the perspective of the end user and the cloud provider. In private clouds, the infrastructure is provisioned for exclusive use by a single organization. In this model, different business units are usually the end users of cloud services. In public clouds, the infrastructure is provisioned for open use by the general public.

Positioning **DBaaS**

IaaS allows one to abstract the actual hardware configuration away, but the issues for properly configuring databases remain. Hence, end users still have to devote time and energy on properly configuring and maintaining database systems, when such energy would be better applied in

developing the system they wanted to write in the first place.

From the cloud computing definition, **DBaaS** has aspects of both **SaaS** and **Paas**: although databases are software packages, they expose a programming interface, the query language, with which developers interact with. In public clouds, **DBaaS** usually is offered in the **Paas** layer.

Advantages of the DBaaS Model

There are many advantages in adopting a **DBaaS** model, all of them resulting from using a cloud-based service model. In **DBaaS**, due to the self-service nature of the cloud, to create new database instances, a user only needs to make a request in the cloud administration portal. Also, there is no need to plan for machines, storage, or replication strategies, since cloud providers either provide options to enable replication automatically in different zones or manage storage transparently, depending on provider and service.

The agility of cloud deployments should be contrasted with traditional **IT** operations. Consider, for example, that a business unit is developing a new application that requires a database server connection. To set up the server, a system administrator would have to be involved to allocate the machine and install the database server for the business unit. Between requesting a database server and actually being able to use it, the business unit could have to wait one or two business days. In the cloud, due to its high levels of automation, a new database instance can be provisioned in a matter of minutes.

Assuming the business unit of the previous example used **IaaS** as a model for installing database servers, whoever provisioned the computing resource would still be required to implement corporate policies, such as creating different accounts for different users and configuring passwords and firewalls according to corporate policy. Essentially, the business unit would still need access to a system administrator to properly configure the computing resource. Some of the work involved in this can be reduced by using

virtual machine templates, but, given the control users can have over virtual machines, some human verification may still be required.

What makes **DBaaS** stand out is the heavy use of abstraction and automation, another characteristic of the cloud. To provision a new database server instance, the user specifies the database engine and version required and the amount of RAM and the amount of storage required, and the cloud provider takes care of actually provisioning the database instance.

In principle, **DBaaS** works well for both small and large users. Teams that need small databases benefit from the fast provisioning times and from the lack of requiring a **DBA**, while teams with large database requirements benefit from the ability to scale up instances whenever needed.

Disadvantages of the DBaaS Model

Although **DBaaS** is a good solution for many companies and teams, it is not without its issues. Users might need database extensions not available in the cloud provider. Consider, for example, PostGIS. PostGIS is an extension that adds support for geographic objects to the PostgreSQL database. To add this support, PostGIS is installed as a set of helper programs, shared library files, and SQL scripts. If an end user needs PostGIS enabled in a database, but the cloud provider does not support it, then the user has no means of adding geographic object support for that database instance. The same argument can be made about legacy versions of database servers or unpopular database engines: if the cloud provider does not support them, they cannot be used.

With regard to scaling, not all providers might support scaling down database server instances. If, for example, a user provisioned a database instance larger than what was actually needed, the only solution to scaling down might be provisioning a new database instance and migrating the data from the old instance to the new one. Scaling database services out might suffer from a similar issue. If the cloud provider lacks support

for multiple server instances serving the same database – this can occur, for example, when a database grows to be bigger than the biggest instance type supported by the cloud provider – then the user has to implement support manually, i.e., by partitioning the data among different database servers.

Depending on the needs of the end user, the premium for using **DBaaS** might be higher than deploying databases traditionally in **IaaS** clouds or on in-house machines. Therefore, a cost-benefit analysis must be made prior to choosing one option or another.

Types of Databases

Currently there are two dominant database paradigms: relational (SQL) and the so-called NoSQL databases. Relational databases are based on the relational calculus theory and make use of the structured query language (SQL). Different relational databases implement different dialects of the SQL, but the language itself is standardized, and SQL databases make use of similar terminology. Relational databases provide ACID (atomicity, consistency, isolation, and durability) guarantees:

Atomicity requires that each transaction happen all at once or not at all – if one part of the transaction fails, then the whole transaction fails – to the outside world, committed transactions appear indivisible;

Consistency ensures that transactions change the database only between valid states, making sure that all defined rules, such as cascades, constraints, and triggers, are always valid;

Isolation ensures that one transaction cannot interfere with another and that the concurrent execution of transactions results in the same state that would be obtained if they were executed sequentially;

Durability ensures that once a transaction has been committed, it will remain committed, even in the event of crashes.

The term NoSQL is newer and relates to databases with different data models, such as

tuples (where row fields are predefined in a schema), documents (which allow attributes to be nested documents or lists of values as well as scalars and without the definition of a schema), extensible records (hybrids between tuples and documents), and objects (analogous to objects in programming languages, but without methods) (Cattell 2011). Opposed to relational databases, NoSQL databases provide BASE (basically available, soft state, eventually consistent) properties.

Basically available meaning that the system guarantees availability, in which every request receives a response, without guarantee of containing the most recent write

Soft state means that state can change, even without input, due to eventual consistency;

Eventually consistent indicates the system will become consistent over time, given it does not receive input during that time.

NoSQL databases became popular due to big Internet companies, such as Amazon, Facebook, and Google, using them for scaling their services. Traditionally, relational databases were considered hard to scale out, particularly due to the ACID guarantees. Hence, companies with millions of users needed better ways to scale their systems. In a way, these database systems were introduced to address the “velocity” and “volume” of the big data Vs. Examples of early successful systems are Dynamo (DeCandia et al. 2007) and BigTable (Chang et al. 2008).

The gains in performance of NoSQL databases over SQL databases come from the BASE properties. By relaxing the ACID properties, NoSQL databases can return from queries faster, allowing for faster responses. Also, the eventual consistency allows for easier load balancing between back-end servers, since the global view does not have to be consistent the whole time. In fact, “customers tolerate airline over-booking, and orders that are rejected when items in an online shopping cart are sold out before the order is finalized” (Cattell 2011), which makes a case for using such databases.

Databases as a Service, Table 1 Non-exhaustive list of **DBaaS** offerings of three big cloud providers as of the fourth quarter of 2017. Table sorted by provider name

Provider	Type	Databases supported
Amazon	Relational	Amazon Aurora, PostgreSQL, MySQL, MariaDB, Oracle, Microsoft SQL Server
Amazon	NoSQL	Amazon SimpleDB, Amazon Redshift, Amazon DynamoDB, Amazon Neptune, JanusGraph
Google	Relational	PostgreSQL, MySQL, Cloud Spanner
Google	NoSQL	Cloud Bigtable, Cloud Datastore
IBM	Relational	IBM DB2, PostgreSQL, MySQL
IBM	NoSQL	IBM Cloudant, MongoDB, JanusGraph, Redis, RethinkDB, ScyllaDB

D

Current DBaaS Offerings

As of the fourth quarter of 2017, all the big cloud providers have a **DBaaS** offering in their cloud systems, whether relational or NoSQL. Table 1 displays a non-exhaustive list of the offerings of three big cloud providers. As can be seen in the table, various databases with different data models are available, allowing users to select the model that best fits the problem being tackled.

Relational database management systems achieve scalability by partitioning data between different database servers, a technique known as “sharding.” One example of how sharding can be done is by splitting the data based on the continent users live in – e.g., the data that belongs to a user from Europe would be placed on a server different from a server that stores data about a user from Asia. When a user migrates between continents, migrating user data between regions would reduce access times but would incur data transfer costs. One interesting study would be to analyze the trade-off between higher latencies for users and the costs of such migrations. Also related to costs, cloud providers could benefit from more accurate cost models that better reflect their fail-over strategies (Mansouri 2017).

In recent years, we have seen database management systems originally written as NoSQL databases adopting SQL as a query language and becoming relational databases (Corbett et al. 2013; Bacon et al. 2017). We have also seen new relational databases being written specifically to work on the cloud (Verbitski et al. 2017). Such systems were designed to overcome the technical limitations of both traditional relational (which were hard to scale horizontally due to the inherent complexity of sharding) and NoSQL databases (which typically only provide eventual consistency), while providing ACID guarantees and without the need of performing explicit sharding. These new relational databases were made generally available to public cloud customers, but currently there seem to be no private cloud alternatives to such database systems. It would

DBaaS and Big Data

Advances in database technologies enabled collection and analysis for big data. As the ideas used by Internet companies to implement scalable database services became popular, application developers started using such technologies to implement faster applications. Today, **DBaaS** enables companies from various industries to collect, process, and analyze big data in the cloud.

Future Directions for Research

Research in **DBaaS** is related to the areas discussed previously: relational and NoSQL databases and cloud computing. Therefore, it makes sense that future research directions should be related to a tighter integration between these areas.

be interesting to investigate how cloud software stacks (e.g., OpenStack (Sefraoui et al. 2012)) could integrate these improvements and whether current **DBaaS** software architectures (as implemented by cloud providers) could accommodate these new designs.

As for the perceived “rigidity” of relational databases and SQL, vendors of database management systems have added support for a JSON data type to their products, resulting in more flexibility in the programming model, as such data types add support for the JSON syntax, allowing for more complex queries without the need for changing the database schema every time a new field is modified (in the JSON columns). Previous research (Chasseur et al. 2013; Tahara et al. 2014) suggests that such integration of SQL and NoSQL properties results in systems with higher performance and better consistency guarantees than only relational or only NoSQL systems, but may need further evaluation on Internet-scale and **DBaaS** systems.

Further Reading

Hacigumus et al. (2002) describe the design of one of the first web-based **DBaaS** systems before the term cloud computing was coined. Mell and Grance (2011) and Armbrust et al. (2010) define the term “cloud computing” and discuss the characteristics of the cloud. DeCandia et al. (2007) and Chang et al. (2008) describe two early successful NoSQL database systems. Cattell (2011) examines SQL and NoSQL systems and categorizes NoSQL according to data model while also presenting use cases for each of the defined categories. Abourezq and Idrissi (2016) present an overview of database as a service for big data, reviewing the database solutions offered as **DBaaS**.

Data-Driven Process Simulation

Benoît Depaire and Niels Martin
Research group Business Informatics, Hasselt University, Diepenbeek, Belgium

Definitions

Data-driven process simulation is a technique which constructs a computer model that imitates the internal details of a business process and extensively uses data – recorded by information systems supporting the actual process – to do so. The model is used to execute what-if scenarios in order to better understand the actual process behavior and predict the impact of potential changes to the process.

Overview

Data-Driven Process Simulation

Every organization executes multiple business processes – e.g., the production, transportation, and billing process – which have to be managed properly to generate customer value (Dumas et al. 2013). An essential part of business process management is the identification and design of process improvement opportunities – e.g., hire more staff to reduce waiting time at a specific step in the process. Since a business process typically has a complex and dynamic nature, it is often impossible to deduce analytically the full impact of a specific process change. In such setting, process simulation is a valuable instrument.

Process simulation is the imitation of the actual process through the use of a (computer) model. It allows an organization to verify the consequences of proposed process modifications prior to implementation (Melão and Pidd 2003). The quality of the results of process simulation is directly dependent on the quality of the process simulation model.

Therefore, to construct a high-quality simulation model, the researcher must gather extensive process information as input. Traditionally, such input is gathered by means of business documents, interviews, and observations. While valuable, it has been shown that these sources also have limitations:

- Process documentation often describes how a process should be executed which can deviate from the actual process behavior (Märüster and van Beest 2009).
- Interviews with business experts can result in contradictory information (Vincent 1998), and the perception of the interviewees might be heavily influenced by recent experiences within the process (Dickey and Pearson 2005).
- Observational data could suffer from the Hawthorne effect (Robinson 2004) – i.e., the performance of staff members increase simply because they know they are being observed – and often require a significant time investment.

Another type of input are the data and records kept by different information systems about the daily process execution. With the rise of process-aware information systems – supporting the entire process rather than a specific activity (Dumas et al. 2005), e.g., enterprise resource planning systems – the amount of these process data is growing rapidly. The benefit of these data is that they provide an objective view on the real process behavior. The challenge, however, is to extract insights from these data which can be used to construct more realistic simulation models.

The goal of data-driven process simulation is to extend the traditional inputs for simulation model construction with such process data and

to extract insights from the data with respect to different aspects of the simulation model. As a consequence, it encompasses several techniques which support specific modeling decisions.

Building Blocks of a Simulation Model

When constructing a simulation model, four building blocks can be distinguished: entities, activities, control-flow, and resources (Martin et al. 2016b). For each of these building blocks, a series of modeling tasks need to be executed during the construction of a simulation model.

An **entity** is the dynamic object that flows through the process model and which instigates action in the process as activities are executed on it by resources (Kelton et al. 2015; Tumay 1996) – e.g., a specific order (entity) in an order picking process. During simulation, multiple entities can be simultaneously present within the process and can influence each other's process flow by, e.g., occupying particular resources.

An **activity** is the execution of a specific task by a specific resource on a given entity (Tumay 1996) – e.g., the registration (task) by employee X (resource) of order Y (entity).

The **control-flow** of a process expresses the temporal relationship between the activities. Control-flow consists of sequence flows – modeling “directly follows” relationships – and gateways – modeling complex process behavior such as choice and parallelism. The control-flow defines the different routes an entity can follow through the process – e.g., an international order might follow a different route in the order picking process than a national order, resulting in different or additional activities that need to be executed on the order.

The actual execution of activities is the responsibility of **resources**. Basic resource types are technical resources, such as software systems, and human resources (Dumas et al. 2013; Tumay 1996).

Key Research Findings

This section provides the key research results on how process data can be used to improve different

modeling aspects of process simulation. It should be noted that, in general, the insights that can be retrieved from process data depend upon the quality and granularity of the available data. To structure the discussion in this section, the four building blocks of a simulation model and their associated modeling decisions are used.

Entities

With respect to the *entity* building block, two modeling decisions will be discussed: the arrival rate and the entity typology.

Entity Arrival Rate

Modeling the entity arrival rate – i.e., the pace at which new entities arrive at the process – typically consists of a deterministic and a stochastic part. The deterministic part can be a constant or dependent on other context-related factors. The stochastic element is typically modeled as a probability distribution (van der Aalst 2015).

Process data is used to learn the parameters of a predefined probability distribution. The exponential distribution is often used under the assumption that the start of the first activity in a process execution defines the actual arrival of the entity and the entities arrive independent from each other (Rozinat et al. 2009). When these assumptions appear too restrictive – e.g., an entity arrived before the first activity was executed on it – the ARPRA algorithm (Martin et al. 2016c) accounts for queue formation before the first activity and discovers the proper gamma distribution – which is a generalization of the exponential distribution.

Entity Types

No two entities are exactly the same, and it is not uncommon that entity properties have a direct impact on the process execution – e.g., the physical dimensions of an order have a direct impact on the duration of the packaging activity. To simplify complex processes, it is common to define entity types which represent a group of entities similar in terms of specific characteristics (i.e., attributes) (Kelton et al. 2015).

When working with entity types, the quality of the defined typology has a direct influ-

ence on the quality of the simulation model. To identify relevant entity types, cluster analysis is a useful technique to segment the entities (Xu and Wunsch 2005). Recently, various algorithms have been developed that discover clusters which group entities that have a common execution path and where clusters – entity types – differ in terms of process execution. Various approaches exist: a vector-based approach where the trajectory of an entity is translated into a set of features (Bose and van der Aalst 2010; de Medeiros et al. 2008; Delias et al. 2015; Greco et al. 2006; Song et al. 2009), an approach based on the generic edit distance (Bose and van der Aalst 2009), Markov model-based clustering (Veiga and Ferreira 2010), and an approach driven by process model accuracy (De Weerdt et al. 2013).

Activities

With respect to activities, five important modeling decisions will be discussed: determining which activities need to be included, activity duration, resource requirements, queue discipline, and activity interruptions.

Activity Definition

Process data is typically captured at the level of events – i.e., specific moments in time which change the state of the process. Even when data is logged at the level of activities, this data might be at a too granular level for process simulation purposes. In both cases, techniques are needed to identify appropriate activities and to map data to higher-level activities. For this purpose, activity mining (Günther et al. 2010) can be used and only requires the event log. Other approaches which incorporate domain knowledge are also available such as in Szymanski et al. (2013), Baier et al. (2014), and Mannhardt et al. (2016).

Activity Duration

Modeling the activity duration typically consists of a deterministic and stochastic element. Deterministic differences in activity duration can be dependent on a wide range of entity properties but also on resource workload (cf. Pospisil and Hruška (2012) and Nakatumba and van der Aalst (2010); Nakatumba et al. (2012)). Process data

can be used to discover these dependencies and model them correctly.

The stochastic element is modeled by means of a probability distribution. Activity durations are extracted from the process data – i.e., difference between the start and completion time of an activity – and used to fit the probability distribution.

When either start or completion time of activities is missing, this approach cannot be applied directly. Literature suggest several approaches to deal with such missing data. When only the completion time is recorded, various proxies are suggested for the corresponding start time, such as the completion time of the previous activity for that entity or the time at which the resource executing the activity finished its previous job (Nakatumba 2013; Wombacher and Iacob 2013). When only the start of an activity is recorded, similar proxies have been suggested in Martin et al. (2016b). Be aware that several issues such as the interruptibility of activities or the presence of batch processing can render the extraction of duration observations more complex.

Resource Requirements

The resource(s) required to execute a particular activity need(s) to be specified. Process data containing resource information can be used to support this modeling task, and different techniques exist to reveal the relationship between activities and resources (Huang et al. 2011; Liu et al. 2008; Ly et al. 2006; Senderovich et al. 2014).

Queue Discipline

In a simulation model, one must define how queues are dealt with at activities. The queue discipline establishes the processing order of queuing entities, such as first-in-first-out (FIFO), last-in-first-out (LIFO), or according to a priority rule.

Process data can be used to discover the queuing discipline that is applied. Suriadi et al. (2017) propose a method to extract FIFO, LIFO, and priority-based processing patterns from process-related data and consider three perspectives: the resource, activity, and case perspective, each representing potential levels of aggregation.

Activity Interruptibility and Unexpected Interruptions

With respect to interruptions, the activity interruptibility and unexpected interruptions need to be modeled. The activity's interruptibility expresses whether it can be interrupted while an entity is being processed. If activities are interruptible, one must still model the interruption frequency, duration, and nature. The nature of an interruption refers to whether the activity execution stops immediately (preemptive) or whether the running entity can still be finished (non-preemptive) (Hopp and Spearman 2011).

Process data containing specific information such as interruption events or resource break information (Senderovich et al. 2014) can be used directly to inform the aforementioned modeling tasks. However, often such specific information is missing, and the interruption time is simply part of the activity duration. Under these circumstances, duration outlier analysis can be used (Pika et al. 2013; Rogge-Solti and Kasneci 2014) to inform the researcher on activity interruptions.

Control-Flow

With respect to the control-flow, two aspects need to be modeled: the control-flow definition between the activities and the gateway routing logic.

Control-Flow Definition

The control-flow determines the path(s) an entity can follow throughout the process and defines sequentiality, choice, and concurrency between activities. A multitude of algorithms exist to retrieve control-flow models from process data (De Weerdt et al. 2012; van der Aalst 2016). Several of these algorithms have been applied in a simulation context such as the alpha-algorithm (Aguirre et al. 2013; Rozinat et al. 2008, 2009), fuzzy mining (van Beest and Mărușter 2007), and heuristic mining (Leyer and Moermann 2015; Mărușter and van Beest 2009).

Gateway Routing Logic

For gateways representing choice, the routing logic needs to be defined, which can be stochastic

(each outgoing path has a specific probability), deterministic (business rules govern the choice), or a combination of both.

In literature, Rozinat and van der Aalst (2006a,b) use decision trees to discover the decision logic from process data, which is also applied in a simulation context (Rozinat et al. 2008, 2009). Schonenberg et al. (2010) use regression analysis to mine decision logic from process data. The work of de Leoni et al. (2013) allows one to mine rules from process data which are linear combinations of multiple entity attributes. All these approaches result in deterministic rules but can be easily extended with a stochastic element as suggested by Pospisil and Hruška (2012). A purely stochastic approach is presented in Leyer and Moermann (2015) which simply learns the routing probabilities for each choice.

Resources

With respect to modeling the resources, three modeling tasks are discussed: the definition of resource roles, resource schedules, and batch processing.

Resource Roles

Resource roles group resources performing similar activities and allow one to simplify the simulation model – e.g., activities are assigned to roles instead of specific resources.

Various work on how to retrieve insights on resource roles from process data exist. One approach is to perform a cluster analysis on resource-activity frequency matrix retrieved from the process data (Song and van der Aalst 2008; Rozinat et al. 2009). Another approach is to focus on handover relationships in the data (Burattin et al. 2013) or to cluster resources on the number of entities they collaborated on (Ferreira and Alves 2012).

Resource Schedules

A resource schedule expresses its availability for the simulated process, which can differ from the official working schedule as a resource is often involved in multiple processes. Process data can

help to gather insights in the resource's availability for the process.

A first approach to use process data is to estimate the start and end time of a working day from the process data (Wombacher et al. 2011). Other approaches estimate resource availability as a percentage of the total time a resource is executing activities (Liu et al. 2012; van der Aalst et al. 2010), which however do not provide exact availability timeframes. If more fine-grained insights are needed, the work of Martin et al. (2016a) provides a method to mine daily availability records for resources.

Batch Processing

Batch processing refers to a resource's tendency to accumulate entities in order to process them simultaneously, concurrently, or sequentially. Again, process data can be used to study the actual batching behavior.

Wen et al. (2013) developed a control-flow discovery algorithm when simultaneous batch processing occurs in a process. Similar to Liu and Hu (2007), they assume that events are only recorded for one of the cases in a batch. While Wen et al. (2013) focus on the control-flow, Nakatumba (2013) states that batching behavior is present when two sets of activity instances on a particular working day are separated by a time period of more than 1 hour. A more systematic approach is proposed in Martin et al. (2017). Based on a distinction between simultaneous, concurrent, and sequential batch processing, an algorithm is proposed which detects batching behavior. Moreover, metrics such as the batch size are calculated which can be used to specify batching parameters in a simulation model (Martin et al. 2017).

Examples of Application

Literature provides examples in which real-life process data is extensively used to support the construction of simulation models. For example, Rozinat et al. (2009) consider the complaint handling process and the invoice handling process in municipalities and use process data to specify the entity arrival rate, activity duration,

control-flow, gateway routing logic, and resource roles. In another example, Leyer and Moormann (2015) simulate the loan application process at a financial institution and use real-life process data to model the activity duration, control-flow, and gateway routing logic.

While the aforementioned references use process data to support multiple modeling decisions, dedicated papers focusing on a single decision also apply their proposed techniques to real-life data. For instance, Mărușter and van Beest (2009) mainly focus on the use of process data to model the simulation model's control-flow and consider three real-life processes: a process of a gas company, the fine collection process of a governmental institution, and the navigation process in an agricultural decision support system. In another example, Martin et al. (2017) retrieve insights in resources' batching behavior from a call center's and a production department's process data.

D

Future Directions for Research

Despite the valuable research efforts outlined above, four key directions of additional work to exploit process data for the development of a simulation model can be distinguished.

Firstly, there is room for new, improved, and dedicated algorithms which support specific modeling decisions using process data. This article only discusses a subset of modeling tasks required to build a simulation model. For other modeling tasks, e.g., the additional ones included in Martin et al. (2016b), no clear starting points for future research could be identified in literature. For some modeling decisions included in this article, the state of the art refers to approaches which were not directly developed with simulation in mind. For instance, the use of clustering to identify entity types results in distinct process models for each entity type, requiring an additional aggregation step to produce a single model. Dedicated algorithms can exploit the specific characteristics of process data and specific needs of process simulation. Additionally, existing (dedicated) algorithms can also be extended to provide even more insights.

For example, the ARPRA algorithm (Martin et al. 2016c) can be extended to discover nonstationary arrival patterns.

Secondly, a common assumption among process discovery techniques is that both start and completion of an activity are logged. Often the data does not meet these assumptions and, e.g., only the completion times are recorded. In such cases, the researcher must make additional assumptions to apply existing algorithms. Therefore, future research on start time estimation and imputation is worth pursuing. Alternatively, existing algorithms can also be extended such that they do not longer require, e.g., explicit start timestamps.

Thirdly, most existing algorithms focus on a single modeling aspect, whereas they are in fact related to other modeling decisions. Future algorithms for supporting modeling tasks could therefore benefit from an integrated approach. For example, the resource schedules can be taken into account when mining the queue discipline as a resource might start prioritizing urgent tasks at the end of the working day.

Finally, a single analysis package should be created which takes process data as an input and provides comprehensive support for a multitude of simulation modeling decisions. This involves an integration of the current algorithms with yet to be developed techniques for other modeling decisions. Even though the development of such an integrated package does not require the development of new scientific knowledge, it is required to facilitate data-driven simulation in practice.

Definitions

In the context of business process analytics, decision discovery is the problem of discovering the set of rules that are de-facto used to make decisions in a business process, by analyzing event logs recording past executions of the process.

Overview

The execution of business processes typically follow some decisions that determine, within the multiple alternative executions, how to carry on executions of the process. These decisions are defined over the characteristics of the single

instances (e.g. loan's amount, applicant's or patient's age). This chapter reports on different approaches to discover these decision rules when unknown to process stakeholders. Most of these techniques in fact leverage on machine-learning. A number of successful real-life case-study applications are discussed along with the open-source tools that were used.

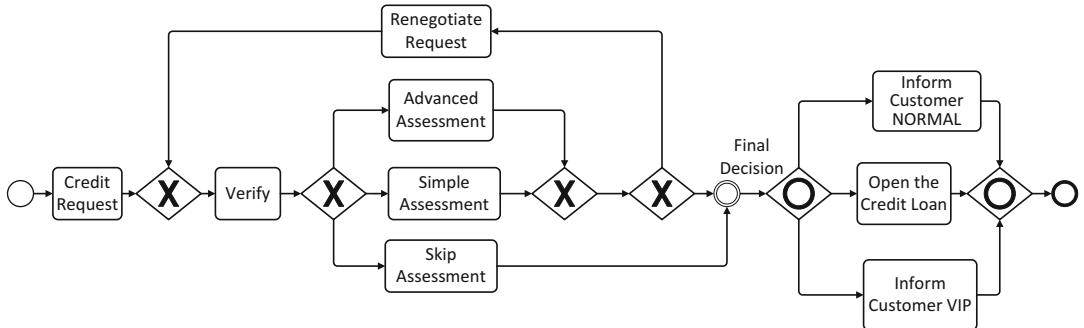

Introduction

The main focus of automatic process discovery has traditionally been in the realm of process mining on the control-flow perspective (cf. the chapter of Automatic Process Discovery). As an example, the recent advances have led to discovery algorithms that can discover models such as that in Fig. 1. This model only shows the control flow, namely, the ordering with which activities can be executed in the process.

Event logs are typically of such a form as in Fig. 2. Automatic process discovery techniques only focus on the first two columns of an event log, the case identifier (e.g., the customer id) and the activity name, thus overlooking a lot of insightful information pertaining other perspectives, such as the organization perspective, the decision perspective (a.k.a. the data or case perspective), and the time perspective (van der Aalst 2016).

The control-flow perspective is certainly of high importance as it can be considered as the process backbone; however, many other perspectives should also be considered to ensure that the model is sufficiently accurate. This chapter will focus the attention on the decision perspective and will not discuss the organization and time perspectives. Readers are referred to van der Aalst (2016) as initial pointer to explore the research results regarding the latter two perspectives.

The decision perspective focuses on how the routing of process instance executions is affected by the characteristics of the specific process instance, such as the amount requested for a loan, and by the outcomes of previous execution steps, e.g., the verification result. The representation

Decision Discovery in Business Processes, Fig. 2 An excerpt of an event log. Each row is an event referring to an activity that happened at a given timestamp. Several

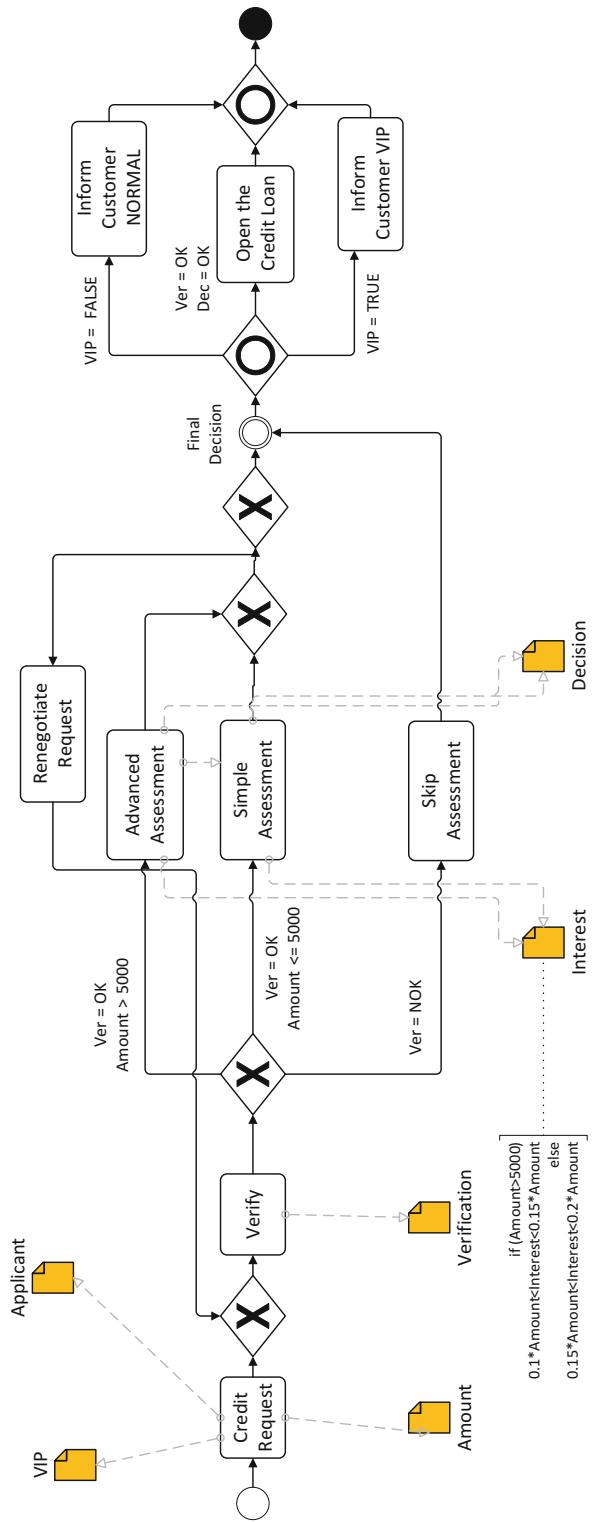

process attributes are written and updated by one or more events. The alternation of two color tones is used to group events referring to the same process instance

of this decision perspective on a process in an integrated model or as separate tables is nowadays gaining momentum. This is also testified by the recent introduction and refinement of Decision Model and Notation (DMN), which is a standard published by the Object Management Group to describe and model the decision perspective (DMN 2016).

The simplest representation of the decision perspective is to attach decision rules to XOR and OR splits, the decision points of a process model. The rules explaining the choices are driven by additional data associated with the process, which is generated by the previous process' steps. In the remainder, this additional data is abstracted as process attributes, each of which is name-value pair. Note that not all decision points are

driven by rules: the process attributes are not able to determine which branch is going to be followed (cf. the XOR split involving *Renegotiate Request*). Figure 3 illustrates a possible extension of the model in Fig. 1 to incorporate the data attributes that are manipulated by the process and how they affect the routing at the decision points. The rules at decision points can be alternatively easily represented as a separate DMN table.

Historically, the discovery of the decision perspective is called *Decision Mining*, a name that was introduced by the seminal work of Rozinat and van der Aalst (2006). In this work, the mined decisions at the decision points are mutually exclusive: when a process instance reaches a decision point, one and exactly one branch is enabled. Rozinat et al. leverage on Petri nets, but

Decision Discovery in Business Processes, Fig. 3 A model that extends what is depicted in Fig. 1. The decision points are annotated with rules enabling the branches

the same idea can trivially be moved to BPMN and other process modeling notations. In this work, decision-mining problems are transformed into classification problems: techniques such as decision-tree learning can be leveraged off. Decision trees are learnt from an observation instance table. For each decision point in the process, the subset of the events that refers to the activities that follow the decision point is extracted. Each observation instance consists of a dependent variable, a.k.a. response variable, and a set of independent variables, a.k.a. predictor variables, that are used for prediction. The dependent variable is the activity of the event following, and (a subset of) the event (i.e., process) attributes are used as independent variables. This chapter denotes variables as the features used in observation instances to learn a (decision-tree) classifier. Attributes are conversely associated with processes and events and indicate the data points manipulated while executing a process instance.

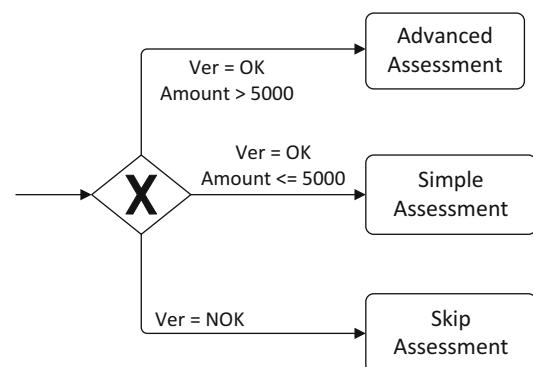

Decision Mining as a Classification Problem

The introduction has illustrated that the problem of decision mining can be translated into a classification problem. Several classification techniques exist; however, one needs to focus on those techniques that return human-readable decision rules in the form of, e.g., formulas. This motivates why most of the decision-mining techniques, such as the seminar work (Rozinat and van der Aalst 2006) and others (Batoulis et al. 2015; de Leoni and van der Aalst 2013; Bazhenova et al. 2016), aim to learn decision trees and use them to build a set of decision rules. In addition, to provide human-readable rules, decision trees have the advantage of creating rules that are clearly highlighting the attributes whose values affect the decisions. These works typically leverages on the C4.5 algorithm for decision-tree learning, which is capable to deal with noise and missing values. In the context of decision mining, noise indicates that in a fraction of situations, the wrong (or unusual) decision is made; missing values indicate that, due to logging errors, cer-

tain assignments of values to attributes are not recorded or, also, process participants forgot to update the value of given attributes. Association rule discovery techniques might be a possibility, but they tend to return a large number of rules that do not necessarily have a discriminatory function on the decision, either.

Let us consider the decision point in Fig. 4, part of the model in Fig. 3. Clearly, the rules are initially not present and the aim is to discover them. From the event log, every event that refers to the activities at the decision point is retained from the event log. Considering the event log in Fig. 2, this results in an observation instance table such as in Fig. 5. The column *Activity Name* refers to the dependent variable, and the other columns are the independent variables, categorical or numerical, that are used to predict the dependent variable. The application of decision-tree learning techniques will produce a tree similar to that in Fig. 6.

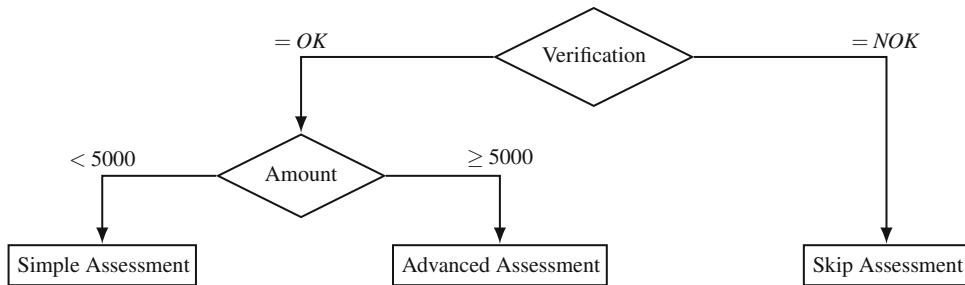

Decision trees classify instances by sorting them down in a tree from the root to some leaf node. Each non-leaf node specifies a test of some variable x_1, \dots, x_n (in decision mining, the process attributes), and each branch descending from that node corresponds to a range of possible values for this variable. In general, a decision tree represents a disjunction of conjunctions of expressions: each path from the tree root to a leaf corresponds to an expression that is, in fact, a conjunction of variable tests. Each leaf node is

Decision Discovery in Business Processes, Fig. 4 One of the decision points. The aim is to start from the control flow and discover the rules

Decision Discovery in Business Processes, Fig. 6 A possible decision tree discovered based on the observation instances of which an excerpt is in Fig. 5

associated with one of the possible values of the dependent variables, namely, with one of the process activities that follows an XOR split: if an expression e is associated with a path to a leaf node a , every input tuple for which e evaluates to true is expected to return a as output. In decision mining, this means that every time a decision point is reached and the process attributes x_1, \dots, x_n take on values that make e evaluate true, the process execution is expected to continue with activity a . In the example tree in Fig. 6, each leaf refers to a different activity. However, multiple leaves can be associated with the same activity a . In that case, each path leading to a would correspond to a different expression. Together all these expressions combined with disjunction (i.e., a logical OR operator) constitute an expression that predicts when the process continues with activity a . As discussed in van der Aalst (2016, pp. 294–296), this procedure is extensible to OR splits, where multiple branches may be activated.

Extension of the Basic Technique

This basic technique has been extended to deal with additional cases. The first extension is re-

lated to the situations when the executions are not always compliant with the control-flow model and/or the model contains invisible steps. The second extension is applicable when the rules at decision points are not mutually exclusive, such as when some information that drives the decisions is missing or the process behavior is simply not fully deterministic. These extensions are discussed in detail below.

There are other valuable extensions, which cannot be elaborated on in detail for the sake of space. In Bazhenova et al. (2016) and De Smedt et al. (2017b), authors extend the basic algorithm to be able to discover the dependencies between process attribute updates and leverage on invariant miners. For example, the values assignable to an attribute *Risk* are a function of the values taken on by attributes *Amount* and *Premium*. While the basic BPMN modeling notation is only able to represent path routing decisions, BPMN can be complemented with DMN where data-related decisions can be represented. As discussed in Batoulis et al. (2015), DMN is especially relevant when models are of significant size. By complementing BPMN with DMN, the decisions are modeled outside the control-flow model. The paper argues that this separation of concerns would

Decision Discovery in Business Processes, Fig. 7 Two non-compliant traces for the model in Fig. 1: they break the assumption of the basic decision-tree algorithm

increase the readability and the maintainability of these models. Here, maintainability of a model is intended as the easiness of extending, adjusting, and updating a model when the internal protocols or the external rules and regulations change.

Non-compliance and Invisible Steps

The first assumption of the basic algorithm is that, when discovering the rules of a decision point, every activity is always executed in the right moment according to the dictation of the control-flow model, e.g., the model in Fig. 1. However, due to logging errors and non-compliances, sometimes executions do not comply with the control-flow model. As an example, consider trace for the customer with id *TH25* in Fig. 7. This trace is clearly not compliant with the model in Fig. 1: activity *Credit Request* is immediately followed by *Simple Assessment*, i.e., activity *Verify* did not occur (or its execution was not logged). This means that the value of attribute *Verification* is missing. Several decision-tree learning algorithms, such as C4.5, are very good at dealing with missing values. However, it is necessary to detect that a value is missing due to non-compliances. As an example, the execution for the customer with id *TH25* and the decision of executing *Simple Assessment* were made without considering the value of attribute *Verification*; in fact, the value of that attribute was undefined because the execution of activity *Verification* never took place. If such cases as this are not detected, one mistakenly could use an old value. For instance, attribute *Verification* is updated multiple times via multiple executions

of activity *Verification*, which is executed once for each loan's renegotiation. If one renegotiation mistakenly skipped the verification, decision mining might use the previous value, updated during the previous renegotiation's loop. The basic algorithm also suffers of the problem that one should ignore updates of attributes that result from the non-compliant execution of activities. As an example, consider trace for the customer with id *TH26* in Fig. 7: activity *Verify* occurs after *Simple Assessment*, which violates the constraints dictated by the model in Fig. 1. As a result of the execution of this activity, attribute *Verification* takes on value *NOK* that is too late because a simple assessment has already been conducted. It is clear that, in this case, activity *Simple Assessment* should not have occurred.

To detect missing values and illegal attribute updates, the work report in de Leoni and van der Aalst (2013) integrates the basic technique with techniques for log-model alignment. An alignment between a recorded process execution (log trace) and a process model is a pairwise matching between activities recorded in the log and activities allowed by the model.

Table 1 illustrates the alignments of the model in Fig. 1 with the traces in Fig. 7. Activity names are abbreviated with the first letter of each name word. Abstracting from the attribute updates and ignoring \gg 's, for each log trace, the log row corresponds to the log trace, and the process row represents the execution allowed by the process model that is the closest to the log traces in terms of number of necessary changes. The yellow and green columns refer to log and model moves, respectively. For further information, readers are

referred to Adriansyah (2014) and to the chapter on Conformance Checking. The events for log moves will be ignored for decision mining. Conversely, activities related to model moves are introduced and will be considered. Attributes that are supposedly updated as a result of the activity executions take on null, a special value to indicate that the value is missing and should be treated as such by the decision-tree learning algorithm. An alternative to using alignments could be to just remove the traces referred to executions not compliant with the control-flow model. However, situations in which most of the traces are almost compliant and few are fully compliant would cause the rules to be mined on the basis of insufficient observation instances. If the missing events refer to activities that do not update attributes relevant for a certain decision point, there would be no reason to discard the corresponding traces when discovering the rules for such a decision point.

In addition to dealing with non-compliance, de Leoni and van der Aalst (2013) allows for

Decision Discovery in Business Processes, Table 1
Alignments of the traces in Fig. 7 wrt. the model in Fig. 1

discovering decision rules for models such as in Fig. 8. In this case, the explicit activity *Skip Assessment*, which indicates that no activity is performed in case of negative verification but, conversely, the execution directly moves to the negative final decision, is not present and recorded in the respective traces. In such a case, no activity can be explicitly identified to indicate that the assessment does not take place. To overcome this, the approach in de Leoni and van der Aalst (2013) would assume that there is a silent activity τ , as illustrated by the cloud in the figure. Using alignments, silent activity τ would be included in the analysis. When an execution of τ is necessary (e.g., when the assessment is skipped), the alignment would automatically add a model move for τ , and as mentioned above, model moves are always considered when mining the decision rules. Of course, the step τ is always involved in model moves since they are never recorded in the event log, being indeed silent.

Overlapping Rules

Existing decision-mining techniques for exclusive choices rely on the strong assumption that the rules attached to the alternative activities of an exclusive choice need to be mutually exclusive. However, business rules are often nondeterministic, and this “cannot be solved until the business rule is instantiated in a particular situation” (Rosca and Wild 2002). This ambiguity can occur due to conflicting rules or missing contextual information. For example, decisions taken by process workers may depend on contextual

Decision Discovery in Business Processes, Fig. 8 A variation of the model in Fig. 1: activity *Skip Assessment* is removed. Ideally, it can be replaced by a silent activity

τ , whose execution is not recorded in any trace of the event log

factors, which are not encoded in the system and, thus, not available in event logs (Bose et al. 2013). In Mannhardt et al. (2016), a technique is proposed that discovers overlapping rules in those cases that the underlying observations are characterized better by such rules. The technique is able to deliberately trade the precision of mutually exclusive rules, i.e., only one alternative is possible, against fitness, i.e., the overlapping rules that are less often violated. In short, as in the basic algorithm, the technique builds an initial decision tree based on observations from the event log, and for each activity a , a decision rule $rule1(a)$ is found (possibly $rule1(a) = \text{true}$). Then, for each decision-tree leaf, the wrongly classified instances are used to learn a new decision tree leading to new rules, such as $rule2(a)$. These new rules are used in disjunction with the initial rules yielding, e.g., overlapping rules of the form $rule1(a) \vee rule2(a)$.

It is worth highlighting here that overlapping rules are appropriate in contexts where information is missing and/or rules are intrinsically not fully deterministic. However, in other contexts, overlapping rules are just the results of wrong decisions made by process modelers and experts. In those cases, overlapping rules should be prevented and, when present, be repaired to ensure them to be mutual exclusive. Calvanese et al. (2016) propose a technique to detect overlapping rules and fix them to ensure their mutual exclusiveness.

Decision-Aware Control-Flow Discovery

De Smedt et al. (2017a) distinguish two categories of decision-mining techniques. The approaches that fall into the first category are named *decision-annotated process mining*: first a suitable control-flow model is discovered, which is later annotated with decision rules. Every approach discussed so far is within this category. A second category aims at *decision-aware control-flow discovery*: the control-flow and decisions are discovered together in a holistic manner.

Any approach in the first category has the disadvantage that it “*imposes the initial struc-*

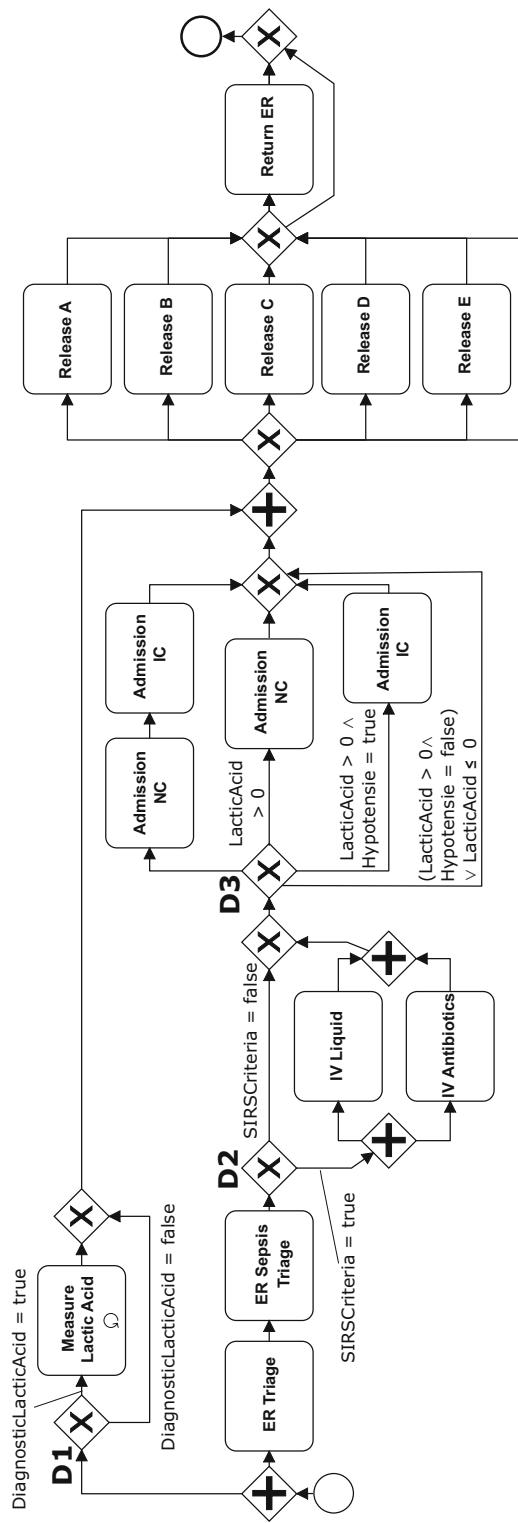

ture on top of which the decision perspective is placed upon” (De Smedt et al. 2017a). This might cause important decisions to remain unrevealed: the control-flow structure is discovered without considering the overall logic of the decisions, and important decision points are not made explicit.

Whereas Maggi et al. (2013) and Schönig et al. (2016) report on works to simultaneously discover data- and control-flow for declarative models (cf. the chapter of Declarative Modelling), Mannhardt et al. (2017) report the only research work about decision-aware control-flow discovery of procedural models (i.e., BPMN-like) where the decision perspective is used to reveal paths in the control flow that can be characterized by deterministic rules over the recorded attributes. If such behavior is infrequently observed, it is often disregarded by control-flow discovery techniques as noise (cf. the chapter on automated process discovery). The idea is that some paths may be executed infrequently because the corresponding conditions are rarely fulfilled. These paths and the conditions are likely to be of great interest to process analysts (e.g., in the context of risks and fraud). In Mannhardt et al. (2017), classification techniques are employed to distinguish between such behavior and random noise.

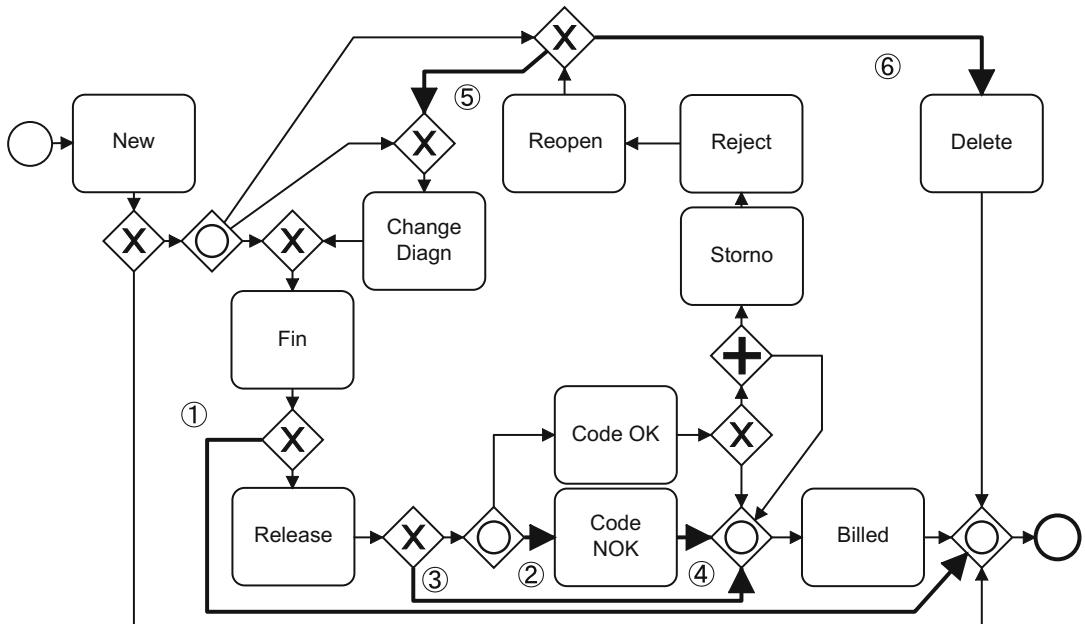

Example Cases and Tool Support

Decision mining has been applied in several domains as testified by many applications reported in literature (Rozinat 2010; de Leoni and van der Aalst 2013; Mannhardt et al. 2016, 2017; De Smedt et al. 2017b; Bazhenova and Weske 2016; Mannhardt 2018) and several implemented tools (van Dongen et al. 2005; Mannhardt et al. 2015; Kalenkova et al. 2014; Bazhenova et al. 2017). Here, two example cases are briefly presented. Both cases are taken from a project that was conducted in a regional hospital in the Netherlands (Mannhardt 2018).

In the first case, the trajectories of patients that are admitted to the *emergency ward* of the hospital with a suspicion for sepsis (Rhodes et al. 2017) were analyzed. A normative model of the expected patient trajectory control flow was de-

Decision Discovery in Business Processes, Fig. 9 Overlapping and nonoverlapping decision rules discovered for the trajectory of patients in a Dutch hospital. This model is an excerpt from the model in Mannhardt et al. (2016) and Mannhardt (2018)

Decision Discovery in Business Processes, Fig. 10 Process model discovered by the decision-aware process discovery method (Mannhardt et al. 2017) for a hospital billing process (Mannhardt et al. 2017)

signed and, then, the overlapping decision rules method (Mannhardt et al. 2016), yielding the model in Fig. 9.

In the second case, the hospital's billing process for medical services was analyzed. Several medical services (e.g., diagnostics, treatments, etc.) are collected in a billing package and validated and invoiced. However, in some cases, the billing package is *reopened*, *rejected*, or *canceled*, and further changes are needed. Figure 10 shows a process model discovered by the decision-aware control-flow discovery method. Six infrequent control-flow paths that are associated with specific data attribute values have been included in the process model. Some of these paths should not be disregarded as noise since they are related to cases with rework. For example, the path between RELEASE and Code NOK (②) occurs mostly for two specific *caseType* values. According to a domain expert, both case types correspond to exceptional cases: one is used for intensive care and the other for cases in which the code cannot be obtained (Code NOK). Another example is the path from Code NOK to Billed (④), which is also related to

the *caseType* attribute as well as to the medical *specialty* attribute. This path is interesting since it could not be explained by the domain expert.

Conclusion

This chapter has discussed the importance of the *decision perspective* and illustrates several techniques that aim to explain how the choices are driven by additional data associated with the process. These techniques leverage on the additional information recorded in data attributes (also denoted as event payload) of the event log to discover process models and enhance existing ones so that the models explain the decisions that drive the process executions. It was illustrated that these choices can be represented as annotations of process models or, alternatively, the decision can be modeled through separate DMN models that highlight the decision-related aspects.

As discussed, the application to real-life cases has illustrated that the maturity of the decision-mining approach has reached a level that certainly allows its application to production

environments. While it is certainly necessary to extend the class of decisions that can be mined, the major drawback is that the decisions are mining locally without considering the other decisions discovered at different points. This means that decision rules at different decision points can be conflicting, leading to models that, if actually enacted, would cause a certain number of executions to be unable to properly terminate. As future work, it is crucial to check whether the models enriched with decision rules are correct and to ensure to some extend that decisions are not conflicting, thus leading to deadlocks.

Definitions

In this chapter, we introduce the techniques existing in the literature in the context of declarative process mining, i.e., process mining techniques based on declarative process modeling languages. A declarative process mining technique is any technique that, in addition to taking as input an event log, takes as input or as output a (business) process model represented in a declarative process modeling notation. Declarative process mining techniques include techniques for process

discovery, conformance checking, and compliance monitoring.

Introduction

Process discovery, conformance checking, and process model enhancement are the three basic forms of process mining (van der Aalst 2016). In particular, process discovery aims at producing a process model based on example executions in an event log and without using any a priori information. Conformance checking pertains to the analysis of the process behavior as recorded in an event log with respect to an existing reference model. Process model enhancement aims at enriching and adapting existing process models with information retrieved from logs.

In the last years, several works have been focused on process mining techniques based on declarative process models (Maggi et al. 2011a, 2012a; de Leoni et al. 2012a; Di Cicco and Mecella 2013; vanden Broucke et al. 2014; Schönig et al. 2016b; Burattin et al. 2016). The dichotomy procedural versus declarative can be seen as a guideline when choosing the most suitable language to represent models in process mining algorithms: process mining techniques based on procedural languages can be used for predictable processes working in stable environments, whereas techniques based on declarative languages can be used for unpredictable, variable processes working in turbulent environments (Zugal et al. 2011; Pichler et al. 2011; Haisjackl et al. 2013; Reijers et al. 2013; Silva et al. 2014).

Indeed, a declarative approach allows the business analyst to focus on the formalization of few relevant and relatively stable-through-time constraints that the process should satisfy, avoiding the burden to model many process control flow details that are fated to change through time. Using declarative formalisms the processes are kept under-specified so that few rules allow for multiple execution paths. In this way, the process representation is more robust to changeable behaviors and, at the same time, remains compact. For these reasons, declarative process mining

techniques have been largely applied in the context of healthcare processes (Grando et al. 2012, 2013; Rovani et al. 2015), since these processes are characterized by a high degree of variability.

Since declarative process modeling languages are focused on ruling out forbidden behavior, these languages are very suitable for defining compliance models that are used for checking that the behavior of a system complies certain regulations. The compliance model defines the rules related to a single instance of a process, and the expectation is that all the instances follow the model. Processes can be diagnosed for compliance violations in an a posteriori or offline manner, i.e., after process instance execution has been finished (conformance checking). However, the progress of a potentially large number of process instances can be monitored at runtime to detect or even predict compliance violations. For this, typically, terms such as compliance monitoring or online auditing are used (Ly et al. 2013, 2015).

In van der Aalst et al. (2009), Westergaard and Maggi (2011a), and Pesic et al. (2007), the authors introduce a declarative process modeling language called DECLARE with formal semantics grounded in LTL (linear temporal logic) (Pnueli 1977). A DECLARE model is a set of DECLARE constraints defined as instantiations of DECLARE templates that are parameterized classes of rules.

The bulk of the declarative process mining approaches proposed in the recent years are based on DECLARE. In the following sections, we give an overview of these approaches grouping them into three categories, i.e., approaches for process discovery, conformance checking, and compliance monitoring. Some of these approaches have been implemented in the process mining toolset ProM (Maggi 2013).

Process Discovery

In the area of process discovery, Lamma et al. (2007a, b) and Chesani et al. (2009a) describe the usage of inductive logic programming techniques to mine models expressed as a SCIFF (Alberti et al. 2008) first-order logic theory. Bel-

lodi et al. (2010a, b) extend this technique by weighting in a second phase the constraints with a probabilistic estimation. In particular, the learned constraints are translated into Markov Logic formulae that allow for a probabilistic classification of the traces. Both the techniques in Lamma et al. (2007a) and Bellodi et al. (2010a) rely on the availability of positive and negative traces of execution.

Maggi et al. (2011b) first proposed an unsupervised algorithm for the discovery of declarative process models expressed using DECLARE. This approach was improved in Maggi et al. (2012a) using a two-phase approach. The first phase is based on an a priori algorithm used to identify frequent sets of correlated activities. A list of candidate constraints is built on the basis of the correlated activity sets. In the second phase, the constraints are checked by replaying the log on specific automata, each accepting only those traces that are compliant to one constraint. Those constraints satisfied by a percentage of traces higher than a user-defined threshold are discovered.

Other variants of the same approach are presented in Maggi et al. (2013a), Bernardi et al. (2014b), Maggi (2014), Kala et al. (2016), and Maggi et al. (2018). The technique presented in Maggi et al. (2013a) leverages a priori knowledge to guide the discovery task. In Bernardi et al. (2014b), the approach is adapted to be used in cross-organizational environments in which different organizations execute the same process in different variants. In Maggi (2014), the author extends the approach to discover metric temporal constraints, i.e., constraints taking into account the time distance between events. Finally, in Kala et al. (2016) and Maggi et al. (2018), the authors propose mechanisms to reduce the execution times of the original approach presented in Maggi et al. (2012a).

In Di Ciccio and Mecella (2012, 2013, 2015), the authors introduce MINERful, a two-step algorithm for the discovery of DECLARE constraints. The first step of the approach is the building of a knowledge base, with information about temporal statistics about the (co-)occurrence of tasks within the log. Then, the validity and the support

of constraints are computed by querying that knowledge base. The value assigned to support is calculated by counting the activations not leading to violations of constraints. In Di Ciccio et al. (2014, 2016), the authors propose an extension of MINERful to discover target-branched DECLARE constraints, i.e., constraints in which the target parameter is replaced by a disjunction of actual tasks.

Another approach for the discovery of DECLARE models is described in Schönig et al. (2016b). The presented technique is based on the translation of DECLARE templates into SQL queries on a relational database instance, where the event log has previously been stored. The query answer assigns the free variables with those tasks that lead to the satisfaction of the constraint in the event log. The methodology has later been extended toward multi-perspective DECLARE discovery (Schönig et al. 2016a), to include data in the formulation of constraints.

Beforehand, an approach for discovering data-aware constraints was proposed in Maggi et al. (2013c). Recently, approaches for taking into account activity life cycles in the discovery task have been proposed in Bernardi et al. (2014a, 2016).

Another approach for the discovery of DECLARE models was presented in vanden Broucke et al. (2014). Here, the authors present the Evolutionary Declare Miner that implements the discovery task using a genetic algorithm.

Approaches for the online discovery of DECLARE models have been presented in Maggi et al. (2013b) and Burattin et al. (2014, 2015). Here, the models are discovered from streams of events generated at runtime during the execution of a business process. The models are adapted on the fly as soon as the behavior of the underlying process changes.

An algorithm for the discovery DCR graphs has been proposed in Debois et al. (2017). In Ferilli (2014), the authors introduce the WoMan framework that includes a method for discovering first-order logic constraints from event logs. It guarantees incrementality in learning and adapting the models and the ability to express triggers and conditions on the process tasks.

Finally, we remark that studies have been conducted to remove inconsistencies and redundancies from discovered declarative models (Di Ciccio et al. 2015, 2017). The proposed solutions resort on the language inclusion and cross-product of the automata underlying the constraints. Approaches for ensuring the relevance of a set of DECLARE constraints discovered from an event log in terms of non-vacuity to the log have been presented in Maggi et al. (2016) and Di Ciccio et al. (2018).

D

Conformance Checking

In recent years, an increasing number of researchers are focusing on the conformance checking with respect to declarative models. For example, in Chesani et al. (2009b), an approach for compliance checking with respect to *reactive business rules* is proposed. Rules, expressed using DECLARE, are mapped to abductive logic programming, and Prolog is used to perform the validation. The approach has been extended in Montali et al. (2010), by mapping constraints to LTL and evaluating them using automata. The entire work has been contextualized into the service choreography scenario.

In Burattin et al. (2012), the authors report an approach that can be used to evaluate the conformance of a log with respect to a DECLARE model. In particular, their algorithms compute, for each trace, whether a DECLARE constraint is violated or fulfilled. Using these statistics the approach allows the user to evaluate the *healthiness* of the log. The approach is based on the conversion of DECLARE constraints into automata, and using so-called activation trees, it is able to identify violations and fulfillments.

The work described in de Leoni et al. (2012b, 2014) consists in converting a DECLARE model into an automaton and perform conformance checking of a log with respect to the generated automaton. The conformance checking approach is based on the concept of alignment, and as a result of the analysis each trace is converted into the most similar trace that the model accepts. Other approaches for trace alignment

with respect to LTL specifications have been presented in De Giacomo et al. (2016, 2017). Here, automated planning is used to improve the performance of the alignment task.

In Grando et al. (2012, 2013), the authors use DECLARE to model medical guidelines and to provide semantic (i.e., ontology-based) conformance checking measures. In a recent work, reported in Borrego and Barba (2014), the data perspective for conformance checking with DECLARE is expressed in terms of conditions on global variables disconnected from the specific DECLARE constraints expressing the control flow.

In Westergaard and Maggi (2012) and Maggi and Westergaard (2014), the authors propose an approach for checking DECLARE constraints augmented with temporal conditions. In Burattin et al. (2016), a conformance checking technique for multi-perspective declarative process models is presented. In particular, in this work, the authors first describe and formalize MP-DECLARE (i.e., a multi-perspective semantics of DECLARE augmented with data and time constraints). Then, they provide an algorithmic framework to efficiently check the conformance of MP-DECLARE with respect to event logs.

One of the most well-known tools for conformance checking with declarative specifications is the *LTL Checker* presented for the first time in van der Aalst et al. (2005). This tool allows the user to check the validity of a declarative specification expressed in terms of LTL rules in the traces of a log.

Compliance Monitoring

Several approaches have been presented for compliance monitoring of business processes with respect to a set of compliance rules. For example, MobiConLTL (Maggi et al. 2011a,c) is a compliance monitoring tool implemented as a provider of the operational support in ProM (Westergaard and Maggi 2011b; Maggi and Westergaard 2017; Maggi et al. 2012b). It takes as input a reference model expressed in the form of DECLARE rules. More generally, every business constraint

that can be expressed as an LTL formula can be monitored using MobiConLTL. At runtime, a stream of events can be sent by an external workflow management system to MobiConLTL through the operational support. The provider returns rich diagnostics about the status of each rule in the reference model with respect to the traces included in the stream. This approach has been extended in De Masellis et al. (2014) to monitor data-aware DECLARE constraints and in De Giacomo et al. (2014) to cover a larger set of rules expressed using LDL (De Giacomo and Vardi 2013).

MobiConEC is a compliance monitoring framework based on a reactive version (Bragaglia et al. 2012) of the event calculus (Kowalski and Sergot 1986). Being based on the event calculus, it can easily accommodate explicit (metric and qualitative) time constraints, as well as data-enriched events and corresponding data-aware conditions. In particular, it has been used to formalize and monitor DECLARE rules augmented with quantitative time constraints, and nonatomic activities and data-aware conditions (Montali et al. 2013a, b).

SeaFlows is a compliance checking framework that addresses design and runtime checking. It aims at encoding compliance states in an easily interpretable manner to provide advanced compliance diagnosis. The core concepts described in Ly (2013) and Ly et al. (2011) were implemented within the prototype named SeaFlows Toolset. With SeaFlows, compliance rules are modeled as *compliance rule graphs* (CRG).

The framework described in Santos et al. (2012) is based on the supervisory control theory. Through this approach, it is possible to supervise the execution of a process in a workflow management system by “blocking” those events that would lead to a violation of a given set of constraints. This can be considered as a very sophisticated form of proactive violation management, which is applicable only when the workflow system can be (at least partially) controlled by the monitor.

ECE rules (Bragaglia et al. 2011) are a domain-independent approach that was not specifically tailored for business process

monitoring. Two key features characterize ECE rules. First, they support an imperfect (i.e., fuzzy and probabilistic) matching between expected and occurred events and hence deal with several fine-grained degrees of compliance. Second, expected events can be decorated with countermeasures to be taken in case of a violation, hence providing first-class support for compensation mechanisms.

With BPPath (Sebahi 2012), Sebahi proposes an approach for querying execution traces based on XPath. BPPath implements a fragment of first-order hybrid logic and enables data-aware and resource-aware constraints.

An approach based on constraint programming is provided in Gomez-Lopez et al. (2013). The main goal of Gomez-Lopez et al. (2013) is to proactively detect compliance violations and to explain the root cause of the violation.

Giblin et al. (2006) presents an approach based on timed propositional temporal logic for transforming high-level regulatory constraints into REALM constraints that can be monitored during process runtime. The paper presents architectural considerations and an implementation of the transformation on the basis of a case study.

Hallé and Villemaire (2008) provides an approach based on LTL-FO⁺.LTL-FO⁺ is a linear temporal logic augmented with full first-order quantification over the data inside a trace of XML messages that focuses on monitoring data-aware constraints over business processes. The data is part of the messages that are exchanged between the process activities.

MONPOLY (Basin et al. 2008, 2011) is a runtime verification framework for security policies, specified in the logic MFOTL, a variant of LTL-FO with metric time. The high expressiveness of MFOTL allows one to express sophisticated compliance rules involving advanced temporal constraints, as well as data- and resource-related conditions.

In Narendra et al. (2008), the authors address the problem of continuous compliance monitoring, i.e., they evaluate the compliance of a process execution with respect to a set of policies at runtime. In particular, the policies are checked when some specific tasks are executed, which

are called control points. The authors define an optimization problem to find the right balance between the accuracy of the compliance checking and the number of control points (each control point has a verification cost).

Thullner et al. (2011) defines a framework for compliance monitoring able to detect violation and to suggest possible recovery actions after the violation has occurred. The framework is focused on the detection of different types of time constraints.

The work by Baresi et al. on Dynamo Baresi and Guinea (2005) constitutes one of the few techniques and tools dealing with monitoring (BPEL) web services against complex rules, going beyond the analysis of quantitative KPIs for service-level agreement. (Timed) Dynamo allows one to model ECA-like rules that mix information about the location (i.e., the target web services and operations), the involved data, and the temporal constraints. Dynamo provides continuous, reactive monitoring facilities based on the messages fetched so far, with sophisticated recovery and compensation mechanisms. Furthermore, the monitoring results can be aggregated and reported to the user, providing useful insights that go beyond a yes/no answer.

In Namiri and Stojanovic (2007), the authors describe an approach that is based on the patterns proposed by Dwyer et al. (1999). In particular, the authors introduce a set of control patterns. Control patterns are triggered by events (such as the execution of a controlled activity). When being triggered, conditions associated with the control are evaluated. In order to provide data for evaluating the associated conditions, the authors introduce a semantic mirror that is filled with runtime data of a process instance. For each control, actions to be carried out if a control fails may be specified.

Conclusion

In this chapter, we have presented the existing literature in the context of declarative process mining. From this analysis, we can derive that the works dealing with process discovery are mainly focused on DECLARE and, in general,

on a limited set of rule patterns. The works on conformance checking are based on larger languages covering the entire LTL or even richer languages like LDL. The approaches developed in the context of compliance monitoring are more variegated and are based on different declarative languages with different characteristics.

Decomposed Process Discovery and Conformance Checking

Josep Carmona

Universitat Politècnica de Catalunya, Barcelona, Spain

Definitions

Decomposed process discovery and *decomposed conformance checking* are the corresponding variants of the two monolithic fundamental problems in process mining (van der Aalst 2011): *automated process discovery*, which considers the problem of discovering a process model from an event log (Leemans 2009), and *conformance checking*, which addresses the problem of analyzing the adequacy of a process model with respect to observed behavior (Munoz-Gama 2009), respectively.

The term *decomposed* in the two definitions is mainly describing the way the two problems are tackled operationally, to face their computational complexity by splitting the initial problem into smaller problems, that can be solved individually and often more efficiently.

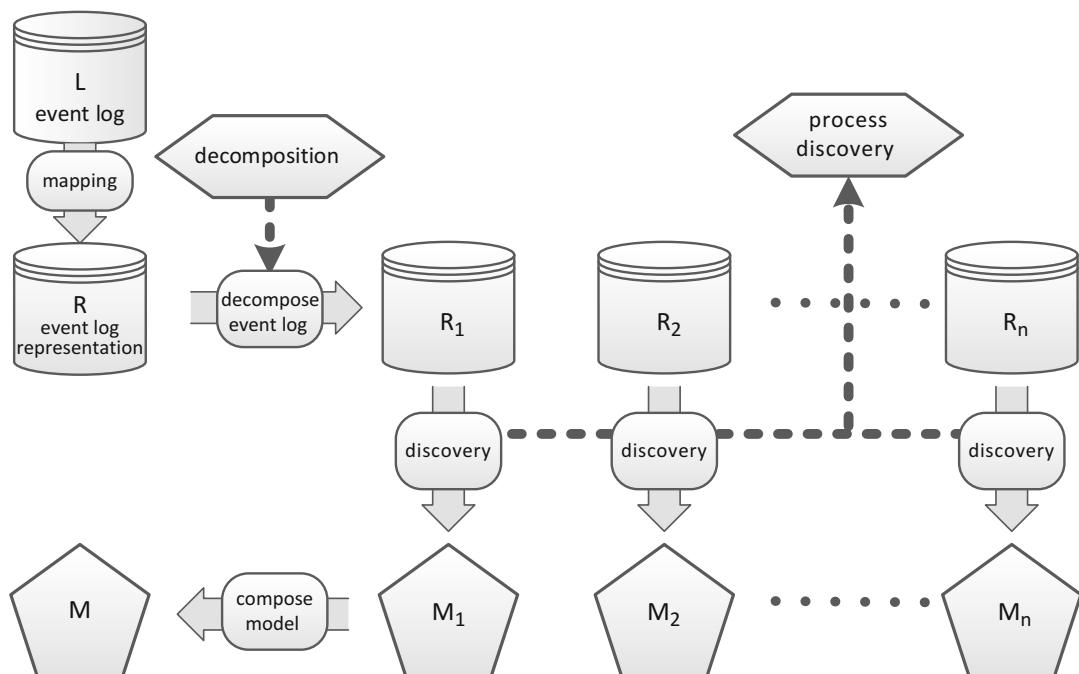

Overview

The input for process discovery is an *event log* (Mendling and Dumas 2009), from which a process model (typically a Petri net Murata 1989) needs to be produced. The input for conformance checking is an event log and a process model (again, typically a Petri net), from which a conformance artifact or a conformance diagnosis will be produced.

General View of Decomposed Process Discovery. The general view of decomposed process discovery is shown in Fig. 1. Initially, the log may be mapped to a different representation R , which is well suited to apply decomposition. Among the different alternatives, a common one is to do the decomposition on the log itself (so, $R = L$). An alternative is to derive a state-based representation, e.g., using the techniques from van der Aalst et al. (2010). Then, instead of directly deriving a process model from the representation of the event log (R), it is first partitioned, deriving

a set of representations R_1, \dots, R_n . In case the event log is used for decomposition, these will be *sublogs* L_1, \dots, L_n of L .

An important distinction should be done: the decomposition that is performed for decomposed process discovery and conformance checking is different from the decomposition that is done by *trace clustering* techniques. Trace clustering techniques partition the traces in the event log into multiple sets of traces, such that each trace in the original log can be found in one of the sublogs. In general, each sublog generated by trace clustering is a set of “similar” traces, and it corresponds to a “variant” of the process. For the purpose of decomposed process discovery, the decomposition does not consider dividing the traces in the log into multiple sets, but instead by splitting each trace into a set of *subtraces*. In other words, one trace is cut into multiple ones, denoted subtraces. After each trace has been split in this way, each set of subtraces is put together into one sublog. Intuitively, the idea is that each sublog produced in this way corresponds to a

Decomposed Process Discovery and Conformance Checking, Fig. 1 General view of decomposed process discovery. (Figure adapted from van der Aalst 2013)

stage or subprocess (or more generally a “fragment”) of the original process.

The available techniques to do the partition are enumerated below. Then, from each representation R_i , a process model M_i is obtained through the application of an automated process discovery technique. The output of decomposed process discovery can be the set of process models or fragments derived, or if some composition mechanism is disposable, a unique final model M that encompasses the unified behavior of the n derived process models.

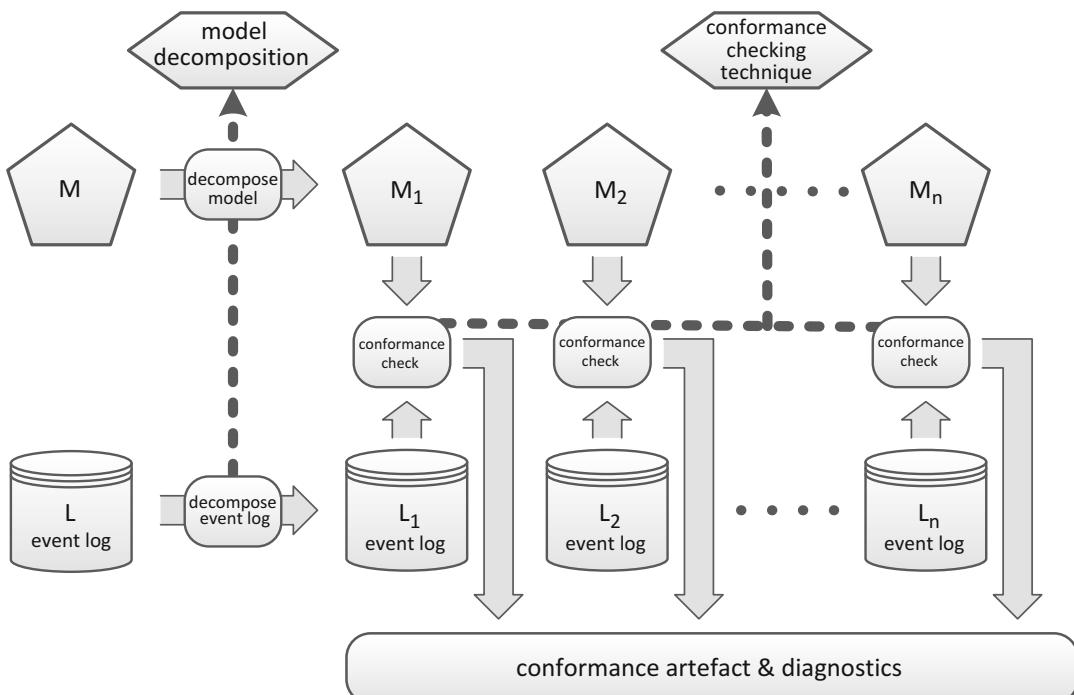

General View of Decomposed Conformance Checking

Checking. The general view of decomposed conformance checking is shown in Fig. 2. Although both process model and event log are decomposed, the process model decomposition is applied first, and then the event log decomposition is performed so that process model fragments and corresponding sublogs match on their alphabet of activities. Then, conformance checking techniques can be applied locally on

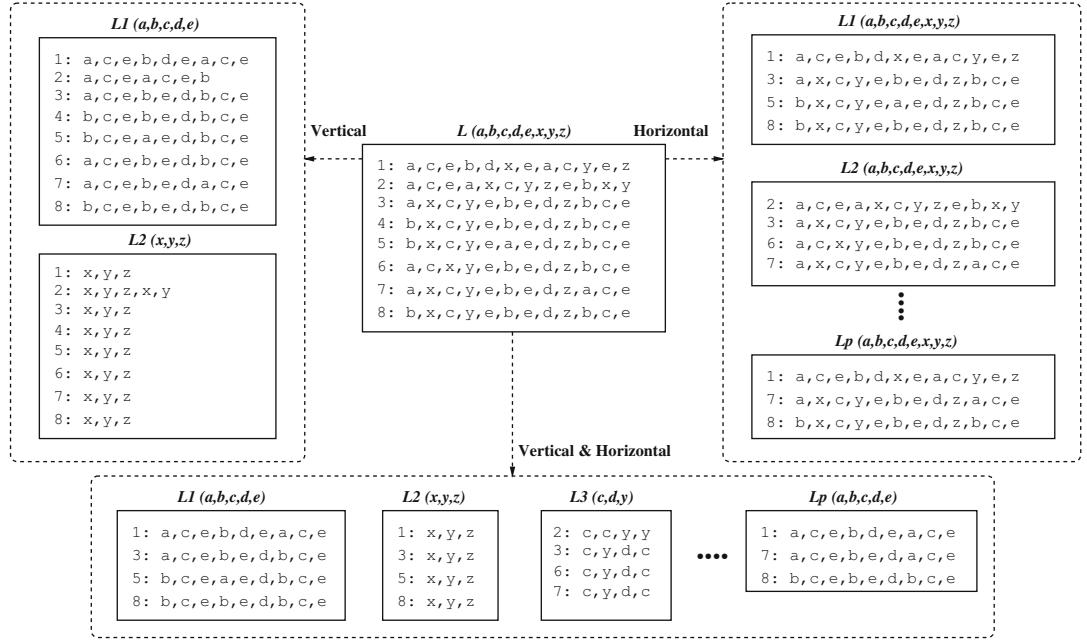

each pair of sublog and fragment generated. As conformance checking strongly relies on relating modeled and observed behavior (Muñoz-Gama 2009), the obtention of a conformance artifact like an *alignment* (Adriansyah 2014) between a sublog L_i and a fragment M_i can be materialized. Likewise, conformance diagnosis can already be obtained on these local problems.

The decompositions mentioned above can then be applied at different levels: *log decomposition* and *process model decomposition* (van der Aalst 2013). Below a general perspective on the two types of decomposition techniques is provided.

Log Decomposition. When the event log is not transformed to a different representation, decomposition can then be applied on top of the event log. Event logs can be either split horizontally, or projected vertically, or both. Figure 3 provides an example of such operations. The horizontal selection of traces can be done in many ways, but *trace clustering* (Greco et al. 2006; Ferreira

Decomposed Process Discovery and Conformance Checking, Fig. 2 General view of decomposed conformance checking. (Figure adapted from van der Aalst 2013)

Decomposed Process Discovery and Conformance Checking, Fig. 3 Log decomposition by either horizontal or vertical selections or a combination thereof

et al. 2007; Bose and van der Aalst 2009 b, c; Weerdt et al. 2013; Hompes et al. 2015) is usually applied. Notice that in the figure, sublogs arising from clusters can overlap, e.g., trace 3 belongs both to $L1$ and $L2$ in the horizontal selection of traces from L . Clearly, by decomposing a log into smaller sublogs, a linear factor on the complexity reduction can be accomplished.

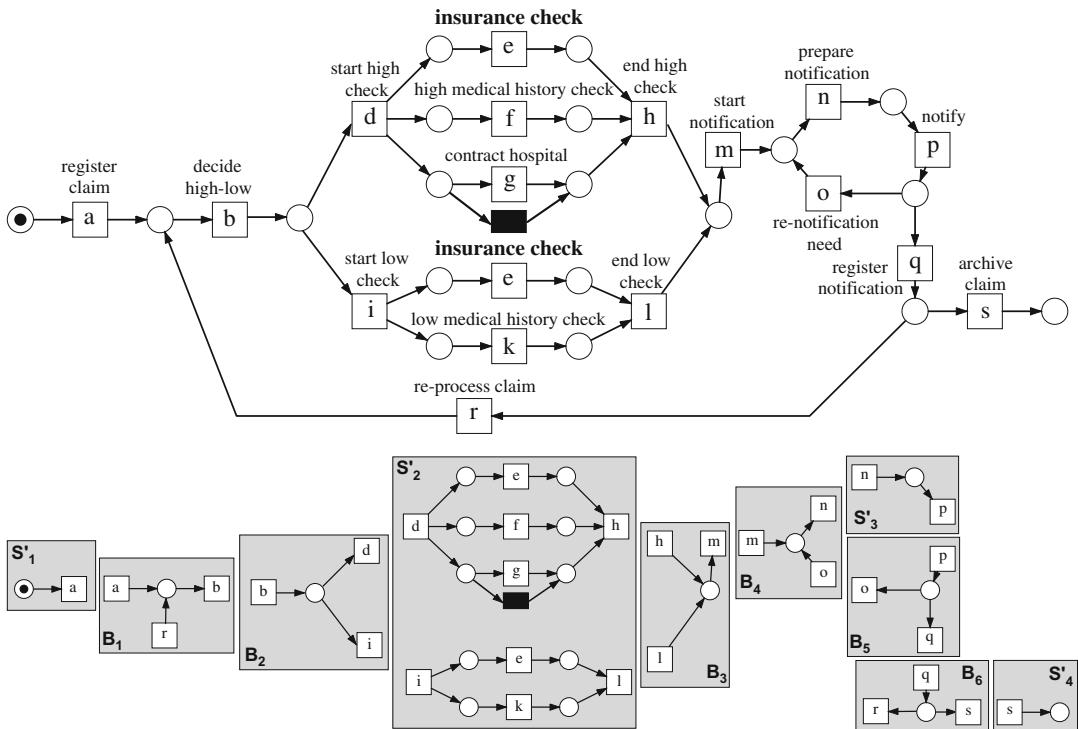

The vertical projection of log traces starts by selecting a proper subset \mathcal{A}' of the log's event alphabet \mathcal{A} . It then projects each trace σ in the log onto activities in \mathcal{A}' , i.e., removing from σ those events in $\mathcal{A} - \mathcal{A}'$, resulting in the trace $\sigma|_{\mathcal{A}'}$. The vertical projection can derive subsets $\mathcal{A}_1, \dots, \mathcal{A}_n$ with $\mathcal{A}_i \subset \mathcal{A}$, deriving the sublogs $L|_{\mathcal{A}_1}, \dots, L|_{\mathcal{A}_n}$. How to select those sets is the crucial decision; there are techniques based on the *directly-follows* relation from the α -algorithm (Carmona 2012) or hierarchical methods that learn patterns which become new labels in the alphabet (Bose and van der Aalst 2009a), among others. The vertical projection has in general a bigger impact in the complexity alleviation than the horizontal split, since the complexity of most of the techniques for discovery or confor-

mance checking is dominated by the size of the alphabet.

In case the log has been transformed into a different representation R , then other forms of decomposition are applicable. For instance, if the log is transformed into a *transition system* (Arnold 1994) which encompasses the behavior underlying in L , then decomposition techniques like the ones presented in de San Pedro and Cortadella (2016) can be applied.

Process Model Decomposition. Process model decomposition only makes sense for conformance checking, where apart from the event log, the process model is also an input. The intuitive idea is to break the process model into fragments and project vertically the log accordingly (see Fig. 2). This way, the problem instances tackled in decomposed conformance checking are significantly smaller than in the monolithic version.

Not every decomposition can be used in the scope of conformance checking: a *valid decomposition* (van der Aalst 2013) of a Petri net into fragments requires that the places and arcs

Decomposed Process Discovery and Conformance Checking, Fig. 4 Process model decomposition based on single-entry single-exit (SESE) components (Munoz-Gama et al. 2014)

of the net are partitioned among the fragments, meaning that the decomposition uniquely assigns each place to a single fragment. Transitions in the frontiers of the cuts deriving the fragments are replicated, while transitions inside one fragment cannot, i.e., transitions inside a fragment cannot occur in other fragments. Figure 4 shows an example of a valid decomposition of a process model. Examples of decompositions are the ones based on *passages* (van der Aalst 2012) or based on *single-entry single-exit* (SESE) (Munoz-Gama et al. 2014).

Key Research Findings

In general, the use of decomposition tends to make automated process discovery and conformance checking problems more tractable. However, current decomposition techniques cannot guarantee optimality in general or even to provide

the same outputs as the ones provided in the monolithic versions of the problems.

Key Research Findings in Decomposed Process Discovery.

Techniques for decomposed process discovery have appeared in different forms in the last years (Solé and Carmona 2012; Carmona 2012; van der Aalst 2013; van der Aalst and Verbeek 2014; van der Aalst et al. 2015; de San Pedro and Cortadella 2016). These approaches not only focus on alleviating the computation of the process discovery task but also consider other goals. For instance, a discovery approach based on van der Aalst (2013) was used in the framework that recently won the *Process Discovery Contest* (Carmona et al. 2016). Decomposition-based process discovery can also be applied to derive a different modeling notation, like it is presented in Solé and Carmona (2012) for *C-nets* (van der Aalst et al. 2011). It can also focus on deriving particular Petri net

subclasses, like *free choice*, *state machines*, or *marked graphs* (Carmona 2012; de San Pedro and Cortadella 2016).

Key Research Findings in Decomposed Conformance Checking. Techniques for decomposed conformance checking have been proposed in the last years (van der Aalst 2013; van der Aalst and Verbeek 2014; Munoz-Gama et al. 2014; vanden Broucke et al. 2014; de Leoni et al. 2014; Verbeek 2017). Apart from the aforementioned techniques for decomposing a process model through a valid decomposition (van der Aalst 2013; van der Aalst and Verbeek 2014; Munoz-Gama et al. 2014), other approaches that have a different focus have been presented. In vanden Broucke et al. (2014), the SESE-based decomposition approach is adapted to boost the computation so that it can be applied online. On a different perspective but again using SESE-based decomposition, the approach in de Leoni et al. (2014) shows how data can also be taken into account.

Fitness, i.e., the capability of a model in reproducing a trace, strongly influences the idea of valid decomposition: on a valid decomposition, the fitness of the whole model with respect to the trace can be regarded as the fitness of the individual fragments (see Fig. 2). Therefore, if none of the fragments has a fitness problem, then the initial model is fitting (van der Aalst 2013). The opposite is not true in general: a valid decomposition where some fragment contains a fitness problem does not necessarily imply that there exists a real fitness problem. Also, by separating the initial problem into pieces, important conformance artifact like *optimal alignments*, i.e., alignments between model and log which contain the minimal number of deviations, cannot be guaranteed. There has been recent work investigating the two aforementioned issues (Verbeek and van der Aalst 2016).

Examples of Application

All areas where process mining techniques have been applied are amenable for the application

of decomposed process discovery and conformance checking. It is suitable for large problem instances, e.g., in healthcare (Mans et al. 2015), software repositories, and finances, among many others.

D

Future Directions for Research

There exist several challenges to face, so that decomposed techniques can be applied in more situations. Below we provide some key challenges that may be faced in the next years:

- *Decomposition in the large*: the techniques available so far do not always guarantee a bound in the complexity of the operations performed. Fundamental research needs to be developed so that lightweight approaches are proposed that guarantee this bound, opening the door to real-time or online approaches.
- *Recomposing the results*: both in Figs. 1 and 2, one can see that the result of the decomposition may not always be a unique object, but several. To deploy a unique final result from these may be a challenge. For instance, in the case of decomposed conformance checking, to compute an alignment, it is well known that there are situations where only a best effort is possible (Verbeek and van der Aalst 2016). Therefore, research on how to recompose the results will be needed.
- *Decomposition beyond Petri nets*: most of the techniques available for decomposition rely strongly on the Petri net semantics. However, other modeling notations are also used, and in particular the industry adoption of Petri nets is low. Therefore, other notations like BPMN will be considered as input for decomposition techniques.
- *Decomposition beyond control flow*: very few approaches have been presented that consider not only the control flow of the process, but also other data attributes (de Leoni et al. 2014). However, the aforementioned techniques decompose only on the basis

of the control flow. Techniques that apply decomposition on different perspectives will enable a different perspective for decomposition.

- *Alternative theories for decomposed conformance checking:* currently, only the notion of valid decomposition has been explored as a viable strategy to decompose a process model. In the future, totally different alternatives to a valid decomposition may be studied.

Definitions

Deep Learning is a family of machine learning methods based on the composition of multiple (simple) processing layers, in order to learn complex (nonlinear) functions, which can be used to cope with many challenging application scenarios (e.g., *Computer Vision, Natural Language Processing, Speech Recognition and Genomics* (Le Cun et al. 2015)).

Overview

In the last few years, advances in digital sensors, computation, communications, and storage technologies and the large diffusion of IoT devices facilitated the production of huge collections of heterogeneous data, which are also susceptible to rapid changes over time. The term *Big Data* is used to define this kind of phenomenon (Wu et al. 2014).

Deep learning (DL) includes a wide range of machine learning techniques that aims at training artificial neural networks (ANNs) composed of a large number of hidden layers. These methods have been effectively used to tackle different types of problems (e.g., *Computer Vision, Natural Language Processing, Speech Recognition, and Recommender Systems*) and allow to handle large amounts of data in an efficient way. Specifically, a deep neural network (DNN) works in a hierarchical way; indeed, each subsequent layer of the architecture generates a set of features with a higher level of abstraction compared with

the previous one. Therefore, it is possible to extract informative and discriminative features even from raw data (e.g., pixels of images, biological sequences, or user preference data). This capability is one of the most important and disruptive advances introduced by the deep learning paradigm; indeed, usually no feature engineering phase and domain experts are required to select a good set of features.

Different from traditional algorithms, based on shallow hierarchies that fail to explore and learn highly complex patterns, Deep Learning-based techniques allow to intrinsically exploit the large amounts of data featuring big data (*Volume*). Moreover, as Deep Learning-based approaches allow to extract data abstractions and representations at different levels, they are also suitable to analyze raw data provided in different formats and by different types of source (*Variety*). Finally, deep architectures can be used within infrastructures for big data storage and analysis (e.g., *Hadoop* and *Spark*) and can exploit GPUs to parallelize the computation and to reduce the learning times. Hadoop, in particular, is widely used in industry for the development of big data applications such as *spam filter*, *click stream analysis*, *social recommendation*, etc. That allows to handle the speed at which new data are being produced in these big data scenarios (*Velocity*).

Deep learning can be used to tackle different types of learning task. The most common machine learning task for DNNs is *supervised learning*. In this case, DNNs allow to learn discriminative patterns for classification purposes, when labeled data are available in direct or indirect forms. The most known DNN architectures for supervised learning are *Convolutional Neural Networks* and *Recurrent Neural Networks*. Deep neural networks for unsupervised or generative learning are used when no information about class labels is available and allow to extract high-order correlation from data for pattern analysis or summarization purposes. Several architectures have been developed to address these learning tasks; in particular *Autoencoders*, (*Deep-/Restricted*) *Boltzmann Machine*, and *Deep Belief Network* are largely recognized as effective tech-

niques. Finally, semi-supervised learning permits to handle the case where only a small subset of the training data is labeled (e.g., they use unlabeled data to define the cluster boundaries and use a small amount of labeled data to label the clusters). To this aim, *Reinforcement learning* can be used to train the weights so that, given the state of the current environment, DNNs can find which action the agent should take next, in order to maximize expected rewards.

In this chapter, first we introduce some basic concepts required to understand how DNNs work. Then, we focus on the most diffused supervised and unsupervised architectures exploited in literature for handling big data. Finally, we discuss some interesting open issues and future research directions.

Deep Neural Networks

ANNs are computational models that try to replicate the neural structure of the brain. In a nutshell, the brain learns and stores information as patterns. These patterns can be highly complex and allow us to perform many tasks, such as recognizing individual from the image of their faces also considering different angles of view. This process of storing information as patterns, applying those patterns and making inferences, represents the approach behind ANNs.

The artificial neuron is the main building block of a neural network and encompasses some interesting capabilities. Its behavior can be thought as composed of two steps. First, the linear combination of the inputs is computed (a weight, usually limited in the range 0–1, is associated with each value of the input vector). Note that the summation function often takes an extra input value b having a weight of 1, which represents the threshold or the bias of a neuron.

The sum-of-product value is provided as input for the second step. Here, the *activation function* is executed to compute the final output the neuron. The activation function limits the output in the range [0, 1] or alternately [-1, 1].

An artificial neural network is essentially a combination of neurons stacked in layers.

The most simple structure for an ANN includes two levels: the neurons placed in the first

layer allow to handle the inputs by distributing them to the next layer, while only the second layer performs a computation. Each of the inputs $x_1, x_2, x_3, \dots, x_N$ are connected to every artificial neuron in the output layer through the connection weight. Since every value of outputs $y_1, y_2, y_3, \dots, y_N$ is calculated from the same set of input values, each output is varied based on the connection weights.

The above-described architecture is quite simple and does not provide high-level computational capabilities. However, this structure can be easily enriched by stacking further computation layers in the network. In this case, the input nodes transfer the data to the processing elements in the first hidden layer, and then the outputs from the first hidden layer are forwarded to the next one and so on. This iterative process is called *forward propagation*, and this type of architecture is an example of *feedforward neural network*, since the connectivity graph does not have any directed loops or cycles. Moreover, if each neuron of a layer is connected with each neuron of the next layer, the neural network is called *fully-connected*.

DNNs exacerbate this scheme by exploiting hundreds of levels in order to learn complex functions, obtained by combining nonlinear operations. The depth of the DNN is the number of levels/layers contained in the architecture.

A DNN can be fully specified by four basic components:

- The *topology of the network*, i.e., the number of layers and the connections among the neurons;
- The learning algorithm (variants of the *gradient descent*);
- The *activation functions* to use within the nodes;
- The *loss function* to minimize.

This chapter introduced the basic concepts that characterize DNNs and their main principles; for the interested reader, more details are supplied in the following reference paper (Le Cun et al. 2015).

Key Research Findings

As mentioned in the introduction, DL gathers a wide range of machine learning methods and techniques, including several layers of nonlinear processing, stacked into a hierarchical scheme. On the basis of their learning goals (e.g., detection/prediction or synthesis/generation), the architectures and the techniques proposed in this area can be broadly classified into architectures for supervised or unsupervised tasks.

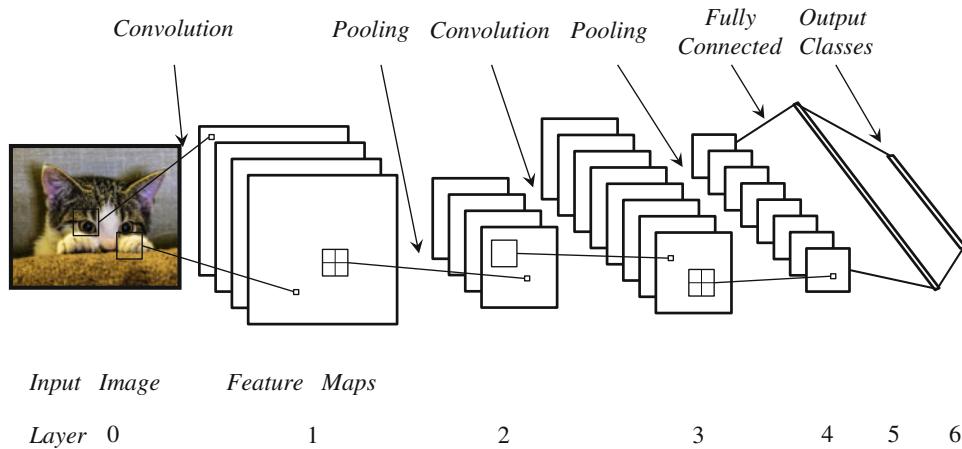

In unsupervised learning, task-specific supervision information (e.g., target class labels) is not used in the learning process. Many DNN architectures belonging to this category have been used for feature extraction and for cleaning data; typical examples are RBMs, DBNs, DBMs, and generalized denoising autoencoders. In supervised environments, the concept to discover is available and provided as target in the learning phase. Typical supervised architectures are CNNs, RNNs, and LSTMs.

On the following, the most common architectures for supervised and unsupervised learning are detailed, with a particular attention to the analysis of big data.

Convolutional Neural Networks

In big data context, CNNs are typically used to tackle *Face Detection* and *Image Recognition* tasks. Several architectures have been proposed to cope with the massive amount of data produced by different types of big data providers (e.g., *Security Cameras and Video Surveillance Systems*, *Autonomous cars*, etc.). Specifically, the deep architectures proposed in Szegedy et al. (2015) allow to analyze massive datasets of images by exploiting the potentialities of deep CNNs.

A convolutional neural network is composed of a stacking of *convolutional layers*. Each layer produces a higher-level abstraction of the input data, called a *feature map* (fmap), which stores essential information about the data. Usually, CNN architectures assume to work with two-dimensional data (e.g., images), and this makes the forward function more efficient to implement and permits to largely reduce the amount of parameters in the network. A basic CNN

Deep Learning on Big Data, Fig. 1 Example of a CNN architecture

architecture can be designed as a sequence of layers, where each layer transforms one volume of activations to another, by using a differentiable function. In literature, three main types of layer are used to learn CNNs: *Convolutional Layer*, *Pooling Layer*, and *Fully-Connected Layer*. In Fig. 1, a simple CNN architecture that combines these layers is shown.

On the one hand, convolutional layers allow to discover local conjunctions of features from the previous layer; on the other hand pooling layers combine semantically similar features in a single feature. It is common to insert a pooling layer in-between successive convolutional layers. In fact, it permits to reduce the dimension of the representation and the amount of parameters in the network and consequently control also the overfitting.

Recurrent Neural Networks and Long Short Time Memory Networks

Many typical DNN architectures have no memory, and the output for a given input is always the same independently from the sequence of inputs previously given to the network. On the contrary RNNs, of which LSTMs are a well-known variant, keep an internal memory to make long-term dependencies influence the output.

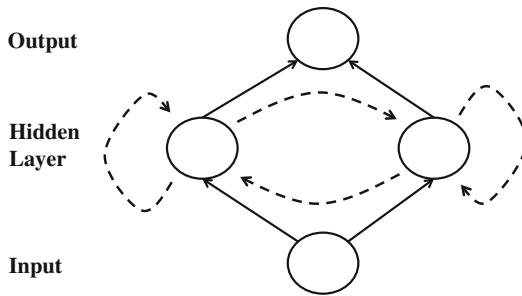

In a nutshell, in these networks, some intermediate operations generate values that are stored internally and used as inputs for other operations.

RNNs receive as input two values, representing the current state and the recent past of the input, which are combined to determine how they respond to new data.

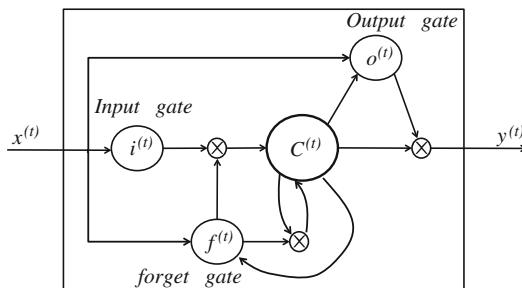

These networks assume that the sequence of the input states is an important information; therefore, the added memory allows to carry out tasks that feedforward networks cannot perform. In particular, this sequential information is kept in the hidden state of the RNNs. Basically, RNNs can be defined as feedforward neural networks featured by edges that join subsequent time steps, including the concept of time within the model. Specifically, like feedforward neural networks, these learning architectures do not exhibit cycles among the standard edges; however, those that connect adjacent time steps (named *recurrent edges*) can have cycles, including self-connections.

At time t , the nodes having recurrent edges receive the input value $x^{(t)}$ from the current data point and also the value $h^{(t-1)}$ from the hidden node, which keeps the previous state of the network. The output $\tilde{y}^{(t)}$ at each time t is computed by exploiting as input the hidden node values $h^{(t)}$ at time t . Input $x^{(t-1)}$ at time $t - 1$ can influence $\tilde{y}^{(t)}$ at time t and later by means of the recurrent connections. Figure 2 shows the above-described scheme.

LSTM improves RNN by introducing the concept of memory cell, a computation unit that

Deep Learning on Big Data, Fig. 2 Simple RNN architecture

Deep Learning on Big Data, Fig. 3 Memory cell structure

replaces traditional nodes in the hidden layer of a network. By using these cells, these networks are able to overcome issues related to the training of the RNN. Specifically, a LSTM can be thought as an evolution of a standard RNN with a hidden layer, but each standard neuron in the hidden layer is replaced by a memory cell, shown in Fig. 3. Each memory cell contains a node with a self-connected recurrent edge of fixed weight equal to one, ensuring that the gradient can pass across many time steps without vanishing.

The term *long short-term memory* is due to the following idea. RNNs keep long-term memory as weights, which can change slowly during the learning phase and encodes information about the data. LSTM introduces an intermediate storage step by means of memory cells in order to overcome this problem. Memory cells are computation units composed of standard nodes connected according to a specific pattern, where the main novelty element is the presence of multiplicative nodes (labeled in Fig. 3 with the symbol \times). *Gates* are the main components of a LSTM ar-

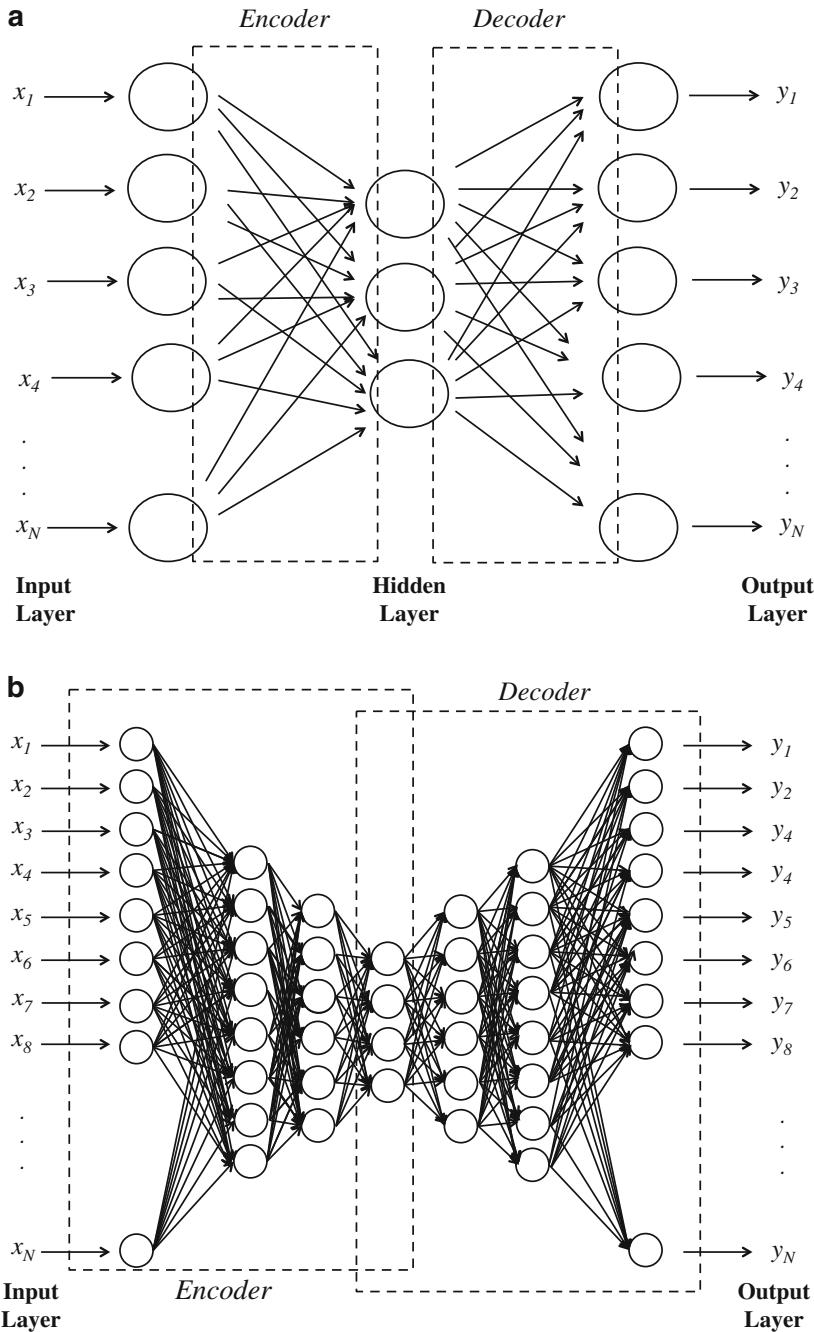

chitecture. They are sigmoidal units that are activated by the current data point $x^{(t)}$ and by the hidden layer at the previous time step. The main component of the memory cell is the node labeled as $C^{(t)}$ that contains a linear activation function. It has a self-connected recurrent edge having a fixed unitary weight.

Recurrent neural networks have been widely used in many different big data scenarios (e.g., *image/video captioning*, *word prediction*, *translation*, *image processing*). The most common application is within the framework of natural language processing (NLP). Recently applications such as handwriting recognition (Graves et al. 2007), language translation (Sutskever et al. 2014), and image and video annotation (Byeon et al. 2015) take advantage of RNNs to incorporate temporal information and to improve the quality of prediction.

Autoencoders

In literature, different types of generative deep architectures have been proposed, but energy-based models and deep autoencoders are the most widely used (Bengio 2009). Autoencoder, named also autoassociator, is a particular (feedforward) NN architecture, whereby the target of the network is the data itself. It is mainly used for *dimensionality reduction* or for *learning efficient encoding*. Specifically, *Machine Translation*, *Word Embeddings and Phrase Representation*, *Document Clustering*, and *Sentiment Analysis* are some challenging (big data) environments where deep architectures have been successfully used (Chandar et al. 2014; Lebret and Collobert 2015; Hinton and Salakhutdinov 2006; Glorot et al. 2011).

Basically, an autoencoder can be thought as an unsupervised feature extraction method. Its network topology is similar to a multilayer ANN. The most simple architecture (shown in Fig. 4a) includes three components: (i) an input layer of raw data to be encoded (e.g., images or audio signals); (ii) a (stack of) hidden layer(s), characterized by a considerable smaller number of neurons; and (iii) an output layer having the same size (i.e., the same number of neurons) of the input layer. An autoencoder is called deep, if the

Deep Learning on Big Data, Fig. 4 Autoencoder architecture. (a) Simple autoencoder. (b) Deep autoencoder

number of its hidden layers is greater than one (Fig. 4b).

Specifically, an autoencoder can be conceptually thought as composed of two subnets, respectively, named *encoder* and *decoder*. The

former allows to learn a mapping between the input layer and the hidden layers (*encoding*) and the second a mapping between the features extracted by the encoder and the output layer (*decoding*). The encoder receives as

input a set of features and extracts a smaller set of new (high-level) features (by using the sigmoid as activation function for each neuron). Hence, the decoder converts these features back to the original input attributes. An interesting variant of this architecture is called (*Stacked*) *Denoising Autoencoder*, which shares some properties with restricted Boltzmann machines and can be used for generative purposes (Vincent et al. 2008). In a nutshell, it tries to minimize the reconstructing error due to applied stochastic noise to the input. In this way, it can be used as a pre-training strategy for learning DNNs.

Boltzmann Machines (BMs)

An alternative approach to autoencoders assumes that the observed data are the result of a stochastic process, which can be interpreted in neural network terms. Deep Boltzmann machine is a very popular deep architecture with generative capability. Basically, it is a parametrized generative model representing a probability distribution modeled by means of a neural network with two (or more) layers. First layer is used to handle the input (i.e., the component of observations x). Hidden units allow to model dependencies between the components of the observations.

These architectures are designed with several stacked layers of hidden variables, and no connection is established among the neurons belonging to the same layer. In practice, it is a particular form of *Boltzmann Machine* (see Fig. 5a), an ANN whose structure is featured by symmetric and bidirectional edges connecting neurons belonging to the same layer. A DBM with a single hidden layer is called *Restricted Boltzmann Machine* (RBM) (see Fig. 5b). It is represented as a bipartite graph, where all the visible neurons are connected to all the hidden ones, and there are no connections among the neurons belonging to the same layer.

DBMs have the potential of learning internal representations that become increasingly complex, and they are able to solve object and speech recognition problems. Moreover, DBMs are often extended with an output layer: the weights

learned can be used as initial weights for the supervised training of the resulting ANN.

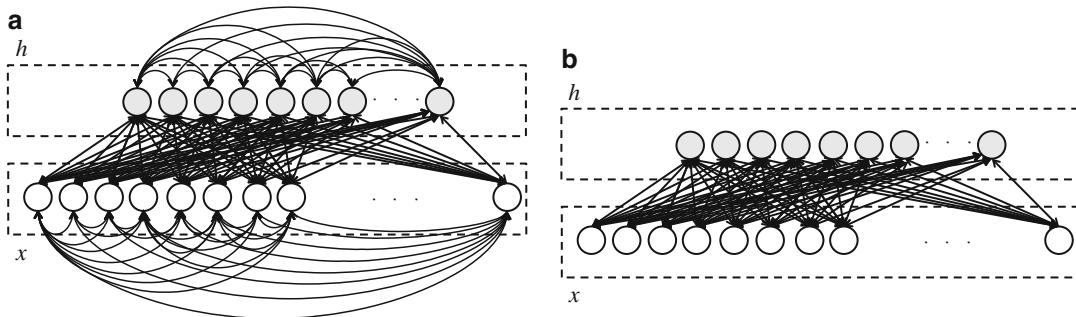

Deep Boltzmann Machines (DBMs) are widely used to analyze large volume of data in different contexts as *Handwritten Digits Recognition*, *Collaborative Filtering* (Salakhutdinov et al. 2007), *Phone Recognition* (Dahl et al. 2010), *Transportation Network Congestion Monitoring and Prediction* (Ma et al. 2015) and *Facial Landmark Tracking* (Wu et al. 2013).

D

Examples of Application

Deep learning can provide layered and hierarchical architectures for representing and learning complex data. Moreover, deep learning can be applied to both labeled/supervised and unlabeled/unsupervised tasks concerning big data (Najafabadi et al. 2015). These features make it a valuable method for analyzing big data and extracting salient patterns from complex and massive data. In the last few years, a number of applications concerning deep learning for big data have been developed; in the following, we cite some of the most significant ones, which includes semantic indexing, data tagging, remote sensing, and fault detection.

Semantic Indexing: Information retrieval is one of the most important tasks when working with big data. Every day, high volumes of data are generated from different sources such as social networks, web pages, and marketing systems. The information retrieval systems need to manage these data. Semantic indexing is a preferable method to present the data rather than store it in a raw format. Semantic indexing provides a data representation, which is more appropriate for faster search and knowledge extraction. The data representations generated by deep learning are more abstract and high level in comparison with other traditional techniques. Examples of these applications include different data types such as text (Huang et al. 2013), image (Zhang et al. 2013), and video data. For example, Shen et al. (2014) suggested a series of new latent semantic models based on convolutional neural networks

Deep Learning on Big Data, Fig. 5 Boltzmann machine architectures. (a) Boltzmann machine. (b) Restricted Boltzmann machine

to extract low-dimensional semantic vectors for search engine queries of web documents.

Discriminative Tasks: Deep learning can be used for discriminative tasks. It extracts nonlinear features from data; subsequently, linear models can be used to find a discriminative function. This property is really useful for applications such as object recognition and image comprehension in big data. For example, in Jia et al. (2016), the authors used different types of deep neural networks for image recognition problems such as gender recognition and face recognition.

Transfer Learning and Domain Adaptation:

In machine learning, transfer learning or inductive transfer is defined as a process, which utilizes the knowledge obtained during solving (learning) one problem, and applied to another different but related problem (Torrey and Shavlik 2009). The properties of big data provide a good opportunity to apply transfer learning and domain adaptation. Deep learning is a good tool to identify similar factors for different data-driven forms and for different problem domains (Bengio 2012). In Shin et al. (2016), the authors evaluated transfer learning by using convolutional neural networks trained over ImageNet on two different diagnosis applications: thoracoabdominal lymph node detection and interstitial lung disease classification.

Anomaly and Fraud Detection: Detecting anomalies and frauds is a challenging problem, especially in the case of big data. In applications such as electronic payments, network flows, and

social networks, frauds and anomalies should be detected coping with a large amount of data. Deep learning can be considered as an appropriate machine learning tool to detect anomalies and frauds, especially in the case of high dimensionality. For example, the authors of Paula et al. (2016) proposed an unsupervised deep learning method to detect frauds in exports. Moreover, Erfani et al. (2016) suggested using deep belief networks to extract robust features from high-dimensional data and then using support vector machine (SVM) to build a one-class model to detect anomalies.

Traffic Flow Prediction: Predicting the traffic flow in accurate and timely fashion is very important for intelligent transportation systems, and deep learning is appropriate to this task. As an example in Lv et al. (2015), the authors used a stacked autoencoder to learn traffic flow features and trained it with a greedy layer-wise method.

The applications of deep learning in big data are not limited to these topics; just to cite a few examples, remote sensing (Kussul et al. 2017) and fault detection (Ren et al. 2017) are two interesting fields in which these techniques were successfully applied for big data problems.

Future Directions for Research

Big data and deep learning are strictly connected as interesting research themes. Indeed, big data issues can benefit from the application of Deep Learning, and in addition, some hard problems

and applications can be solved by deep learning techniques by using big data developments and tools.

Some of the most relevant issues to be addressed by using deep learning techniques exploiting the potentialities of big data techniques include:

- **Large scale Deep Learning:** using parallel and distributed infrastructures permits to train in acceptable times really large deep networks or to train in near real-time deep networks. However, many issues must be addressed to make the process efficient, such as the model of parallelism, the efficient partitioning of the networks and of the layers, reducing the overhead of the messages, etc.
- **Real time data streaming:** only the usage of big data resources can address problematics as data changes and streaming in real-time; in addition, issues as the integration of multiple data streams, often coming from heterogeneous IoT objects, the need of adapting the layers or the parameters of the networks to frequent changes in data makes it necessary the adoption of big data solutions.
- **Heuristics to automatically generate or customize deep networks:** tuning the structure and the parameters of deep neural networks requires extensive and expensive training phases; big data technologies, by employing distributed heuristic and meta-heuristic algorithms for supporting this phase can strongly speedup this process.

On the other side, deep learning networks can be really helpful to cope with many modern big data problems and applications. We would like to mention, among the others, the following applications: natural language processing, human vision, video tagging, hybrid deep learning, self-driving cars, and cybersecurity problems.

Finally, an open field of research concerns the integration of different deep learning strategies, such as convolutional neural networks, deep belief network and Boltzmann machines, which can be efficiently used to cope with unstructured data

and to deal with the entire automatic process of analyzing these data, from the analysis and the extraction of information from audio and video files to the recognition of objects and faces and to the transcription of audio tracks and up to recognize real-time fake news.

Definitions

A data stream is a countably infinite sequence of elements. Different models of data streams exist that take different approaches with respect to the mutability of the stream and to the structure of stream elements. Stream processing refers to analyzing data streams on-the-fly to produce new results as new input data becomes available. Time is a central concept in stream processing: in almost all models of streams, each stream ele-

ment is associated with one or more timestamps from a given time domain that might indicate, for instance, when the element was generated, the validity of its content, or when it became available for processing.

Overview

A data stream is a countably infinite sequence of elements and is used to represent data elements that are made available over time. Examples are readings from sensors in an environmental monitoring application, stock quotes in financial applications, or network data in computer monitoring applications.

A stream-based application analyzes elements from streams as they become available to timely produce new results and enable fast reactions if needed (Babcock et al. 2002; Cugola and Margara 2012).

In the last decade, several technologies have emerged to address the processing of high-volume, real-time data without requiring custom code (Stonebraker et al. 2005). They are commonly referred to as stream processing systems, and they are the topic of this section on “Big Stream Processing.”

In the remainder of this entry, we overview the main models of data streams and stream processing systems, and we briefly introduce some central concepts in stream processing, namely, time and windows. Furthermore, we summarize the main requirements of stream processing.

Stream Models

Streams can be structured or unstructured. In a structured stream, elements follow a certain format or schema that allows for additional modeling of the stream. In contrast, unstructured streams can have arbitrary contents often resulting from combining streams from many sources (these are also referred to as event showers or event clouds Doblander et al. 2014).

There are three major models for structured streams, which differentiate in how the elements of the stream are related to and influence each other: the turnstile model, the cash register

model, and the time series model. The most general model is the *turnstile model*. In this model, the stream is modeled as a vector of elements, and each element s_i in the stream is an update (increment or decrement) to an element of the underlying vector. The size of the vector in this model is the domain of the stream elements. This model is also the model typically used in traditional database systems, where there are inserts, deletes, and updates to the database. In the *cash register model*, elements in the stream are only additions to the underlying vector, but elements can never leave the vector again. This is similar to databases recording the history of relations. Finally, the *time series model* treats every element in the stream s_i as a new independent vector entry. As a result, the underlying model is a constantly increasing vector and generally unbounded vector. Because each element can be processed individually in this model, it is frequently used in current stream processing engines.

Time

Time is a central concept in many stream processing applications, either because they are concerned with updating their view of the world by taking into account *recent* data received from streams or because they aim to detect temporal trends in the input streams.

For this reason, in most models of stream and stream processing, data elements are associated with some timestamp from a given time domain. Common semantics of time include *event time*, which is the time when the element was produced, and *processing time*, which is the time when the stream processing system starts processing the element (Akidau et al. 2015).

Different time semantics introduce different problems in terms of order and synchronization. Intuitively, while event time and processing time should ideally be equal, in practice unsynchronized clocks at the producers as well as variable communication and processing delays produce a skew between event time and processing time which is not only non-zero but also highly variable (Akidau 2015). On the one hand, processing elements in event time order is necessary in

many application scenarios. On the other hand, this requires waiting for out-of-order elements and reorder them before processing. This is a nontrivial problem, which is analyzed in detail in the entry related to “Time management.”

Windows

Windows are one of the core building blocks of virtually all stream processing systems. They define bounded portions of elements over an unbounded stream. They are used to perform computations that would be impossible (nonterminating) in the case of unbounded data, such as computing the average value of all the elements in a stream of numbers.

The most common types of windows are *count-based* and *time-based* windows. The former define their size in terms of the number of elements that they include, while the latter define their size in terms of a time frame and include all the elements with a timestamp included in that time frame.

In both cases, we distinguish between *sliding* windows, which continuously advance with the arrival of new elements, thus always capturing new elements, and *tumbling* windows, which can accumulate multiple elements before moving (Botan et al. 2010).

More recently, new types of windows have been defined to better capture the needs of applications. They include *session* and *data-defined* windows that are variable in size and define their boundaries based on the data elements: for instance, in a software monitoring application, a window can include all and only the elements that refer to a session opened by a specific user of that software (Akidau et al. 2015).

Stream Processing

Several types of stream processing systems exist that are specialized on different types of computations (Cugola and Margara 2012).

Data stream management systems are designed to update the answers of *continuous queries* as new data becomes available. They typically adopt declarative abstractions similar to traditional database query languages that they enrich with constructs such as windows to deal

with the unbounded nature of the input data (Arasu et al. 2006).

Complex event processing systems, instead, aim to detect (temporal) patterns over the input stream of elements (Etzion and Niblett 2010; Luckham 2001). These systems are discussed in the entry on “Event recognition.”

Modern Big Data stream processing systems, such as Flink (Carbone et al. 2015), provide general operators to transform input streams into output streams, thus offering the possibility to implement heterogeneous streaming applications by integrating these operators. These systems are designed to scale to multiple processing cores and computing nodes and persist intermediate results for fault tolerance. Flink and other systems are discussed in several entries within this section of the encyclopedia. The “Introduction to stream processing” entry overviews the main classes of algorithms for stream processing.

General Requirements of Stream Processing

Data streams could theoretically be stored and processed with traditional database systems or other analytic solutions. However, real-time processing of streams introduces specific requirements that stream processing systems need to satisfy (Stonebraker et al. 2005). Although the following requirements are not necessarily fulfilled by all current stream processing systems, they are frequently necessary in stream processing applications.

In order to do advanced analytics on streams, which involve more than a single operation, a stream processing system needs to integrate (pipeline) basic operations with each other. This can be done by (micro-)batching the stream, that is, splitting it in small chunks such that each operator processes a chunk at a time, or by true streaming, where each element is processed individually.

Because streams are often generated in a distributed fashion, for example, in sensor networks, a streaming system must handle small inconsistencies in the stream, such as out-of-order data, missing values, or delayed values. This is related to the topic of time management, discussed

earlier. Even if a stream contains small inconsistencies, the result of the stream processing needs to be predictable. This demands for clear semantics of the operations available and for robust mechanisms that guarantee deterministic results.

A high-level interface to specify stream processing jobs is desirable. The section on stream processing languages and abstractions gives an overview of current solutions.

An area of active research is the combination of streaming and batch data. Interestingly, this combination forms the missing link between database systems and streaming systems. Early attempts to address this challenge have led to the idea of a lambda architecture, which consists of separate systems for streaming and batch processing (Marz and Warren 2015). However, especially problems with robustness and model mismatches call for an integrated solution. Current streaming systems address this by enabling advanced state management (Carbone et al. 2017; Affetti et al. 2017).

Future Directions of Research

Streaming is a very active area of research. However, there are several topics that have found limited attention in current research but will be increasingly important for future applications and systems. Here, we will highlight two areas that found little attention so far.

Current stream processing systems frequently differentiate themselves from database systems in that they see all streams and all analytic jobs as conceptually unbounded. However, in many scenarios, streams as well as the analytic jobs on them are bounded. Furthermore, both can arrive at high frequencies, which is a challenge for current systems.

Another challenge, not solved by current systems, is transactional guarantees. Current stream processing systems provide basic guarantees like processing each stream element exactly once or at least once but have no concept of transactions that span multiple stream elements or operations (Affetti et al. 2017).

Summary

In this entry, we presented an overview on stream processing and introduced the basic concepts and terminology adopted in other entries of this section.

Given a (di)graph $G = (V, E)$ (strongly) connected, where $n = |V|$ and $m = |E|$ (note that, since the graph is connected, we have $m \geq n - 1$), the distance between two vertices $u, v \in V$ is the number of edges along the shortest path from u to v and is denoted as $d(u, v)$. The number of nodes separating u and v , i.e., $d(u, v) - 1$, is also called degree of separation.

The eccentricity of a node u is $\text{ecc}(u) = \max_{v \in V} d(u, v)$, which measures in how many hops u can reach any other node in the graph. Hence, the diameter D (resp. the radius R) of G is defined as the maximum (resp. minimum) eccentricity among all the nodes, i.e., $D = \max_{u \in V} \text{ecc}(u)$ (resp. $R = \min_{u \in V} \text{ecc}(u)$).

Given a node $u \in V$ and an $h \in [D]$ (where, for any positive integer x , $[x]$ denotes the set $\{1, 2, \dots, x\}$), we call $B_h(u)$ the set $\{v : v \in V, d(u, v) \leq h\}$ and, similarly, $N_h(u)$ the set $\{v : v \in V, d(u, v) = h\}$, which are, respectively, the sets of nodes reachable from u with at most (resp. exactly) h edges. We denote $N_1(u)$ also as $N(u)$.

Moreover, we call B_h (resp. N_h) the fraction of pairs of nodes $x, y \in V$ such that $d(x, y) \leq h$ (resp. $d(x, y) = h$). Clearly, for $h > 0$, we have $N_h = B_h - B_{h-1}$, and the average distance of G is defined as $\sum_{u, v \in V} \frac{d(u, v)}{n^2} = \sum_h h \cdot N_h$.

Overview

The problem with computing the average distance and the diameter in the case of huge networks (like, for instance, the Facebook friendship network and the Internet Movie Database collaboration network) is the time and space complexity. Indeed, this basically consists of computing all-pairs shortest paths. If the number of nodes is very large (millions or billions), the time complexity of this operation is not acceptable. Moreover, the space required to store huge networks and the intermediate data used by the algorithms into the main memory of the computer might be prohibitive. For this reason, a combination of graph compression techniques (Boldi and Vigna 2003) and of algorithmic methods has been proposed and practically used in order to compute both the average and the maximum distance within a graph. In this entry we describe some algorithmic techniques for computing the distance distribution, which can be roughly divided into two main categories: classical and sketch-based sampling. Moreover, we describe very simple algorithm for computing the diameter

of huge real-world complex networks, which is in practice extremely efficient.

Lower bounds and techniques. As distance distribution, radius, and diameter can be computed using any algorithm computing all-pairs shortest path (in short, APSP), their total time cost can be $O(nm)$, for instance, computing n breadth-first searches (in short, BFSs), one for each node. This cost is clearly prohibitive in real-world huge networks, but it has been proved that, unfortunately, this worst-case time bound seems hard to improve unless the so-called strong exponential time hypothesis (SETH) is false (Impagliazzo et al. 2001). Indeed, under this hypothesis, even deciding whether a graph has diameter 2 or 3 requires $\Omega(n^2)$ (Roditty and Williams 2013).

For this reason, heuristics or approximation algorithms are often used. In the case of distance distribution, approximation algorithms have been designed to approximate N_h with bounded absolute error (Crescenzi et al. 2011) or to approximate B_h with bounded relative error (Cohen 1994, 2015; Boldi et al. 2011; Flajolet and Martin 1985). These approximations turn out to be approximations also for the average distance (Boldi et al. 2011; Backstrom et al. 2012).

Approximation algorithms have been also proposed in the case of diameter computation (Roditty and Williams 2013; Abboud et al. 2016; Cairo et al. 2016). However, by the reduction provided by Roditty and Williams (2013), we have that unless SETH fails, $\Omega(n^2)$ time is required to get a $(3/2 - \epsilon)$ -approximation algorithm for computing the diameter even in the case of sparse graphs.

In the case of the radius and diameter of real-world networks, some heuristics have been shown to work surprisingly well (Magnien et al. 2009; Borassi et al. 2015; Akiba et al. 2015). Some of them are designed to approximate the diameter with a constant number of BFSs providing lower (or upper) bounds. Even if their approximation ratio can be asymptotically 2 (Crescenzi et al. 2013), they often turn out to be tight in practice (Magnien et al. 2009; Crescenzi et al. 2010). Other heuristics have been designed to compute

exactly the diameter. Even though, consistently with the time lower bound provided by Roditty and Williams (2013), these algorithms may be $O(nm)$, they turn out to be linear in practice in real-world graphs.

In the following we will discuss the approximation methods for the distance distribution and then we will focus on the exact computation of diameter.

D

Key Research Findings

On Approximating the Distance Distribution

Classical Sampling

The idea of classical sampling is to select a random set of vertices U and to approximate the distribution of distances of the whole graph with the distribution of distances starting from U (Crescenzi et al. 2011). In other words, given a random set $U \subseteq V$, for any h , with $h \in [D]$, classical sampling approximates N_h with $N_h(U)$, where $N_h(U) = |\{(u, v) \in U \times V : d(u, v) = h\}|/(|U|n)$. Classical sampling is often classified as a Monte Carlo method and, in the field of network analysis, has been applied, for example, for closeness centrality (Eppstein and Wang 2001) and betweenness centrality (Brandes and Pich 2007).

The algorithm works as follows: (i) perform a random sample of k vertices from V obtaining the multiset $U = \{u_1, u_2, \dots, u_k\} \subseteq V$; (ii) run iteration $i = 1, 2, \dots, k$, computing the distances $d(u_i, v)$ for all $v \in V$, by executing a BFS traversal of G starting from vertex u_i ; and (iii) return the approximation $N_h(U)$. The running time of the algorithm is $O(km)$, with additional space of $O(n)$. By applying the Azuma-Hoeffding bound (Hoeffding 1963), it is possible to prove that choosing $k = \Theta(\epsilon^{-2} \log n)$, this algorithm computes an approximation of the distance distribution N_h of G whose absolute error is bounded by ϵ , with high probability.

As the number of connected pairs is not known a priori in directed weakly connected graphs, this

method does not directly extend to this kind of graph.

Sketch-Based Sampling

These methods aim to study the cumulative distance distribution B_h by noting that for any u :

$$\begin{aligned} B_1(u) &= \{u\} \cup N(u) \\ B_h(u) &= B_{h-1}(u) \cup \bigcup_{v \in N(u)} B_{h-1}(v). \end{aligned}$$

This relationship immediately gives an exact dynamic programming algorithm that in D steps computes the sets $B_h(u)$ for any u and B_h .

The time cost is $\Theta(Dm\Delta)$, where Δ is the maximum degree in G , and the memory usage is $\Theta(n^2)$, since the size of $B_{h-1}(u)$ for any u can be $\Theta(n)$. Sketch-based approaches represent the sets $B_h(u)$ for each u , in a compressed approximated form of (almost) constant size k (typically $O(\log(n))$). By using sketches in place of real sets, this allows to obtain a dynamic programming approximation algorithm that costs $O(Dmk)$ time and $\Theta(nk)$ space, which is shown in Algorithm 1 and explained next using sketches. Note that the number of iterations needed by the dynamic programming algorithm is the diameter of G , which can be computed by using the methods shown in this entry. Whenever this is not possible, one can stop the algorithm when the amount of sketch changes are below a certain threshold (Palmer et al. 2002; Boldi et al. 2011).

Sketches. Given a set A , a sketch $S(A)$ is a compressed form of representation of A of size $O(k)$, with $k \in \mathbb{N}$, providing the following operations:

INIT ($S(A)$) How a sketch $S(A)$ for A is initialized.

UPDATE ($S(A), u$) How a sketch $S(A)$ for A modifies when an element u is added to A .

UNION ($S(A), S(B)$) Given two sketches for A and B , provide a sketch for $A \cup B$.

SIZE ($S(A)$) Estimate the number of distinct elements of A .

The following two requirements are needed for sketches: (i) Given two sketches $S(A)$ and

Algorithm 1: Approximation algorithm for distance distribution

```

Input : Graph  $G = (V, E)$ ,  $D$  the diameter for  $G$  or an upper bound.
Output: An estimate for  $B_h$ , with  $h \in [D]$ .
1 for  $u \in V$  do
2   INIT ( $S(B_1(u))$ )
3   for  $v \in N(u)$  do
4     UPDATE ( $S(B_1(u)), v$ )
5 Output  $\sum_u \text{SIZE}(S(B_1(u))) / n^2$ 
6 for  $h \in 2 \dots D$  do
7   for  $u \in V$  do
8      $S(B_h(u)) \leftarrow S(B_{h-1}(u))$ 
9     for  $v \in N(u)$  do
10       $S(B_h(u)) \leftarrow$ 
11        UNION( $S(B_h(u)), S(B_{h-1}(v))$ )
11 Output  $\sum_u \text{SIZE}(S(B_h(u))) / n^2$ 

```

$S(B)$ for any two sets A and B , $S(A \cup B)$ can be computed just by looking at $S(A)$ and $S(B)$; (ii) The order in which the elements are added and adding any element twice does not affect the sketch. We assume that $|A| > k > 1$.

In the following, we present the most popular methods for sketches that have been used to compute distance distributions.

k -min. A k -min sketch includes the item of smallest rank in each of k independent permutations (Cohen 1997). Hence, a sketch $S(A)$ is a sequence of exactly k entries, a_1, \dots, a_k , where each entry can be an element of A or \perp .

Similar ideas have been applied for near duplicate document detection in Broder (1997).

Let r_1, r_2, \dots, r_k be mapping functions $r_i : U \rightarrow \{1/n, 2/n, 3/n, \dots, 1\}$, setting $r(\perp) = \infty$.

INIT ($S(A)$): $a_i = \perp$ for any i .

UPDATE ($S(A), u$): for every $i \in [k]$, if $r_i(a_i) > r_i(u)$, a_i is replaced with u .

UNION ($S(A), S(B)$): return $\{c_1, \dots, c_k\}$ such that $c_i = \arg\min_{x \in \{a_i, b_i\}} \{r_i(x)\}$.

SIZE ($S(A)$): return $\frac{k-1}{\sum_{a_i \in S(A)} -\ln(1-r_i(a_i))}$

Note that, as $|A| > 1$, $r_i(a_i) \neq 1$ for each $a_i \in S(A)$. The mean relative error is bounded by $0.79/\sqrt{(k-2)}$ (Cohen 1994, 1997).

Bottom- k . This paradigm relies on the technique introduced by Cohen and Kaplan (2008, 2007a,b). Given a mapping $r : U \rightarrow \{1/n, 2/n, \dots, 1\}$ and a subset A of U , we denote as $H_k(A)$ the first k elements of A according to r and with $\max(A)$ the element of A having maximum rank. A bottom- k sketch for A is $H_k(A)$.

INIT ($S(A)$): $S(A) = \emptyset$.

UPDATE ($S(A), u$): If $|S(A)| < k$, add u to $S(A)$. Otherwise, if $r(\max(S(A))) > r(u)$, replace $\max(S(A))$ with u .

UNION ($S(A), S(B)$): return $H_k(S(A) \cup S(B))$

SIZE ($S(A)$): return $\frac{k-1}{r(\max(S(A)))}$

It corresponds to the sampling without replacement version of the k -min approach.

LogLog counters. This approach exploits the LogLog counters introduced in Flajolet and Martin (1985). The implementation of this paradigm for computing distance distribution is called ANF (Palmer et al. 2002). Here a sketch $S(A)$ is a sequence of exactly k entries, a_1, \dots, a_k , where each entry is a sequence of h bits. Given k partition functions $p_i : U \rightarrow \{1, 2, \dots, h\}$, for each j , with $j \in [h]$, the bit $a_{i,j} = 1$ if there exists an element in A that is mapped to j according to p_i , 0 otherwise. Each partition function p_i is such that $1/2$ of the elements are randomly mapped to 1, $1/4$ of the elements are mapped to 2, ..., $1/2^i$ of them are mapped to i .

INIT ($S(A)$): $a_{i,j} = 0$ for any i, j .

UPDATE ($S(A), u$): for any i , let $p_i(u) = j$, set $a_{i,j}$ to 1.

UNION ($S(A), S(B)$): return $\{c_1, \dots, c_k\}$ where c_i is the OR between a_i and b_i .

SIZE ($S(A)$): let b be the average position of the least zero bits in a_1, \dots, a_k (i.e., $b = \frac{1}{k} \sum_{i=1}^k \min\{j - 1 : a_{ij} = 0\}$), return $2^b / 0.77351$.

The standard error is bounded by $0.78/\sqrt{k}$ using space $\log n + O(1)$ bits.

HyperLogLog Counters. This approach is inspired by the method proposed in Flajolet et al.

(2007). We refer to the description given by Boldi et al. (2011). In this case, let h be a hash function from U to 2^∞ . As in the case of LogLog counters, a sketch $S(A)$ is a sequence of exactly k entries a_1, \dots, a_k where $k = 2^b$ and b is given in input. Each entry a_i is a counter. Let $h_b(x)$ be the sequence of the b leftmost bits of $h(x)$, while let $h^b(x)$ be the remaining bits. Moreover, given a binary sequence w , let $\rho^+(w)$ be the number of leading zeroes in w plus one.

Intuitively, as in the case of LogLog counters, the elements of U are partitioned in k groups according to their value of $h_b(x)$, and in the sketch $S(A)$ in a_i , there is the maximum $\rho^+(h^b(y))$ among the elements y of A mapped in the i -th group.

INIT ($S(A)$): $a_i = -\infty$ for any i .

UPDATE ($S(A), u$): Let $i = h_b(u)$. Set a_i equal to $\max\{a_i, \rho^+(h^b(u))\}$.

UNION ($S(A), S(B)$): return $\{c_1, \dots, c_k\}$ where $c_i = \max\{a_i, b_i\}$.

SIZE ($S(A)$): return $\frac{\alpha_k \cdot k^2}{\sum_{j=1}^k 2^{-a_j}}$.

The constant α_k can be approximated to 0.72134 and is more precisely provided in Flajolet et al. (2007). The standard error is bounded by $1.04/\sqrt{k}$ using space $\log \log n + O(1)$ bits.

On Computing the Diameter

In this section we focus on the exact computation of the diameter in undirected graphs by using the i FUB algorithm, whose pseudocode is shown in Algorithm 2 (Crescenzi et al. 2013). First of all, recall that the *textbook* algorithm runs a BFS for any node, computing its eccentricity and finally returning the maximum eccentricity found. i FUB also computes the eccentricity of each node but processing the nodes in a specific order π . While doing this (i) it refines a lower bound lb (i.e., the maximum eccentricity found until that moment), and (ii) it refines an upper bound ub for the eccentricities of the remaining nodes. Finally, it stops when $ub \leq lb$ meaning that the remaining nodes cannot have eccentricity higher than our current lower bound.

Algorithm 2: *iFUB*

Input: A graph G , a node u , e.g., the node with highest degree.
Output: The diameter D

```

1  $i \leftarrow \text{ecc}(u)$ 
2  $lb \leftarrow \text{ecc}(u)$ 
3  $ub \leftarrow 2 \cdot \text{ecc}(u)$ 
4 while  $ub > lb$  do
5   let  $e$  be the maximum eccentricity of all nodes
      at distance  $i$  from  $u$ 
6    $lb \leftarrow \max\{lb, e\}$ 
7    $ub \leftarrow 2 \cdot (i - 1)$ 
8    $i \leftarrow i - 1$ 
9 return  $lb$ 
```

The order π is obtained sorting the nodes in decreasing order according to their distance from a given node, e.g., the highest degree node.

The time complexity of *iFUB* is in the worst case the same of the textbook algorithm, i.e., $O(nm)$, which is consistent with the time lower bound provided by Roditty and Williams (2013). This worst case is achieved when the nodes in the graph have close eccentricity or their BFSS' trees are isomorphic. However, the experiments in Crescenzi et al. (2013) have shown that in real-world graphs, this algorithm is almost always linear time, as the number of BFSS it performs seems to be constant. Moreover, an implementation of the algorithm in the WebGraph framework has computed the diameter of Facebook in 2011. At that time, Facebook network was composed by 721.1 millions of users and 68.7 billions of edges, and its diameter was computed by *iFUB* using 17 BFSs (Backstrom et al. 2012).

The above algorithm has been adapted to work for directed strongly connected graphs in Crescenzi et al. (2012). In Borassi et al. (2015) and Akiba et al. (2015), the algorithm has then been improved, in terms of practical performances, both for directed and undirected graphs, and it has been extended to directed weakly connected graphs, that is, directed graphs whose corresponding undirected graphs in which the direction of the edges is removed are connected.

Examples of Application**The six degrees of separation phenomenon.**

The *small-world experiment* was conducted by Stanley Milgram and other researchers in the 1960s in order to determine the average “social distance” between people in the United States. A package containing a letter, basic information about a target person, and an empty table on which the participants could write their name was sent to randomly selected individuals. Each participant was asked whether he/she personally knew the contact person. If so, the letter could be directly sent to that person. Otherwise the participant was asked to add his/her name on the table and to send the package to a person he/she knew personally who was more likely to know the target (who became a new participant of the experiment). In this way, for each package that reached the target person, by looking at the name table, it was possible to count the number of times it had been forwarded from person to person, that is, to estimate the social distance from the original participant to the target person. The observed average path length was less than or equal to six. For this reason, the researchers concluded that people in the United States were separated by about six “handshakes.” This hypothesis was so fascinating that a theater play was written in 1990, and later a film in 1993 popularized the play itself. The play is one of the main reasons why the small-world experiment has become popular as the *six degrees of separation* phenomenon. In the field of complex network analysis, this phenomenon has been tested on several different kinds of (online) social networks using the techniques presented in this entry. The HyperANF tool (Boldi et al. 2011) has been used to show that the degrees of separation in the Facebook network in 2011 (Backstrom et al. 2012) was four on the average instead of six.

Diameter computation. The diameter is a relevant measure (whose meaning depends on the semantics of the network itself), which

has been almost always considered while analyzing real-world networks such as biological, collaboration, communication, road, social, and web networks (Brandes 2005). Differently from the small-world experiment, in this case we are not interested on the average distance but on the worst-case distance. This information can be very useful in order to determine, for example, an upper bound on the number of rounds a specific protocol (like, for example, a flooding protocol) should run. Algorithm 1 is an example of such an application, as the diameter is the number of iterations needed to propagate neighborhood information inside the network and to stop the algorithm.

Software libraries. The *iFUB* algorithm and its improvements have been implemented in several graph algorithm libraries. These include Lasagne (<http://lasagne-unifi.sourceforge.net>), Sage (www.sagemath.org), NetworkKit (<http://networkkit.itい.Kit.edu>), and Webgraph (<http://webgraph.di.unimi.it>). The first library contains also the classical sampling algorithm for the distance distribution, while the last one includes the implementation of the HyperLogLog counters.

Future Directions for Research

The design of new sketching methods is currently an active area of research and, for instance, new estimators have been proposed in Cohen (2015). Moreover, future directions involve understanding why the *iFUB* works so well in the case of real-world networks despite its worst-case running time. Some steps in this direction have been done in Borassi et al. (2017).

Delta Compression Techniques

Torsten Sue

Department of Computer Science and Engineering, Tandon School of Engineering, New York University, Brooklyn, NY, USA

Synonyms

Data differencing; Delta encoding; Differential compression

Definitions

Delta compression techniques encode a target file with respect to one or more reference files, such that a decoder who has access to the same reference files can recreate the target file from the compressed data. Delta compression is usually applied in cases where there is a high degree of redundancy between target and references files, leading to a much smaller compressed size than could be achieved by just compressing the target file by itself. Typical application scenarios include revision control systems and versioned file systems that store many versions of a file or software or content updates over networks where the recipient already has an older version of the data. Most work on delta compression techniques has focused on the case of textual and binary files, but the concept can also be applied to multimedia and structured data.

Delta compression should not be confused with Elias delta codes, a technique for encoding integer values, or with the idea of coding sorted sequences of integers by first taking the difference (or delta) between consecutive values. Also, delta compression requires the encoder to have complete knowledge of the reference files

and thus differs from more general techniques for redundancy elimination in networks and storage systems where the encoder has limited or even no knowledge of the reference files, though the boundaries with that line of work are not clearly defined.

Overview

Many applications of big data technologies involve very large data sets that need to be stored on disk or transmitted over networks. Consequently, data compression techniques are widely used to reduce data sizes. However, there are many scenarios where there are significant redundancies between different data files that cannot be exploited by compressing each file independently. For example, there may be many versions of a document, say a Wikipedia article, that differ only slightly from one to the next. Delta compression techniques attempt to exploit such redundancy between pairs or groups of files to achieve better compression.

We define delta compression for the most common case of a single reference file. Formally, we have two strings (files): $f_{tar} \in \Sigma^*$ (the target file) and $f_{ref} \in \Sigma^*$ (the reference file). Then the goal for an encoder E with access to both f_{tar} and f_{ref} is to construct a file $f_\delta \in \Sigma^*$ of minimum size, such that a decoder D can reconstruct f_{tar} from f_{ref} and f_δ . We also refer to f_δ as the *delta* of f_{tar} and f_{ref} .

Given this definition, research on delta compression techniques has focused on three challenges: (1) How to build delta compression tools that result in f_δ of small size while also achieving fast compression and decompression speeds and small memory footprint. (2) How to use delta compression techniques to compress collections of files, i.e., how to select suitable reference files given a target file, or how to select a sequence of delta compression steps between files to achieve good compression for a collection ideally while also allowing fast retrieval of individual files. (3) How to apply delta compression in various application scenarios.

Key Research Findings

String-to-String Correction and Differencing

Some early related work was done by Wagner and Fisher (1974), who studied the *string-to-string correction problem*. This is the problem of finding the best (shortest) sequence of insert, delete, and update operations that transform one string f_{ref} to another string f_{tar} . The solution in Wagner and Fisher (1974) is based on finding the longest common subsequence of the two strings using dynamic programming and adding all remaining characters to f_{tar} explicitly. However, the string-to-string correction problem does not capture the full generality of the delta compression problem. In particular, in the string-to-string correction problem, it is implicitly assumed that the data common to f_{tar} and f_{ref} appears in (roughly) the same order in the two files, and the approach cannot exploit the case of substrings in f_{ref} appearing repeatedly in f_{tar} .

This early work motivated Unix tools such as *diff* and *bdiff*, which create a *patch*, i.e., a set of edit commands, that can be used to update the reference file to the target file. Such tools are widely used to create patches for software updates, and one advantage is that these patches are easily readable by humans who need to understand the changes. However, the tools typically do not generate delta files of competitive size, due to (1) limitations in the type of edit operations that are supported, as discussed in the previous paragraph, and (2) the absence of native compression methods for reducing the size of the patch. The latter issue can be partially addressed by applying general purpose file compressors such as *gzip* or *bzip* to the generated patches, though this is still far from optimal.

The first problem was partially addressed by Tichy (1984), who defined the *string-to-string correction problem with block moves*. For a file f , let $f[i]$ denote the i th symbol of f , $0 \leq i < |f|$, and $f[i, j]$ denote the block of symbols from i until (and including) j . Then a *block move* is a triple (p, q, l) such that $f_{ref}[p, \dots, p + l - 1] = f_{tar}[q, \dots, q + l - 1]$, representing a nonempty common substring of f_{ref} and f_{tar} of length l .

The file f_δ can now be constructed as a minimal *covering set* of block moves, such that every $f_{tar}[i]$ that also appears in f_{ref} is included in exactly one block move.

Tichy (1984) also showed that a greedy algorithm results in a minimal cover set, leading to an f_δ that can be constructed in linear space and time using suffix trees. However, the multiplicative constant in the space complexity made the approach impractical. A more practical approach uses hash tables with linear space but quadratic time worst-case complexity (Tichy 1984). Subsequent work in Ajtai et al. (2002) showed how to further reduce the space used during compression while avoiding a significant increase in compressed size, while Agarwal et al. (2004) showed how to reduce size by picking better copies than a greedy approach. Finally, Xiao et al. (2005) showed bounds for delta compression under a very simple model of file generation where a file is edited according to a two-state Markov process that either keeps or replaces content.

Delta Compression Using Lempel-Ziv Coding

The block move-based approach proposed in Tichy (1984) leads to a basic shift in the development of delta compression algorithms, as it suggests thinking about delta compression as a sequence of copies from the reference file into the target file, as opposed to a sequence of edit operations on the reference file. This led to a set of new algorithms based on the Lempel-Ziv family of compression algorithms (Ziv and Lempel 1977, 1978), which naturally lend themselves to such a copy-based approach while also allowing for compression of the resulting patches.

In particular, the LZ77 algorithm can be viewed as a sequence of copy operations that replace a prefix of the string being encoded by a reference to an identical previously encoded substring. Thus, delta compression could be viewed as simply performing LZ77 compression with the file f_{ref} representing previously encoded text. In fact, we can also include the part of f_{tar} that has already been encoded in the search for a longest matching prefix. A few extra changes are needed to get a practical implementation of

LZ77-based delta compression. Implementations of this approach include *vdelta* (Hunt et al. 1998), several versions of *xdelta* (MacDonald 2000), *zdelta* (Trendafilov et al. 2002), the recent and very fast *ddelta* (Xia et al. 2014b) and *edelta* (Xia et al. 2015), and a number of implementations following the *vcdiff* differencing format.

A Sample Implementation

We now describe a possible implementation in more detail, using the example of *zdelta*. In fact, *zdelta* is based on a modification of the *zlib* library implementation of *gzip* by Gailly and Adler (Gailly 2017), with some additional ideas inspired by *vdelta* (Hunt et al. 1998). Note that *zlib* finds previous occurrences of substrings using a hash table. In *zdelta*, this is extended to several hash tables, one for each reference file and one for the already coded part of the target file. The table for f_{tar} is essentially handled as in *zlib*, where new entries are inserted as f_{tar} is traversed and encoded. The table for f_{ref} can be built beforehand by scanning f_{ref} , assuming f_{ref} is not too large. When looking for matches, all tables are searched to find the best match. Hashing of substrings is done based on the initial three characters, with chaining inside each hash bucket.

As observed in Hunt et al. (1998), in many cases, the location of the next match in f_{ref} is a short distance after the end of the previous match, especially when the files are very similar. Thus, the locations of matches in f_{ref} are usually best represented as offsets from the end of the previous match in f_{ref} . However, sometimes there are isolated matches in other parts of f_{ref} . This motivates *zdelta* to maintain two pointers into each reference file and to code locations by storing which pointer is used, the direction of the offset, and the offset itself. Pointers are initially set to the start of the file and afterward usually point to the ends of the previous two matches in the same reference file. If a match is far away from both pointers, a pointer is only moved to the end of it if it is the second such match in a row. Other more complex pointer movement policies might give additional moderate improvements.

To encode the generated offsets, pointers, directions, match lengths, and literals, *zdelta* uses

the Huffman coding facilities provided by *zlib*, while *vdelta* uses a byte-based encoding that is faster but less compact.

Window Management in LZ-Based Delta Compressors

The above description assumes that reference files are small enough to completely fit into the hash table. However, this is usually not realistic. By default, *zlib* only indexes a history of up to 32 KB of already processed data in the hash table, in two blocks of 16 KB each. Whenever the second block is filled, the first one is freed up, temporarily reducing indexed history to 16 KB. This is for efficiency reasons: Indexing more than 32 KB would result in larger hash tables that lead to increased L1 cache misses (as L1 cache sizes have not increased much over the last two decades) and, more importantly, result in very long hash chains for common three-character substrings that would be traversed when searching for matches.

In the target file, we could just index the last up to 32 KB in the hash table by their first 3 bytes, as done in *zlib*. But which parts of the reference files should we index? There are several possible choices, as follows:

- **Sliding Window Forward:** In *zdelta*, a 32 KB window is initially placed at the start of the reference file and then moved forward by 16 KB whenever the median of the last few copies comes within a certain distance from the end of the current window. This works well if the content is reasonably aligned between the reference and target case, which is the common case in many applications, but can perform very badly when large blocks of content occur in a very different order in the two files.
- **Block Fingerprints:** Another possible approach chooses the parts in the reference files that should be indexed based on their similarity to the content currently being encoded. This is done by computing fingerprint for certain substrings and then indexing parts of the reference file that share many fingerprints with the content we

are currently encoding. This approach was considered by Korn and Vo in the context of implementing *vcdiff* (Korn and Vo 2002).

- **Hashing Longer Substrings:** Another approach indexes the entire reference file and avoids long hash chains by hashing substrings much longer than three characters. This allows finding copies from anywhere in the reference and target files, as long as copies are longer than the hashed substrings. This approach was taken in earlier versions of *xdelta*, making it very robust against content reordering between the files, but compression may be slightly worse than other approaches on well-aligned files, since only large copies are supported. However, the approach can be combined with the others above, to allow both longer and shorter copies, by first using larger fixed-size chunks as proposed in Bentley and McIlroy (1999) and Tridgell (2000) or with content-defined chunking and then finding smaller copies more locally; see, e.g., *ddelta* (Xia et al. 2014b).

D

Compressing Collections of Files

Larger collections of files can be compressed by repeatedly applying delta compression to pairs or groups of files. This raises the question of what reference files to choose for which target files in order to achieve a cycle-free compression of the entire collection with minimum compressed size. In some scenarios, it is also crucial to be able to quickly decompress individual files without having to decompress too many other files.

In the case of revision control systems, older files are usually compressed using a newer version as a reference file, since newer versions are more frequently accessed. However, retrieving an old version could be very slow if it requires decompressing a long chain of more recent versions before reaching the one that is needed. For this reason, such systems may often create shortcuts, where versions are occasionally encoded using a much later version as reference, at the cost of a slight increase in size.

Delta compression can also be used to compress collections of non-versioned files that share

some degree of similarity. For the case of a single reference file, finding an optimal and cycle-free assignment of reference files to target files can be modeled as an *optimum branching* problem on a complete graph (Tate 1997; Ouyang et al. 2002), which can be solved in $|V|^2$ time on dense graphs where $|V|$ is the number of vertices. For the case of more than one reference file, the problem is known to be NP-complete (Adler and Mitzenmacher 2001). However, the cost of computing the edge weights of the input graph is prohibitive, motivating (Ouyang et al. 2002) to propose using text clustering to identify for each target file a small set of promising reference file candidates. Work in Bagchi et al. (2006) showed that an optimum branching on a reduced degree graph of highest weight edges in fact provides a provable approximation ratio to the solution on the full graph.

Work by Molfetas et al. (2014b,a) studied how to optimize and trade off access speed and compression ratio in delta-compressed file collections, e.g., by avoiding references to substrings in certain files when other copies could be used instead. It is shown that significant improvements are possible by judiciously picking copies during compression.

However, for bulk archival and retrieval of large collections of non-versioned web pages, work in Trendafilov et al. (2004), Chang et al. (2006), and Ferragina and Manzini (2010) suggests that better speed and compression can be achieved by applying optimized compression tools for archiving large data sets on top of a suitable linear ordering of the files, say one obtained via text clustering or URL ordering. The main reason is that such tools can identify repeated substrings over very long distances, while delta compressors are limited to one or a few reference files.

Examples of Applications

There are a number of scenarios where delta compression can be applied in order to reduce networking and storage cost. A few of them are now discussed briefly.

- **Software Revision Control Systems:** Delta compression techniques were originally proposed and developed in the context of systems used for maintaining the revision history of software projects and other documents (Berliner 1990; Rochkind 1975; Tichy 1985). In such systems, there are multiple, often almost identical, versions of each document, including different branches, that have to be stored, to enable users to retrieve and roll back to past versions. See Hunt et al. (1998) for more discussion on delta compression in the context of such systems.
- **Software Patch Distribution:** Delta compression techniques are used to generate software patches that can be efficiently transmitted over a network in order to update installed software packages. A good delta compressor can significantly reduce the cost of rolling out updates, say, for security-critical updates to popular software that need to be quickly disseminated. The case of updating automobile software over wireless links was recently discussed in Nakanishi et al. (2013), while Samteladze and Christensen (2012) addresses efficient app updates on mobile devices. Tools such as *bspatch* and *bsdiff* are especially optimized for the case of updating executables, and even better algorithms for this case are proposed in Percival (2006) and Motta et al. (2007).
- **Improving Data Downloading:** There is a long history of proposals to employ delta compression to improve web access, by exploiting the similarity between the current and an older cached version of a page or between different pages on the same site. A scheme called *optimistic delta* was proposed in Banga et al. (1997) and Mogul et al. (1997), where a caching proxy hides server latency by first returning a potentially outdated cached version, followed if needed by a small patch once the server replies. In another approach, a client with a cached old version sends a tag identifying the version as part of the HTTP request and then receives a patch (Housel and Lindquist 1996; Delco and Ionescu, xProxy: a transparent caching and delta transfer sys-

tem for web objects. Unpublished manuscript, 2000). A specialized tool called *jdelta* for XML data in push-based services is proposed in Wang et al. (2008)

It is well known that pages from the same web site are often very similar, mostly due to common layout and menu structure and that this could be exploited with delta compression. Work in Chan and Woo (1999) and Savant and Suel (2003) studies how to identify cached pages that make good reference files for delta compression, while Douglis et al. (1997) proposes a similar idea for shared dynamic pages, e.g., different stock quotes from a financial site.

While delta compression has the potential to significantly reduce latency and bandwidth usage, particularly over slower mobile links, such schemes have only seen limited adoption. Examples of widely used implementations are the *Shared Dictionary Compression over HTTP* mechanism implemented by Google in the Chrome browser and in their Brothli compressor (Alakuijala and Szabadka 2016) (which is based on the vcdiff differencing format and employs a mechanism similar to delta compression) and the use of delta compression for reducing network traffic in Dropbox (Drago et al. 2013).

- **Delta Compression in File and Storage Systems:** Delta compression is also useful for versioning file systems that keep old versions of files. The *Xdelta File System* (MacDonald 2000) aimed to provide efficient support for delta compression at the file system level using *xdelta*. Delta compression is also used for redundancy elimination in backup systems. In particular, Kulkarni et al. (2014), Shilane et al. (2012), and Xia et al. (2014b,a) showed that adding delta compression between similar files or chunks of data on top of duplicate elimination (removal of identical files or chunks) can give significant additional size reductions, though at some processing cost. Delta compression was implemented, e.g., in the EMC Data Domain line of products.
- **Efficient Storage of File Collections:** As discussed in the previous section, delta com-

pression has been considered as a way to improve compression of general collections of files that share some degree of similarity; see, e.g., Ouyang et al. (2002). However, subsequent work (Trendafilov et al. 2004; Chang et al. 2006; Ferragina and Manzini 2010) indicates that this approach is often outperformed by optimized compression tools for archiving large data sets, after suitable reordering of the files.

- **Exploring File Differences:** Delta compression tools can be used to visualize differences between documents. For example, the *diff* utility displays the differences between two files as a set of edit commands, while the *HtmlDiff* and *topblend* tools in Chen et al. (2000) visualize the difference between HTML documents. Here, the focus is less on compressed size and more on readability.

Future Directions for Research

Delta compression is a fairly mature technology, and future gains in compression may thus be modest for general scenarios. However, there are still a number of challenges that remain, including the following:

- **Speed Improvements:** Recent years have seen significant improvements in speed for many compression techniques, in some cases due to use of available data parallel (SIMD) instruction sets in modern processors. Examples of recent high-speed methods for delta compression are *ddelta* (Xia et al. 2014b) and *edelta* (Xia et al. 2015), and future work should further improve on these results.
- **Alternative Approaches:** Almost all current delta compressors use LZ-based approaches. While this is a natural approach, there might be alternative approaches (e.g., methods based on Burrows-Wheeler compression Burrows and Wheeler 1994) that could lead to improvements. On a more speculative level, researchers have recently started using recurrent neural networks for better compression, and such an approach might also lead to better delta compression.

- Formal Analysis of Methods:** Current delta compression algorithms are very heuristic in nature, and there is limited work on formally analyzing their performance or optimality with respect to information theoretic measures. An exception is the work in Xiao et al. (2005), which shows some bounds under a very simple model of document generation, but there is a need for more formal analysis.
- Integration in Storage Systems:** As discussed, delta compression techniques have been deployed inside storage systems in conjunction with other redundancy elimination techniques. In such systems, it can be challenging to identify suitable reference files for a target file that needs to be stored and to decide when it is worth to apply delta compression techniques, which require fetching the reference files for coding and decoding, in conjunction with other redundancy elimination techniques. Future research could look for new methods that use fingerprints and associated indexes to quickly find good reference files or explore better tradeoffs between compression and the amount of knowledge that is needed about the reference data (where delta compression is the case of full knowledge).

D**Delta Encoding**► [Delta Compression Techniques](#)**Dictionary-Based Compression**► [Grammar-Based Compression](#)**Differential Compression**► [Delta Compression Techniques](#)**Dimension Reduction**

Kasper Green Larsen
Aarhus University, Aarhus, Denmark

Definitions

Dimensionality Reduction is a technique for taking a high-dimensional data set (data objects with many features/attributes) and replacing it with a much lower-dimensional data set while still preserving similarities between data objects. Dimensionality reduction is useful for reducing

the memory requirements for storing a data set, as well as for speeding up algorithms.

Overview

In modern algorithm design and data analysis, we often face very high-dimensional data. High-dimensional data comes in many forms. As examples, we can think of a 10-megapixel image as a point with ten million coordinates, one for each pixel. In this way, an image becomes a ten million-dimensional point. Another often encountered example arises when we wish to compare documents based on similarity. One way to do this is to simply count how many times each dictionary word occurs in a document and compare documents based on these counts. This yields a representation of a document as a point with one coordinate for each of the about 10^5 common English words. The distance between these high-dimensional points naturally captures the similarity of documents. The dimensionality grows even more dramatically when one compares documents based on so-called w -shingles (sets of w consecutive words in the text). With a typical choice of $w = 5$, the number of possible 5-shingles grows to $(10^5)^5 = 10^{25}$, and thus a document becomes an extremely high-dimensional point (albeit with few non-zero coordinates).

Dimensionality Reduction is an approach to “compressing” such high-dimensional points. Dimensionality reduction works by taking a high-dimensional point set and then mapping/embedding it to another point set in much lower-dimensional space. Said more formally, we take a set $X = \{p_1, \dots, p_n\}$ of d -dimensional points and map them to a set $f(X) = \{f(p_1), \dots, f(p_n)\}$ of m -dimensional points, hopefully with m much smaller than d . Since the points have much fewer coordinates after this *embedding*, they take up much less storage space. In addition to reducing the size of data sets, dimensionality reduction can also help speed up algorithms: The running time of many algorithms depends naturally on the dimensionality of the input data. If we reduce the

dimensionality, we also reduce the running time of such algorithms.

The difficulty in dimensionality reduction comes from the conflicting goal of also preserving the geometry of the point set. Preserving the geometry can have many interpretations, but roughly speaking, it means that we want close points to remain close and far points to remain far apart. This chapter surveys the most popular notion of dimensionality reduction, namely, dimensionality reduction under Euclidian distances. Here the goal is to preserve Euclidian distances between points while reducing the dimension as much as possible. For two points $x = (x_1, \dots, x_d)$ and $y = (y_1, \dots, y_d)$ in d -dimensional space, their Euclidian distance is simply the generalization of distances in the plane to higher dimensions, that is, the distance from x to y is

$$\sqrt{\sum_{i=1}^d (y_i - x_i)^2}.$$

If we think of points as vectors, then the distance between vectors x and y is the so-called ℓ_2 -norm of the vector $y - x$. For a vector z , we use the notation $\|z\|_2 = \sqrt{\sum_{i=1}^d z_i^2}$ to denote the ℓ_2 -norm of z . Thus the distance from x to y equals $\|y - x\|_2$. When we say *dimensionality reduction* in this chapter, we thus think of the task of taking a set of d -dimensional points $X = \{p_1, \dots, p_n\}$ and mapping them to m -dimensional points $f(X) = \{f(p_1), \dots, f(p_n)\}$, such that the distance $\|f(p_i) - f(p_j)\|_2$ roughly equals the original distance $\|p_i - p_j\|_2$ for all pairs of points p_i, p_j in X .

Key Research Findings

The cornerstone result in dimensionality reduction is the famous Johnson-Lindenstrauss lemma due to Johnson and Lindenstrauss (1984). For any set $X = \{p_1, \dots, p_n\}$ of n points in d -dimensional space (denoted \mathbb{R}^d), and for any approximation factor $\varepsilon \in (0, 1/2)$,

the result says that there exists an embedding $f(X) = \{f(p_1), \dots, f(p_n)\}$, with each $f(p_i)$ in \mathbb{R}^m and $m = O(\varepsilon^{-2} \lg n)$, such that for all points $p_i, p_j \in X$, it holds that

$$\|f(p_j) - f(p_i)\|_2 \geq (1 - \varepsilon) \|p_j - p_i\|_2$$

and

$$\|f(p_j) - f(p_i)\|_2 \leq (1 + \varepsilon) \|p_j - p_i\|_2.$$

Let us take a minute to parse the result. When given a point set X in \mathbb{R}^d , it says that the “user” can specify an approximation factor $\varepsilon \in (0, 1/2)$. For that chosen approximation factor, it is possible to take the points X and embed them into only $m = O(\varepsilon^{-2} \lg n)$ dimensions while guaranteeing that the distance between any two points is only distorted by a multiplicative factor $(1 \pm \varepsilon)$. Thus if two points were close to each other before embedding, they will remain close afterward. Similarly, if two points were far apart before embedding, they will remain far apart. It is quite remarkable that the *target dimension* m doesn’t even depend on the original dimensionality of the point set. Furthermore, the dependency on the number of points in X is only logarithmic.

The original construction of Johnson and Lindenstrauss (1984) is not meant to be practical, and as you may have observed, the above only talks about the *existence* of an embedding $f(X)$. In practice, we naturally care about computing $f(X)$ efficiently. The following simple algorithm can be found in Dasgupta and Gupta (2003):

Embed(X):

- Let $m = \Theta(\varepsilon^{-2} \lg n)$. Form an $m \times d$ matrix A with each entry chosen independently and uniformly at random among $\{-1, +1\}$.
- Embed each point $x \in X$ to the point $f(x) = (Ax)/\sqrt{m}$ (compute Ax and divide all entries by \sqrt{m}).

Intuitively, the above algorithm chooses m random directions and projects the data onto those directions. The algorithm is randomized, and there is a small probability that it fails in the sense that some pair of points has their distance distorted by more than $(1 \pm \varepsilon)$. The failure probability is polynomially small in n when $m = C\varepsilon^{-2} \lg n$ for a big enough constant $C > 0$. If one cannot live with this small probability of failure, one can always run through all n^2 pairs of points and explicitly check if any pair have their distance distorted by too much. If that is the case, one can start over with a new random matrix A . Of course this is very time-consuming as we have to check n^2 pairs. Thus one would typically just hope for the best and not try to verify whether all distances were preserved. Finding an efficient deterministic construction remains an intriguing open problem (see Future Directions for Research).

Computing $f(x)$ for a data point $x \in X$ takes $O(md)$ time by a straightforward implementation of matrix-vector multiplication.

Remark 1 The paper by Dasgupta and Gupta (2003) actually has each entry of A a uniform random $\mathcal{N}(0, 1)$ distributed random variable. This makes their proof simpler but makes the construction less efficient when implemented in practice. For a correctness proof when using $-1/ + 1$ entries, see, e.g., Nelson (2015).

Remark 2 Much research has gone into determining whether the number of dimensions $m = O(\varepsilon^{-2} \lg n)$ is the best possible when given the desired approximation factor ε . This question was only answered very recently, where Larsen and Nelson (2017) showed that there exist point sets where one cannot embed into fewer than $\Omega(\varepsilon^{-2} \lg n)$ dimensions while preserving all pairwise distances to within $(1 \pm \varepsilon)$. Thus the Johnson-Lindenstrauss lemma is *optimal* when it comes to the target dimension m .

Speeding Up the Embedding

In many applications, the embedding time of $O(md)$ may not be sufficiently fast. For instance, if the original dimensionality is in the millions

and one embeds into a couple of thousand dimensions, then the matrix-vector multiplication takes in the order of billions instructions for each single data point. Several approaches have been suggested for speeding up the embedding time. We discuss the two main directions in the following:

Fast Johnson-Lindenstrauss Transforms. The first approach, due to Ailon and Chazelle (2009), replaces the matrix A from the previous algorithm with another carefully chosen matrix B , such that computing Bx can be done faster than computing Ax . To be precise, they actually replace Ax/\sqrt{m} by the product of three matrices PHD and x , i.e., $f(x) = PHDx$. The matrix D is a $d \times d$ diagonal matrix with each diagonal set independently and uniformly at random among $\{-1, +1\}$ (and all off-diagonals are 0). The matrix H is the $d \times d$ normalized Walsh-Hadamard matrix, where the entry $h_{i,j}$ is equal to $(-1)^{\langle i-1, j-1 \rangle}$ and $\langle i, j \rangle$ is the inner product modulo 2 of the vectors corresponding to the binary representations of i and j . Finally, P is an $m \times d$ matrix where the entries are chosen independently as follows: With probability $1-q$, set $p_{i,j}$ to 0 and otherwise let $p_{i,j}$ be $\mathcal{N}(0, 1/q)$ distributed. Here

$$q = \min \left\{ \Theta((\lg^2 n)/d), 1 \right\}.$$

While the embedding algorithm seems more complicated, observe first that computing Dx takes $O(d)$ time since D is a diagonal matrix. Applying H can be done in $O(d \lg d)$ time using the fast Fourier transform. Finally, P has an expected $qmd = O(m \lg^2 n) = O(\varepsilon^{-2} \lg^3 n)$ non-zeroes; thus applying P can be done in $O(m \lg^2 n)$ time, resulting in an embedding time of $O(d \lg d + m \lg^2 n)$. This may or may not be faster than the original embedding time of $O(md)$ depending on the relationship between m and d , but for most natural values of m and d , this would be preferred.

Sparse Matrices. The second approach replaces the matrix A with a much sparser matrix C . If

C has few non-zeroes, then computing Cx can again be done faster than computing Ax . Before we present the results, let us first make another comment on the time it takes to compute Ax in the first algorithm we presented. Here A was an $m \times d$ matrix with all entries either -1 or $+1$. If our input vector x has few non-zeroes, then computing Ax can also be done faster. To see this, note that Ax is simply $\sum_j x_j a_j$ where a_j is the j 'th column of A . All terms in this sum where $x_j = 0$ can be ignored. Thus if we let $\|x\|_0$ denote the number of non-zero coordinates of x , the embedding time actually improves to $O(m\|x\|_0)$. In many real-life applications (such as the example of documents and w -shingles earlier), the input vectors are very sparse, and thus exploiting the sparsity is crucial. Also observe that the fast Johnson-Lindenstrauss transform above (computing PHD) cannot exploit the sparsity of x as applying H using the fast Fourier transform takes time $O(d \lg d)$ regardless of the sparsity of Dx .

Kane and Nelson (2014) proposed the following way to choose the matrix C : Let $m = \Theta(\varepsilon^{-2} \lg n)$ and let $s = \Theta(\varepsilon^{-1} \lg n)$. Think of the m output dimensions as being partitioned into s chunks of m/s consecutive coordinates each. In each column of C , we choose one uniform random entry in each chunk and set it uniformly at random to either $-1/\sqrt{s}$ or $+1/\sqrt{s}$. All other entries are set to 0. They proved that letting $f(x) = Cx$ for each point $x \in X$ also preserves all pairwise distances to within $(1 \pm \varepsilon)$ with high probability. The embedding time improves to $O(s\|x\|_0)$ instead of $(m\|x\|_0)$, saving an ε^{-1} factor over the original approach.

Feature Hashing. Taking the sparse matrix approach to the extreme, Weinberger et al. (2009) proposed *feature hashing*. Their suggestion is to simply have one non-zero in each column of C , placed at a uniform random location and being uniform random among $\{-1, +1\}$. This of course gives the fastest possible embedding time of just $O(\|x\|_0)$. The downside is that the algorithm only works with high probability if the difference between any two input vectors is *spread out* on

many coordinates. More concretely, the current best analysis due to Dahlgaard et al. (2017) proves that feature hashing preserves all pairwise distances to within $(1 \pm \varepsilon)$ with high probability, as long as all pairwise differences $x - y$ satisfy that

$$\|x - y\|_\infty = O\left(\|x - y\|_2 \sqrt{\frac{\varepsilon \lg(1/\varepsilon)}{\lg n \lg(mn)}}\right).$$

Here $\|x - y\|_\infty$ is the largest absolute value of a coordinate in $x - y$. Thus feature hashing works as long as for any pairwise difference $x - y$, there is no single coordinate that is responsible for a large fraction of the distance between x and y . Feature hashing seems to work very well in practice and has been successfully applied in many applications.

Remarks In both feature hashing and the sparse matrix approach, we described the algorithms as first computing the matrix C and then computing Cx when embedding a point. In the introductory example with w -shingles, the input dimension d was 10^{25} , making it infeasible to store C explicitly. What one does instead is to use a *hash function* that allows you to compute the columns of C corresponding only to the non-zero coordinates of an input vector x . Thus C is never stored explicitly. We refer the reader to Kane and Nelson (2014) for how to implement a hash function for their sparse approach and to the paper by Dahlgaard et al. (2017) for suggestions and experiments on how to implement feature hashing in practice.

Examples of Application

Dimensionality reduction in the form presented in this chapter is of course only applicable in applications where Euclidian distance between data points is a natural similarity measure. For text documents, if we have a coordinate for each w -shingle (w consecutive words) counting how many times it occurs in the text, using Euclidian

distance as a similarity measure makes good sense.

Dimensionality reduction may also serve as a preprocessing step in nearest neighbor search applications. In (Euclidian) nearest neighbor search, we must store a set of high-dimensional points X , such that when given a query point q , we can efficiently find the point $x \in X$ that is closest (most similar) to q . An important property of all the above algorithms is that they are all based on sampling a random matrix *independently* of the data points. Thus if we are to store a set of high-dimensional points X for nearest neighbor search, what we can do instead is as follows: Sample a matrix A (using any of the distributions described earlier) and compute $f(x) = Ax$ for each $x \in X$. Store the embedded data set in a data structure for nearest neighbor search (on m -dimensional points instead of d -dimensional points). When we wish to answer a query q (find the point closest to q), we first compute $f(q) = Aq$ and then search for the nearest point $f(x)$ to $f(q)$. If this finds a point $f(x)$ of distance a from $f(q)$, we know that the original point x has distance at most $(1 + \varepsilon)a$ from q and thus is also very close to q . The crucial point here is that A was chosen independently of q (and X), and thus one can simply apply the standard analysis on the point set $X \cup \{q\}$ to conclude that the distance from q to any point in X is preserved to within $(1 \pm \varepsilon)$ with high probability. For more information on nearest neighbor search in high dimensions, see, e.g., the survey Andoni and Indyk (2008).

Another exciting application of dimensionality reduction is in k -means clustering. In k -means clustering, we are given a set of n points $X = \{p_1, \dots, p_n\}$ in d -dimensional space. The goal is to find k cluster centers $\mu_1, \dots, \mu_k \in \mathbb{R}^d$ such that

$$\sum_{p_i \in X} \min_j \|\mu_j - p_i\|_2^2$$

is minimized. That is, we have to find the set of k centers such that the sum of squared distances from each data point to its nearest center is minimized. Lloyd's algorithm and the k -means++ algorithm in Arthur and Vassilvitskii (2007) give

efficient heuristics for finding good clusterings (finding the optimal clustering is known to be NP-hard). These algorithms have a running time of $O(tknd)$ where t is the number of iterations of local improvements. Boutsidis et al. (2009) proposed that one first performs dimensionality reduction on the input data in order to speed up Lloyd’s algorithm and the k -means++ algorithm. More concretely, they proved that if the embedded point set preserves all distances to within $(1 \pm \varepsilon)$, the cost of all clusterings are also preserved to within $(1 \pm \varepsilon)$. Thus one can run clustering algorithms on $m = O(\varepsilon^{-2} \lg n)$ dimensional points and find almost as good clusterings as before. This reduces the running time from $O(tknd)$ to $O(tknm)$ plus the time for the embedding. The current state of the art in dimensionality reduction for k -means clustering can be found in Cohen et al. (2015) where bounds better than $m = O(\varepsilon^{-2} \lg n)$ can be obtained for small values of k .

Future Directions for Research

A number of important open problems remain. We will present a few in the following.

Best Sparsity Achievable. As we saw earlier, the current best approach using sparse matrices has $O(\varepsilon^{-1} \lg n)$ non-zeroes in each column of the embedding matrix C . Since the number of non-zeroes per column dictates the running time, finding even sparser (random) matrices that work for any point set is an important open problem. So far, we know that one must have at least $\Omega(\varepsilon^{-1} \lg n / \lg(1/\varepsilon))$ non-zeroes per column if one insists on embedding into the optimal number of dimensions $m = O(\varepsilon^{-2} \lg n)$, see Nelson and Nguyen (2013). Thus there remains a gap of $\lg(1/\varepsilon)$ between the upper and lower bounds.

Best Feature Hashing Guarantees. Feature hashing took the extreme approach and had only one non-zero entry per column of C . Since this is already more sparse than the above lower bound tells us is possible, this comes at the cost of only having any guarantees when no coordinates

are too large in any pairwise difference vector $x - y$. It remains an open problem whether the requirement

$$\|x - y\|_\infty = O\left(\|x - y\|_2 \sqrt{\frac{\varepsilon \lg(1/\varepsilon)}{\lg n \lg(mn)}}\right).$$

is necessary or if perhaps feature hashing works with even larger coordinates.

Fast Johnson-Lindenstrauss Transforms. We also studied the fast Johnson-Lindenstrauss transform and saw that it gave an embedding time of $O(d \lg d + m \lg^2 n)$. Can this be improved to something closer to $O(d + m)$? Or maybe $O((d + m) \lg d)$?

Overview

In this chapter, we discuss approaches leveraging distant supervision for relation extraction. We start by introducing the key ideas behind distant

supervision as well as their main shortcomings. We then discuss approaches that improve over the basic method, including approaches based on the at-least-one-principle along with their extensions for handling false negative labels, and approaches leveraging topic models. We also describe embeddings-based methods including methods leveraging convolutional neural networks. Finally, we discuss how to take advantage of auxiliary information to improve relation extraction.

D

Definitions

Definition 1 A *knowledge graph*, or knowledge base, is a semantic network defined as a set of triples (s, p, o) specifying that a node s (subject) is connected to another node o (object) by the property p . Sets of such triples form a directed graph, where nodes in the graph represent the subject and object in the triples and labeled edges represent the predicates connecting the subjects to the values. Generally, knowledge graphs can be seen as a collection of RDF triplets (see <https://www.w3.org/RDF/>).

Definition 2 *Distant supervision* is a technique to automatically annotate input data using information contained in the knowledge graph. Given a knowledge graph \mathcal{G} and a text corpus \mathcal{C} (i.e., a collection of texts), the key idea of distant supervision is to align \mathcal{G} to \mathcal{C} . More specifically, the idea is to first collect those sentences from the corpus \mathcal{C} that mention the entity pair (e_1, e_2) where both e_1 and e_2 exist in the knowledge graph \mathcal{G} . If a sentence mentions (e_1, e_2) and there exists one triple (e_1, r, e_2) in the knowledge graph, then the distant supervision approach *labels* this sentence as an instance (also called *mention*) of relation r . The task of extracting such triples from raw text is called *relation extraction*.

Basic Approach

The idea of using a knowledge graph as a source of labels for training data was first proposed

by Mintz et al. (2009) and relies on the following assumption:

Assumption 1 *If two entities participate in a relation, any sentence that contains those two entities might express that relation.*

For example, the following sentence:

South African entrepreneur **Elon Musk** is known for founding **Tesla Motors** and SpaceX.

mentions the tuple (*Elon Musk*, *Tesla Motors*). Assuming that the triple (*Elon Musk*, *created*, *Tesla Motors*) exists in the knowledge graph, the textual sentence is labeled with the relation *created* and can be used as training data for subsequent relation extractions. In this context, the set of sentences sharing the same entity pair is typically called a *bag of sentences*.

The relation extraction task can be considered as a classification problem, where the goal is to predict, for every entity pair, the relation it participates in from multiple classes. The classifier needs training data where every entity pair is represented as a *feature vector* (a binary representation of the input) and labeled with a corresponding relation. After learning on the training data, the testing step is performed, where the classifier predicts the relation labels for previously unseen entity pairs.

The transformation of the text corpus \mathcal{C} into a usable training set involves several steps illustrated in Fig. 1. The first step is a preprocessing step where classical natural language processing

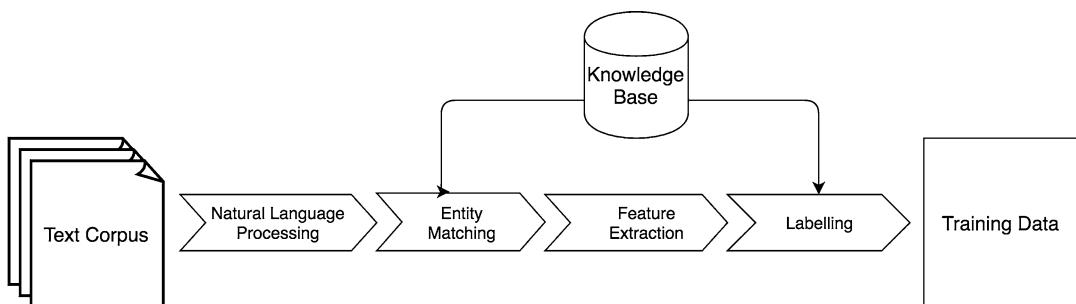

tools are used to identify potential entities from the text.

The second step, entity matching, takes as input the textual entities identified in the previous step and tries to match them to one of the instances in the knowledge graph (e.g., it tries to match “William Tell” as found in the text to its corresponding instance in Wikidata, e.g., instance number “Q30908” (see <https://www.wikidata.org/wiki/Q30908>)).

In the third step, sentences where two entities are correctly matched to the knowledge graph are processed to extract features. Two types of features, lexical and syntactic, were originally proposed by Mintz et al. (2009). Similar features were used in many subsequent approaches. Lexical features include the sequence of words between the two entities, flags indicating which entity name comes first in the sentence as well as the words immediately to the left of the first entity and to the right of the second entity. In addition to these features, syntactic features can be taken from a dependency parser – which extracts syntactic relations between words such as the dependency path between two entities.

Finally, the last step is called labeling, i.e., obtaining relation labels corresponding to the entity pair from the knowledge graph.

The test set is obtained as above when generating training data, except for the labeling part, i.e., the first three steps (natural language processing, entity matching, and feature extraction) remain the same. After the training and test sets are constructed, a standard classifier can be applied for relation extraction. In this context, Mintz

Distant Supervision from Knowledge Graphs, Fig. 1 The pipeline of preparing training data with distant supervision

et al. (2009) used a multi-class logistic classifier optimized using L-BFGS with Gaussian regularization.

Shortcomings of Distant Supervision

Automatically labeled training data are typically noisy, i.e., they contain false positives and false negatives, and this is also the case for distant supervision. On one hand, false negatives are mostly caused by the incompleteness of the knowledge graph. Two entities can be related in reality, but their relation might be missing in the knowledge graph; hence their mentions will be wrongly labeled as negative examples by distant supervision. On the other hand, two entities may appear in the same sentence because they are related to the same topic, but not necessarily because the sentence is expressing the relation. Such examples might yield false positives using distant supervision.

Distant Supervision Improvements

This section lists several extensions aimed at improving the basic distant supervision method.

At-Least-One Principle

Riedel et al. (2010) replace Assumption 1 with the following:

Assumption 2 *If two entities participate in a relation, at least one sentence that mentions those two entities will express that relation.*

This relaxed assumption, while more intuitive, comes at the cost of a more challenging classification problem. To tackle this problem, the authors propose an undirected graphical model that solves both the task of predicting a relation between two entities and the task of predicting which sentence expresses this relation. The model is developed on top of a *factor graph*, a popular probabilistic graphical network representation where an undirected bipartite graph connects relation *variables* with *factors* representing their joint probabilities.

The original model cannot capture the case when two entities participate in more than one relation. In our above example, the relation between *Elon Musk* and *Tesla Motors* is not only *co-founder_of* but also *CEO_of*. Hoffmann et al. (2011) and Surdeanu et al. (2012) propose undirected graphical models, called MultiR and MIML – RE, respectively, to perform *multi-instance multi-label* classification. Both models infer a relation expressed by a particular mention; thus the models are able to predict more than one relation between the two entities. The MultiR model is a conditional probability model that learns a joint distribution of both mention-level and bag-level assignments. The MIML – RE model contains two layers of classifiers. The first-level classifier assigns a label to a particular mention. The second level has k binary classifiers, where k is the number of known relation labels for the particular pair of entities. Each bag-level classifier y_i decides if the relation r_i holds for the given entity pair, using the mention-level classifications as input.

Negative Labels

In distant supervision, the knowledge graph only provides positive labels. Thus, negative training data is produced synthetically, e.g., by sampling the sentences containing two entities which are not related in the knowledge graph. The standard method to generate negative training data is to label mentions of unrelated entity pairs as negative samples. However, since the knowledge graph is incomplete, the absence of any relation label does not necessarily mean that the corresponding entities are not related. Hence, such a method potentially brings additional errors to the training data.

Several extensions of this model are proposed to overcome this problem. Min et al. (2013) propose an additional layer to MIML – RE in order to model the bag-level label noise. Ritter et al. (2013b) extend the MultiR model to handle missing data. Xu et al. (2013) explore ideas to enhance the knowledge graph, i.e., to infer entity pairs that are likely to participate in a relation even if they are unlabeled in the knowledge graph, and add them as positive samples.

Fan et al. (2014) propose an alternative approach to tackle the problems of both erroneous labeling and incompleteness of the knowledge graph. They formulate the relation extraction task as a *matrix completion* problem.

Topic Models

Another widely used approach to improve text analysis and text classification is topic models. In this context, topics represent clusters of terms (words or patterns) which often co-occur in the documents together. The goal of topic models is to assign a topic to every term.

Topic models can be applied to distant supervision by mapping a *document* to a sentence mentioning an entity pair and a *topic* to a relation. Words are represented by lexical and syntactic features, such as POS-tags or dependency paths between the entities. While the mention-level classifiers described above assign a relation to every sentence individually, the topic model classifiers are capable to capture more general dependencies between textual patterns and relations, which in practice can lead to improved performance.

Yao et al. (2011) propose a series of generative probabilistic models in that context. Though the presented models are designed for unsupervised, open relation extraction (i.e., the set of the target relations is not prespecified), the authors also show how the detected clusters can improve distantly supervised relation extraction. All their proposed models are based on *latent Dirichlet allocation* (LDA). The models differ in the set of features used and thus in their ability to cluster patterns. The advantage of generative topic models is that they are capable to “transfer” information from known patterns to unseen patterns, i.e., to associate a relation expressed by an already observed pattern to a new pattern.

Alfonseca et al. (2012) distinguish patterns that are expressing the relation from the ones that are not relation-specific and can be used across relations. For instance, the pattern “was born in” is relation-specific, while the pattern “lived in” can be used across different relations, i.e., *mayorOf* or *placeOfDeath*. Their proposed models are also based on LDA. Different submodels

have been suggested to capture three subsets of patterns:

- general patterns that appear for all relations;
- patterns that are specific for entity pairs and not generalizable across relations;
- patterns that are observed across most pairs with the same relation (i.e., relation-specific patterns).

Embedding-Based Methods

The methods discussed above are based on a large variety of lexical and syntactic features. We discuss below approaches that map the textual representation of relations and entity pairs onto a vector space. A mapping from discrete objects, such as words, to vectors of real number is called an embedding in this context. Embedding-based approaches for relation extraction do not require extensive feature engineering and natural language processing, but they still require NER tags to link entities in the knowledge graph with their textual mentions.

Riedel et al. (2013a) apply matrix factorization for the relation extraction task. The authors compute a low-rank factorization of the probability matrix M , where rows correspond to entity pairs and columns correspond to relations. The elements of the matrix correspond to the probability that a relation holds between two entities. This factorization provides an embedding of entity pairs and of relations, which is then used to predict the probability of new triplets using a logistic function and one of the following feature models:

1. The latent feature model (F) defines $\theta_{r,t}$ as a measure of compatibility between relation r and tuple t via the dot product of their embeddings a_r and v_t , respectively.
2. The neighborhood model (N) defines $\theta_{r,t}$ as a set of weights $w_{r,r'}$, corresponding to a directed association strength between relation r and r' , where both relations are observed for tuple t .

3. The entity model (E) also measures a compatibility between tuple t and relation r , but it provides latent feature vectors for every entity and every argument of relation r and thus can be used for n -ary relations. Entity types are implicitly embedded into the entity representation.
4. The combined model (NFE) defines $\theta_{r,t}$ as a sum of the parameters defined by the three above models.

Neural Networks

Another direction in text classification is applying convolutional neural networks (CNNs). CNNs are able to find specific n -grams in the text and classify the relations expressed in the sentences based on these n -grams.

Zeng et al. (2015) perform relation extraction via piecewise convolutional neural networks (PCNNs). The learning procedure of PCNNs is similar to standard CNNs. It consists of four parts: *vector representation, convolution, piecewise max pooling and softmax output*. In contrast to the embedding-based approaches above, the proposed model does not build word embeddings itself but uses pre-trained word vectors instead. Additionally, the model encodes a position of the word in the sentence with *position features* introduced by Zeng et al. (2014). Position features represent the relative distance between the current word in the sentence and both entities of interest e_1 and e_2 . The vector representation of a word is then the concatenation of word embedding and a position feature. In their work, the authors consider that the model predicts a relation for a bag (i.e., for an entity pair) if and only if a positive label is assigned to at least one entity mention.

Lin et al. (2016) extend the PCNN approach. The authors explore different methods to overcome the wrong labeling problem. More specifically, the model learns weights of the sentences in a bag in order to select sentences that are true relation mentions. Two ways of defining the weights are explored:

- Average, where every sentence has the same weight;

- Selective Attention, where sentence weight depends on the query-based function which scores how well the sentence expresses a given relation.

D Leveraging Auxiliary Information for Supervision

A number of distant supervision improvements use additional knowledge to enhance the model. Angeli et al. (2014) and Pershina et al. (2014) study the impact of extending training data with manually annotated data, which is generally speaking more reliable than the labels obtained from the knowledge graph. Pershina et al. (2014) propose to perform feature selection to generalize human labeled data into training guidelines and include them into the MIML – RE model. Angeli et al. (2014) propose to initialize the MIML – RE model with manually annotated data, since the original model is sensitive to initialization. As manual annotation is very expensive, carefully selecting which sentences to annotate is of utmost importance. The authors study several criteria to pick the most valuable sentences for manual annotation.

Another explored direction is improving entity identification, i.e., extract sentences mentioning entities not only by their canonical names but also by abbreviated mentions, acronyms, paraphrases, and even pronouns. Given the following sentences:

Elon Musk is trying to redefine transportation on earth and in space.
Through Tesla Motors – of which he is cofounder, CEO and Chairman – he is aiming to bring fully-electric vehicles to the mass market.

The second sentence contains a relation mention (Elon Musk, cofounderOf, Tesla Motors) that cannot be extracted without *co-reference resolution*, which refers to the task of clustering mentions of the same entity together, typically within a single sentence or document.

Augenstein et al. (2016) explore a variety of strategies for making entity identification tools more robust across domains. Moreover, they per-

form co-reference resolution for extracting relations across sentence boundaries. The approach is designed to perform relation extraction on very heterogeneous text corpuses, such as those extracted from the Web.

Koch et al. (2014) use entity types and co-reference resolution for a more accurate relation extraction. Two sets of entity types are available: coarse types (PERSON, LOCATION, ORGANIZATION, and MISC) come from the named entity recognizer (NER), while fine-grained types come from the knowledge graph. To bring type-awareness into the system, the authors build separate relation extractors on top of the MultiR model for each pair of coarse types, e.g., (PERSON, PERSON), (PERSON, LOCATION), and combine the extractions from the extractors of every type signature. Candidate mentions with incompatible entity types are then discarded, which improves precision at the cost of a slight drop in recall.

Chang et al. (2014) propose a tensor decomposition approach that also uses entity-type information and can be stacked with other models. In particular, it helps to overcome the fact that the matrix factorization model does not share information between rows, i.e., between entity pairs (including pairs containing the same entity).

Type-LDA is a topic model proposed by Yao et al. (2011) that considers fined-grained entity types based on latent Dirichlet allocation. In contrast to the previous approaches, it learns fine-grained entity types directly from the text.

Finally, a few relation extraction approaches integrate logical connections or constraints between the relations. As an example, the relation *capitalOf* between two entities directly implies another relation *cityOf*. Furthermore, many relation pairs are mutually exclusive, e.g., *spouseOf* and *parentOf*.

Rocktäschel et al. (2015) propose to inject logical formulae into the relations and entity pair embeddings. Their model is based on the matrix factorization approach from Riedel et al. (2013a). They explore two methods, namely, pre-factorization inference and joint optimization, and choose to focus on direct relation implication.

The approach proposed by Han and Sun (2016) is also based on the idea of using indirect supervision. The authors rely on a Markov logic network as a representation language and use:

- the consistency of relation labels, i.e., the interdependencies between relations that were mentioned previously (implications and mutual exclusion);
- the consistency between relation and arguments, i.e., entity-type information retrieved from the knowledge graph is used to filter inconsistent candidates;
- the consistency between neighboring instances: the authors define the similarity function between two relation candidates as the cosine similarity of their feature vectors.

Technology, Wuhan, China

Definitions

File system is a subsystem of an operating system which aims to organize, retrieve, and store data files. A distributed file system (DFS) is a file system with files shared on dispersed storage resources across a network. The DFS makes it convenient to share files among clients in a controlled and authorized manner, and the clients can benefit from DFS since they can locate all the file shares within a single server or domain name.

Overview

A wide variety of applications of big data analytics rely on distributed environments to analyze large amounts of data. As the amount of data increases, the need to provide reliable and efficient storage solutions has become one of the main concerns of big data infrastructure administrators. The traditional systems and methods of storage are suboptimal due to their price or performance restrictions, while DFS, as a paradigm shift in the storage arena, has been developed to

Distributed File Systems, Table 1 Types of transparencies

Transparency	Description
Access	Clients can access the files in a DFS in the same way as in a local file system
Location	Clients are unaware of the physical location of files
Concurrency	Clients have the same view of the state of the file system
Replication	Clients are unaware of replication of files across multiple servers
Migration	Clients are unaware of the movement of files across multiple servers

bring convenience to sharing files in both local area networks (LANs) and wide area networks (WANs).

The convenience is mainly brought by the technique of *transparency*. Transparency makes files accessed, stored, and managed on the local client machines, while the transparency process is actually held on the servers, such that the DFS implements its access control and storage management control to the client machines efficiently in a centralized way via the network file system, and one or more central servers store files that can be accessed by any client in the network. In other words, a DFS is a distributed implementation of the classical time-sharing model of a file system with multiple clients dispersed across the whole network of multiple and independent clients and makes it possible to restrict access to the file system depending on access lists or capabilities on both the servers and the clients.

The main goal of transparency in the DFS is to hide from the clients the fact that processes and resources are physically distributed across the network and provide a common view of a centralized file system. That is, DFS aims to be “invisible” to clients, who consider the DFS to be similar to a local file system. The different types of transparencies are listed in Table 1.

Key Points of Reliability

Reliability is of special significance in DFSes because the usage site of files can be different from

their storage site, so failure modes are substantially more complex in DFSes compared to local file systems. Replication and erasure coding are two typical techniques to achieve high reliability, and the following are key research findings based on the above two reliability schemes.

Replication Policy

DFSes use replication by making several copies of a data file on different servers. When a client requests the file, he transparently accesses one of the copies.

Replica placement plays a critical role in both performance and reliability of DFSes. Replicas are stored on different servers according to a placement scheme. Many DFSes (e.g., HDFS (Shvachko et al. 2010), GFS (Ghemawat et al. 2003)) use *random replication* as default, in which replicas are stored randomly on different nodes, on different racks, at different geographical locations, so that if a fault occurs anywhere in the system, data is still available. However, it cannot effectively separate the cluster into tiers while maintaining cluster durability and thus is quite susceptible to frequent data loss due to correlated failures. Facebook HDFS implementation (Borthakur et al. 2011) limits the placement of block replicas to smaller groups of nodes, thereby reducing the block loss probability with multiple node failures. Nonrandom replication schemes, like Copyset Replication (Cidon et al. 2013), improve Facebook scheme, by restricting the replicas to a minimal number of sets for a given scatter width. Scarlett (Ananthanarayanan et al. 2011) carefully stores replicas based on workload patterns to alleviate hotspots. Sinbad (Chowdhury et al. 2013) improves write performance by identifying the variance of link capacities in a DFS and avoiding storing replicas on nodes with congested links. Also, some studies address the efficient transitions between replication and erasure coding schemes (called *asynchronous encoding*) in DFSes. AutoRAID (Wilkes 1996) leverages access patterns to switch between replication for hot data and RAID-5 for cold data. DiskReduce (Fan et al. 2009) addresses the transition replication to erasure coding in

HDFS. EAR (Li et al. 2015) focuses on how replica placement affects the performance and reliability of asynchronous encoding.

In addition, replication disperses multiple copies of a file, and the changes have to be propagated to all the replicas in a consistent manner, especially in *cache consistency*, that is, how to update all copies of a data in cache when one of them is modified. The first method to ensure cache consistency is *write once read many* (WORM) (Quinlan 1991), in which cached files are in read-only mode (i.e., once a file is created, it cannot be modified) such that only the latest version of the data can be read. The second method is *transactional locking* (Dice et al. 2006), in which a read lock is obtained on the requested data file such that any other clients cannot write this file or a write lock in order is obtained to prevent any access on this file, allowing that each read reflects the latest write and each write is done in order. The third method is *leasing* (Gray and Cheriton 1989), in which the client is guaranteed that any other client cannot modify the data when the data file is requested during the lease. When the lease expires or the client releases its rights, the file is available again.

Erasure Coding

DFSes typically adopt replication as the fault tolerance scheme, while more and more studies propose and implement efficient erasure codes in DFSes for lower storage overhead. Zhang et al. (2010) apply erasure coding on the write path of HDFS to study the performance impact on various MapReduce (Dean and Ghemawat 2013) workloads. Silberstein et al. (2014) propose lazy recovery for erasure-coded storage to reduce repair bandwidth. Li et al. (2014) also propose degraded-first scheduling to improve scheduling of MapReduce jobs running on erasure-coded storage. HACFS (Xia et al. 2015), built on HDFS, dynamically switches encoded blocks between two erasure codes to balance storage overhead and repair performance. Repair pipelining (Li et al. 2017) speeds up the repair performance as a middleware system on HDFS. Many enterprises (e.g., Google (Ghemawat et al. 2003), Azure (Huang et al. 2012), and Facebook (Mu-

ralidhar et al. 2014)) have also deployed erasure coding in production DFSes to reduce storage overhead. Piggybacked-RS codes (Rashmi et al. 2013, 2014) embed parities of one stripe into that of the following stripe, thereby reducing repair bandwidth, which have also been evaluated in Facebook clusters. Facebook f4 (Muralidhar et al. 2014) protects failures at different levels including disks, nodes, and racks, by manipulating different redundancies of erasure coding.

Some studies propose new erasure code constructions and evaluate their applicability in DFSes. Local repairable codes (LRC) are a new family of erasure codes that reduce I/O during recovery by limiting the number of surviving nodes to be accessed. Azure's LRC (Huang et al. 2012) and Facebook's LRC (Sathiamoorthy et al. 2013) present and design a novel family of LRCs that are efficiently repairable based on a trade-off between locality and minimum distance.

Regenerating codes (Dimakis et al. 2007) are a state-of-the-art family of erasure codes that achieve the optimal trade-off between storage redundancy and repair traffic in DFSes. Constructions of regenerating codes have been proposed and implemented in DFSes, such as FMSR codes (Hu et al. 2012, 2017a), PM-RBT codes (Rashmi et al. 2015), and Butterfly codes (Pamies-Juarez et al. 2016). CORE (Li et al. 2015) extends regenerating codes to support the optimal recovery of multi-node failures atop HDFS. DoubleR (Hu et al. 2017b) proposes and implements new regenerating code constructions for hierarchical data centers atop HDFS.

Examples of Application

DFSes are the foundation of storage mechanisms of big data applications. Google GFS (Ghemawat et al. 2003) is an expandable DFS to support large-scale and data-intensive applications, using commodity servers to provide data reliability and high-performance services. In addition, there are other solutions to achieve different demands for storage of big data. For example, HDFS (Shvachko et al. 2010) is a derivative of open-source codes of GFS. Microsoft uses Cosmos

(Chaiken et al. 2008) to support its search and advertisement business. Facebook uses Haystack (Beaver et al. 2010) to store a large number of photos.

DFSes have been relatively mature after years of development, and it is hard to make a complete study given the number of existing DFSes. This section chooses to study two popular DFSes, HDFS (Shvachko et al. 2010) and Ceph (Weil et al. 2006a), from four aspects: architecture, client access, replication, and fault detection.

HDFS

Architecture: An HDFS cluster consists of a single *namenode*, which is the master node that manages the file system namespace and regulates the access to files by clients. The data stream is divided into blocks distributed across *datanodes*, which manage the storage attached to the nodes that they run on. HDFS provides a secondary namenode as a persistent copy of the namenode to handle namenode failures by restoring the namespace from the secondary namenode. The namenode executes different file system operations like opening, closing, and renaming files and directories. The datanodes serve clients' read or write requests and also perform block creation, deletion, and replication from the namenode.

Client Access: HDFS uses a code library that allows clients to read, write, and delete file and create and delete directories. Clients use a file's path in the namespace to access it, contact the namenode to get or put files' blocks, and do the transfer by connecting directly with the datanodes.

Replication Policy: HDFS divides data into blocks which are replicated across datanodes according to a placement policy, by which each datanode holds at most one copy of a block and each rack holds at most two copies of the block. The namenode verifies that each block follows the above policy: (1) when a block is over-replicated, the namenode removes a replica on the datanode that has the least amount of available space and tries not to reduce the number

of racks; (2) when a block is under-replicated, the namenode creates a new replica and places it in a priority queue which is verified periodically; and (3) when all replicas of a block are on the same rack, the namenode will add a new replica on a different rack to trigger the over-replicated policy.

Fault Management: Each datanode compares the software version and the namespace ID with those of the namenode. If they don't match, the datanode shuts down to preserve the integrity of the system. Datanodes do a registration with the namenode whenever they restart with a different IP address or port. After this registration and every hour, datanodes tell a current view of the location of each block to the namenode. Every 3 s, datanodes send heartbeats to the namenode, and the namenode considers datanodes as failed if it does not receive any heartbeats during 10 min.

Ceph

Architecture: Ceph uses metadata servers (MDS) to provide a dynamic distributed metadata management by performing queries of metadata and managing the namespace. Ceph stores data and metadata in object storage devices (OSDs) which mainly perform I/O operations. Ceph stripes each data into blocks which are assigned to objects, which are identified by the same inode number plus an object number and placed on storage devices using a function called CRUSH (Weil et al. 2006b).

Client Access: Ceph uses MDSs to get the inode number and the file size for client requests. Then, the client can calculate how many objects comprise the file and contacts the OSDs to get the data via CRUSH.

Replication Policy: Ceph stores data as objects which are put on different placement group (PG) and then stored on OSDs, which are chosen by the CRUSH. Ceph has three synchronous replication strategies, primary-copy, chain, and splay replication: (1) primary-copy replication updates all replicas in parallel; (2) chain replication updates

replicas in series; and (3) splay replication combines the parallel updates of primary-copy replication with the serial updates of chain replication.

Fault Management: Each OSD periodically exchange heartbeats to detect failures. Ceph has monitors that implement management of the cluster map. Each OSD can send a failure report to any monitor. When OSDs fail, monitors detect and maintain a valid cluster map.

Future Directions for Research

Although DFSes (e.g., HDFS) have become a mainstay in big data analytics file system platform, there are still improvements to be made. First, many DFSes (e.g., GFS and HDFS) originally designed for large files cannot meet the storage requirements of lots of small files, which will lead to the production of a large number of metadata, affect the metadata server management and restorability, and decline the entire system performance. Second, many DFSes have multiple copies (six copies in many cases) due to the need for data locality in maintaining performance, which makes it harder for already “big” data to store. Third, many DFSes often offer very limited SQL support and lack basic SQL functions which are actually useful for big data analytics. Finally, some DFSes for big data storage organize thousands or even hundreds of thousands of servers, which incurs substantial energy consumption, and thus the deployment of DFS should consider its energy efficiency.

- ▶ [Distributed Incremental View Maintenance](#)
-
- ## Distributed Incremental View Maintenance
- Milos Nikolic
University of Oxford, Oxford, UK
- ### Synonyms
- [Distributed Incremental Query Computation](#); [Distributed View Update](#)
- ### Definitions
- A database view is a virtual table defined by a query over the given data sources. Database systems recompute the contents of a view upon each reference to its name. A materialized view precomputes and stores the result of its definition query. Incremental view maintenance keeps the contents of materialized views up-to-date for changes in the source relations. Distributed incremental view maintenance is the procedure of updating materialized views when the data is distributed at multiple sites in a computer network.
- ### Overview
- Modern applications require real-time analytics over changing datasets. In a growing number of domains – Internet of Things (IoT), clickstream

analysis, algorithmic trading, network monitoring, and fraud detection to name a few – applications monitor streaming data to promptly detect certain patterns, anomalies, or future trends. Such applications implement their logic using queries, or *views*, that continuously provide up-to-date results as the underlying data changes.

Providing fresh analytical results by recomputing views from scratch on every change is almost always inefficient. Since most datasets evolve through small changes, storing (materializing) previously computed results and combining them with incoming changes can yield computationally cheaper methods for updating query results. Maintaining the contents of a materialized view up to date for changes in its base relations is known as *incremental view maintenance* (IVM). Materialized views and incremental view maintenance are critical for speeding up the execution of frequently asked queries in database systems (e.g., Oracle, SQL Server, and DB2 all support incremental view maintenance) and achieving high-throughput, low-latency processing in stream management systems (Murray et al. 2013; Chandramouli et al. 2014; Zaharia et al. 2013; Nikolic et al. 2016). Chirkova and Yang (2012) survey the topic of materialized views.

Emerging data-intensive applications also demand scalable systems for querying and managing large datasets. In applications with large stateful working sets, like real-time data warehouses, distributed execution aims to speed up query evaluation and accommodate growing memory requirements. Scalable behavior is also essential when processing many concurrent activities like in IoT applications, which typically run the same query logic over a large collection of signals from sensor devices.

This chapter studies the topic of incremental view maintenance in distributed environments. It starts with an overview of incremental computation in local settings and then presents a technique for transforming local maintenance programs into data-parallel processing tasks. This technique applies a set of optimizations to speed up the maintenance task and minimize network overheads during distributed execution.

Incremental View Maintenance

Materialized views require maintenance to keep their contents up to date with changes in base tables. Refreshing materialized views using recomputation is expensive for frequent, small-sized updates. In such cases, applying only incremental changes, or *deltas*, to materialized views is often more efficient than recomputing the views from scratch.

Consider a materialized view represented as a pair $(Q, M(\mathbf{D}))$, where Q is the view definition query expressed in a declarative language such as SQL and $M(\mathbf{D})$ is the materialized contents of Q on a given database \mathbf{D} . When the database changes from \mathbf{D} to $(\mathbf{D} + \Delta\mathbf{D})$, where $\Delta\mathbf{D}$ can contain inserts, deletes, and updates to base tables, incremental view maintenance evaluates a delta query ΔQ to refresh $M(\mathbf{D})$.

$$M(\mathbf{D} + \Delta\mathbf{D}) = M(\mathbf{D}) + \Delta Q(\mathbf{D}, \Delta\mathbf{D})$$

Classical incremental view maintenance computes ΔQ on every input change $\Delta\mathbf{D}$. The delta ΔQ involves typically smaller delta tables instead of large base tables, thus computing ΔQ and updating $M(\mathbf{D})$ becomes cheaper than reevaluating Q from scratch. Incremental view maintenance derives one delta query for each referenced base table. The derivation process relies on a set of change propagation rules defined for each operator of the view definition language. Each derived delta query takes its role in the associated view maintenance trigger.

Example 1 Consider query Q that counts the tuples in the natural join of $R(A, B)$, $S(A, C, D)$, and $T(A, C, E)$.

```
Q = SELECT SUM(1)
    FROM R NATURAL JOIN S
        NATURAL JOIN T
```

For succinctness, the query is written as $Q = \text{Sum}_{[]} (R \bowtie S \bowtie T)$, where $[]$ denotes no group by variables. Let M_Q be the materialized view storing the result of Q . Incremental view maintenance keeps the contents of M_Q fresh for changes in the base relations. For instance, the

maintenance trigger handling a set of insertions ΔR into R is (the schemas are omitted for clarity):

```
ON UPDATE R BY ΔR:
M_Q += Sum[ ](ΔR ⋈ S ⋈ T)
R += ΔR
```

This trigger first increments the count by computing the delta query for updates to R and then updates the contents of R . In practice, ΔR is often much smaller than R , making incremental computation cheaper (faster) than reevaluation.

□

Data Model. Storing materialized views as generalized multiset relations (Koch 2010; Green et al. 2007) greatly simplifies the view maintenance task. Under this data model, each relation is treated as a map (dictionary) containing a finite number of unique tuples (keys) mapped to a non-zero payload (value). Such relations can uniformly represent insertions and deletions as tuples mapping to positive and, respectively, negative payloads (multiplicities). This unified representation admits simpler, more efficient view maintenance where insertions and deletions are commutative (i.e., applicable to the database in any order) and follow the same set of delta rules, which contrasts with the view maintenance under classical set and bag (multiset) semantics (Qian and Wiederhold 1991; Griffin and Libkin 1995).

This unified model also allows using tuple payloads for storing (potentially non-integer) aggregate values (e.g., SUM, AVG). Traditional SQL represents these aggregates as separate columns in the query result, while this model keeps them in the payload to facilitate incremental processing – updating aggregate values means changing only tuple payloads rather than deleting and inserting tuples from the result.

Query Language. The query language for generalized multiset relations consists of union $+$, natural join \bowtie , selection σ_θ , and grouping sum aggregation $\text{Sum}_{A;f}$. These operations naturally generalize those on multiset relations: for instance, $Q_1 \bowtie Q_2$ matches tuples of Q_1 with tuples of Q_2 on their common columns, multiplying their payloads (multiplicities); the SQL equivalent of $\text{Sum}_{A;f} R$ is `select A, SUM(f)`

from R group by A , except that the aggregate value is stored inside the payload of the group by tuples; for clarity, $\text{Sum}_A R$ is used when $f = 1$. This fragment of the language suffices to express flat queries with sum aggregates; Koch et al. (2014) further extend this language to support queries with nested aggregates.

Delta Queries. Delta queries capture changes in query results for updates to base relations. For any query expression Q expressed as an operator tree, its delta query ΔQ is constructed by applying delta derivation rules to the tree in a bottom-up fashion. If Q represents a relation R , then $\Delta Q = \Delta R$ if there are updates to R and $\Delta Q = 0$ otherwise. The delta rules for the other operators are:

$$\begin{aligned}\Delta(Q_1 + Q_2) &:= \Delta Q_1 + \Delta Q_2 \\ \Delta(Q_1 \bowtie Q_2) &:= (\Delta Q_1 \bowtie Q_2) + (Q_1 \bowtie \Delta Q_2) \\ &\quad + (\Delta Q_1 \bowtie \Delta Q_2) \\ \Delta(\sigma_\theta Q) &:= \sigma_\theta(\Delta Q) \\ \Delta(\text{Sum}_{A;f} Q) &:= \text{Sum}_{A;f}(\Delta Q)\end{aligned}$$

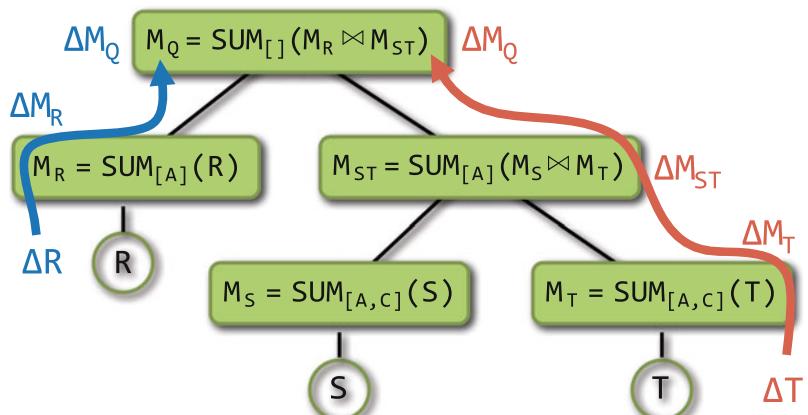

Previous work (Koch 2010; Koch et al. 2014) studies these rules in detail.

Higher-Order IVM. Incremental view maintenance is often cheaper than naïve reevaluation but is not free. Computing deltas can be expensive, like in Example 1, where ΔQ is a nontrivial join of one (small) input update and two (large) base tables. To speed up the delta evaluation, higher-order IVM materializes and recursively maintains update-independent parts of delta queries. This maintenance strategy creates a hierarchy of increasingly simpler materialized views that support each other's incremental maintenance.

Example 2 Consider the count query from Example 1 and the hierarchy of materialized views shown in Fig. 1. This IVM strategy materializes the top-level view M_Q along with four additional views M_R , M_S , M_T , and M_{ST} in order to speed up the maintenance task: for instance, updates to R and T exploit the precomputed partial counts in M_{ST} and respectively M_S and M_R for faster delta propagation. This approach is an instance of

Distributed Incremental View Maintenance, Fig. 1

View hierarchy for the query in Example 1. Delta propagations for updates to R (left blue) and to T (right red)

higher-order IVM since an update to one relation may cause the maintenance of several views. The triggers for updates to R and T look as:

```

ON UPDATE R BY ΔR:
  ΔMR := Sum[A](ΔR)
  ΔMQ := Sum[](ΔMR ⋙ MST)
  MR += ΔMR
  MQ += ΔMQ

ON UPDATE T BY ΔT:
  ΔMT := Sum[A,C](ΔT)
  ΔMST := Sum[A](MS ⋙ ΔMT)
  ΔMQ := Sum[](MR ⋙ ΔMST)
  MT += ΔMT
  MST += ΔMST
  MQ += ΔMQ

```

The trigger for updates to S is similar. For this example and this maintenance strategy, processing one update tuple takes a constant amount of work per statement: for instance, the join operation in the R trigger requires only one lookup in M_{ST} for each tuple of $ΔM_R$. Processing single-tuple updates in constant time is impossible to achieve in this example using classical incremental view maintenance, which evaluates $ΔQ = ΔR ⋙ S ⋙ T$, or recomputation, which evaluates $Q = (R ∪ ΔR) ⋙ S ⋙ T$. In both cases, the maintenance time is linear in the size of the database. □

View maintenance code, like that of Examples 1 and 2, consists of trigger statements, which are executed upon changes in the underlying database. The discussion so far has assumed that

the database and code are stored and respectively run on a single machine.

Distributed IVM

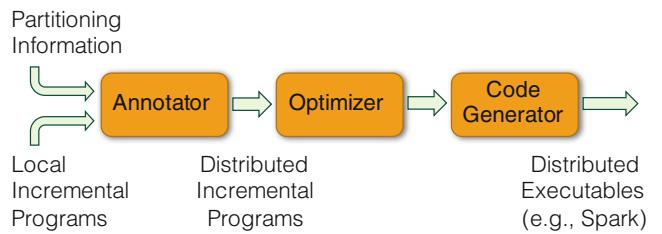

This section describes how to transform local maintenance code into maintenance programs optimized for running on large-scale processing platforms. The presented approach targets systems with synchronous execution, such as Spark (Zaharia et al. 2012) and Hadoop MapReduce (Dean and Ghemawat 2008), where one driver node orchestrates job execution among workers. Processing one batch of updates may require several computation stages, where each stage runs view maintenance code in parallel. All workers are stateful, preserve data between stages, and participate in every stage.

Materialized views are classified depending on the location of their contents. *Local views* are stored and maintained entirely on the driver node. They are suitable for materializing aggregates with small output domains. *Distributed views* have their contents spread over all workers to balance CPU and memory pressure. Each distributed view has an associated partitioning function that maps each tuple to a non-empty set of nodes storing its replicas.

Compilation Overview

Figure 2 shows the process of transforming a local incremental program into a functionally

Distributed Incremental View Maintenance, Fig. 2
Compilation of incremental programs

equivalent, distributed program. The input consists of maintenance statements expressed using the aforementioned query language. To distribute their execution, the compiler relies on the partitioning information about each materialized view, which is provided by the user.

The compilation process consists of three phases. The first phase annotates a given input program with partitioning information and, if necessary, introduces operators for exchanging data among distributed nodes in order to preserve the correctness of query evaluation. The second phase optimizes the annotated program using a set of simplification rules and heuristics that aim to minimize the number of jobs necessary for processing one update batch. The final stage uses code generation to specialize incremental programs for running on a specific processing platform.

Forming Distributed Programs

The semantics of the discussed query operators cannot be directly translated to distributed environments. For instance, unioning one local and one distributed view has no clear meaning. Even among distributed views only, naïvely executing query operators at each distributed node might yield wrong results. For instance, a natural join between two distributed views produces a correct result only if the views are identically partitioned over the join keys; otherwise, one or both operands need to be repartitioned.

The query language needs new location-aware primitives to allow reasoning about the correctness of distributed query evaluation. For that purpose, each query expression is extended (annotated) with a *location tag*: (1) Local tag

means the result is stored on the driver node, (2) $\text{Dist}(\mathcal{P})$ tag denotes the result is distributed among all workers according to partitioning function \mathcal{P} , and (3) Random tag means the result is randomly distributed among all workers. One relation or materialized view can take any of these tags. A query Q with a location tag T is written as Q^T .

To support distributed execution, the query language needs new operators for manipulating location tags and exchanging data over the network. These operators are called *location transformers*:

- Repart transformer reshuffles the distributed result of query Q using a partitioning function \mathcal{P} :

$$\text{Repart}_{\mathcal{P}}(Q^T) = Q^{\text{Dist}(\mathcal{P})}$$

where $T \in \{\text{Dist}(\cdot), \text{Random}\}$.

- Scatter transformer distributes the local result of query Q using a partitioning function \mathcal{P} :

$$\text{Scatter}_{\mathcal{P}}(Q^{\text{Local}}) = Q^{\text{Dist}(\mathcal{P})}$$

- Gather transformer aggregates the distributed result of query Q on the driver node:

$$\text{Gather}(Q^T) = Q^{\text{Local}}$$

where $T \in \{\text{Dist}(\cdot), \text{Random}\}$.

The location transformers are the only mechanism for exchanging data among nodes. Repart and Gather operate over distributed expres-

sions, while Scatter works with local expressions.

Location-Aware Query Operators. The semantics of the query operators is now extended to support location tags.

- Relation $R(A_1, A_2, \dots)^T$ stores its contents at location T.
- Bag union $Q_1^T + Q_2^T$ merges tuples locally or in parallel on every node, and the result retains tag T. Both operands must have the same location tag.
- Natural join $Q_1^T \bowtie Q_2^T$ has the usual semantics when $T = \text{Local}$. For distributed evaluation, both operands need to be partitioned on the join key; the result is also distributed and consists of locally evaluated joins on every node. Joins involving randomly partitioned operands are disallowed.
- Sum $_{A;f} Q^T$, when $T = \text{Dist}(\mathcal{P})$, computes partial aggregates on every node. The result retains tag T only if Q is key partitioned on one of the group by columns; otherwise, it gets a Random tag. When $T \neq \text{Dist}(\mathcal{P})$, the result retains tag T.

The remaining language constructs – constants, variable values, and comparisons – are location independent and can freely participate in both local and distributed expressions.

Algorithm. The procedure for transforming a local program into a valid distributed program operates as follows. For each program statement, the procedure starts by assigning a location tag to all relational terms in its expression tree based on the given partitioning scheme. Then, in a bottom-up fashion, it annotates each node of the tree with a location tag and introduces location transformers where necessary to preserve the semantics and correctness of each query operator, as discussed above. Upon reaching the root node of the statement, the procedure checks whether the right-hand side expression evaluates at the same location as the left-hand side view and, if not, introduces a Gather or Scatter transformer. The procedure repeats these steps for every statement.

Example 3 Consider the following statement obtained from the trigger for updates to T in Example 2.

$$M_{ST}(A) += \text{Sum}_{[A]}(M_S(A, B) \bowtie \Delta M_T(A, B))$$

D

Assume that M_{ST} and M_S are partitioned by A while ΔM_T is partitioned by B . Let $M^{[A]}$ denotes that M is partitioned on column A . The join operands M_S and ΔM_T have incompatible location tags, which requires a Repart transformer around one of the operands, say the left one:

$$\text{Repart}_{[B]}(M_S(A, B)^{[A]})^{[B]} \bowtie \Delta M_T(A, B)^{[B]}$$

The join result remains partitioned on B . The Sum expression computes partial aggregates grouped by column A . Such an expression cannot have location tag $[B]$ since B is not in the output schema; instead, it gets a Random tag. Upon reaching the root of the expression tree, another Repart ensures that the right-hand side expression has the same location tag as the target view.

$$\begin{aligned} M_{ST}(A)^{[A]} &+= \\ &\text{Repart}_{[A]}(\\ &\quad \text{Sum}_{[A]}(\text{Repart}_{[B]}(M_S(A, B)^{[A]})^{[B]} \\ &\quad \bowtie \Delta M_T(A, B)^{[B]})^{\text{Random}})^{[A]} \end{aligned}$$

□

The algorithm for constructing distributed expressions has no associated cost metrics and might produce suboptimal solutions. In the above example, the final statement involves two communication rounds (Reparts) between the driver and workers. But this overhead can be minimized: repartitioning the right join operator at first instead of the left one produces an equivalent, less expensive statement with only one communication round:

$$\begin{aligned} M_{ST}(A)^{[A]} &+= \\ &\text{Sum}_{[A]}(M_S(A, B)^{[A]} \bowtie \\ &\quad \text{Repart}_{[A]}(\Delta M_T(A, B)^{[B]})^{[A]})^{[A]} \end{aligned}$$

Optimizing distributed programs relies on a set of simplification and heuristic rules, which are presented next.

Optimizing IVM Programs

This section describes how to optimize distributed programs to minimize their processing and communication costs. The optimization procedures are divided into three groups based on their scope.

Local Optimization

Preprocessing a batch of updates can speed up incremental view maintenance. Early selection using a query's predicates eliminates irrelevant update tuples, while projection retains only the columns needed for the maintenance task. For instance, the R trigger of Example 2 preprocesses ΔR as $\text{Sum}_{[A]}(\Delta R(A, B))$ to retain only distinct A values needed for the later computation. Batch pre-aggregation can produce much fewer tuples and significantly decrease the maintenance cost and the amount of data sent over the network.

Intra-statement Optimization

Intra-statement optimizations aim to minimize the amount of network traffic generated by one distributed statement. The cost model considered here takes the number of communication rounds as the basic metric for cost comparison. Each location transformer (Repart, Scatter, and Gather) sends data over the network; thus, statements with fewer transformers require less communication. Considering more complex cost models that take into account the amount of data being exchanged is beyond the scope of this chapter.

The optimizer shown here also relies on few heuristics to resolve ties between statements with the same cost. For instance, it favors reshuffling of expressions that involve batch updates rather than whole materialized views as the former are usually smaller in size; also, it favors expressions with fewer Gather transformers to distribute the computation over workers as much as possible.

The optimizer uses a trial and error approach to recursively optimize a given statement. It tries to push each location transformer down the expression tree, following the rules from Fig. 3. Note that these rules might produce more expensive expressions, in which case the optimizer

$$\begin{aligned} \text{Repart}_{\mathcal{P}}(Q_1 \bowtie Q_2) &\Leftrightarrow \\ \text{Repart}_{\mathcal{P}}(Q_1) \bowtie \text{Repart}_{\mathcal{P}}(Q_2) & \\ \text{Repart}_{\mathcal{P}}(Q_1 + Q_2) &\Leftrightarrow \\ \text{Repart}_{\mathcal{P}}(Q_1) + \text{Repart}_{\mathcal{P}}(Q_2) & \\ \text{Repart}_{\mathcal{P}}(\text{Sum}_{A:f}(Q)) &\Leftrightarrow \\ \text{Sum}_{A:f}(\text{Repart}_{\mathcal{P}}(Q)) & \end{aligned}$$

Distributed Incremental View Maintenance, Fig. 3

Bidirectional optimization rules for Repart (same are for Scatter and Gather)

$$\begin{aligned} \text{Repart}_{\mathcal{P}}(Q^{\text{Dist}(\mathcal{P})}) &\Rightarrow Q^{\text{Dist}(\mathcal{P})} \\ \text{Gather}(Q^{\text{Local}}) &\Rightarrow Q^{\text{Local}} \\ \text{Repart}_{\mathcal{P}_1} \circ \text{Repart}_{\mathcal{P}_2} &\Rightarrow \text{Repart}_{\mathcal{P}_1} \\ \text{Repart}_{\mathcal{P}_1} \circ \text{Scatter}_{\mathcal{P}_2} &\Rightarrow \text{Scatter}_{\mathcal{P}_1} \\ \text{Gather} \circ \text{Repart}_{\mathcal{P}} &\Rightarrow \text{Gather} \\ \text{Gather} \circ \text{Scatter}_{\mathcal{P}} &\Rightarrow \text{Gather} \\ \text{Scatter}_{\mathcal{P}} \circ \text{Gather} &\Rightarrow \text{Repart}_{\mathcal{P}} \end{aligned}$$

Distributed Incremental View Maintenance, Fig. 4

Simplification rules for location transformers. The \circ sign is operator composition

backtracks. During each optimization step, it tries to simplify the current expression using the rules from Fig. 4. Each simplification rule always produces an equivalent expression with fewer location transformers.

In Example 3, the optimizer pushes the outer $\text{Repart}_{[A]}$ through the Sum and \bowtie operators and then simplifies $\text{Repart}_{[A]} \circ \text{Repart}_{[B]}$ to $\text{Repart}_{[A]}$. The optimized statement now requires only one communication round.

Inter-statement Optimization

Location transformers represent natural pipeline breakers in query evaluation since they need to materialize and shuffle the contents of their expression before continuing processing. Analyzing inter-statement dependencies can minimize the number of pipeline breakers and their communication overhead.

To facilitate inter-statement analysis, the optimizer first converts a given program into *single transformer form*, where each statement has at most one location transformer and that trans-

former, if present, always references one materialized view. This normalization procedure repeats the following three steps: (1) it materializes the contents being transformed (if not already materialized), (2) it extracts the location transformers targeting the materialized contents into separate statements, and (3) it updates the affected statements with new references. The optimizer normalizes each statement in a bottom-up traversal of its expression tree.

Example 4 Consider the maintenance trigger from Example 2 and assume that ΔR is randomly distributed among workers, M_R and M_{ST} are partitioned on A , and M_Q is stored at the driver node. The distributed trigger for updates to R consists of statements annotated with location tags in single transformer form:

```

ON UPDATE R BY ΔR:
1  ΔMRRandom := Sum[A](ΔRRandom)Random
2  ΔMR[A] := Repart[A](ΔMRRandom)[A]
3  ΔMQRandom := Sum[](ΔMR[A] ⋈ MST[A])Random
4  ΔMQLocal := Gather(ΔMQRandom)Local
5  MR[A] += ΔMR[A]
6  MQLocal += ΔMQLocal

```

Statement 1 pre-aggregates in parallel the update batch to minimize the amount of data being reshuffled by the subsequent statement. Statement 3 performs a distributed join followed by an aggregation that computes a partial count at each worker node. Statement 4 sums these partial counts at the driver. The remaining statements maintain the distributed view M_R and the local view M_Q . \square

The single transformer form sets clear boundaries around the contents that need to be communicated, which eases the implementation of further optimizations. Common subexpression elimination and dead code elimination can detect shared parts among statements and eliminate redundant network transfers. In contrast to the classical compiler optimizations, these routines take into account the location where each expression is executed.

The location tag of the expressions from both sides of one statement determines where and how that statement is executed. Statements targeting local materialized views are, as expected, executed at the driver in *local mode*. Statements involving distributed views run in *distributed mode*, where the driver initiates the computation. All location transformations run in *communication mode*, but materializing the contents to be reshuffled can happen in both local and distributed mode. For instance, preparing contents for Scatter takes place on the driver while for Repart and Gather happens on every worker.

Statement Blocks. Distributed statements are more expensive to execute than local statements. To run a distributed statement, the driver needs to serialize a task closure, ship it to all workers, and wait for the completion of each one of them. For short-running tasks, non-processing overheads can easily dominate in the execution time.

To amortize the cost of executing distributed statements, the optimizer can pack them together into processing units called *statement blocks*. A statement block consists of a sequence of distributed statements that can be executed at once on every node without compromising the program correctness. The optimizer analyzes the data-flow dependencies among statements to decide on valid statement reorderings.

Example 5 The trigger from Example 4 consists of three distributed statements (1, 3, and 5), two communication statements (2 and 4), and one local statement (6). Statements 3 and 5 can be grouped together into one block as the latter commutes with statement 4; thus, computing ΔM_Q^{Random} and updating $M_R^{[A]}$ happens in one distributed task. The same is not true for statements 1 and 3 because of the data-flow dependencies among the first three trigger statements. \square

To minimize network overheads, the optimizer can coalesce consecutive communication statements of the same type (i.e., with the same type of location transformer) into one compound request carrying a container with their individual payloads. This technique amortizes the intrinsic

start-up overhead associated with each network operation over multiple communication statements.

Conclusion

This chapter studies incremental view maintenance in local and distributed environments. The presented approach compiles local maintenance programs into distributed code optimized for the execution on large-scale processing platforms. Nikolic et al. (2016) provide details of the compilation process and analyze the performance of distributed IVM using Apache Spark as the data processing framework. The technique discussed here is general and applicable to other distributed data management systems and stream processing engines.

Dynamic scaling; Provisioning and decommissioning

Overview

In data stream processing, elasticity refers to the ability of autonomously provisioning and decommissioning resources (e.g., threads or nodes) in order to match, at each point in time, the computational power needed to run a set of user-defined continuous queries.

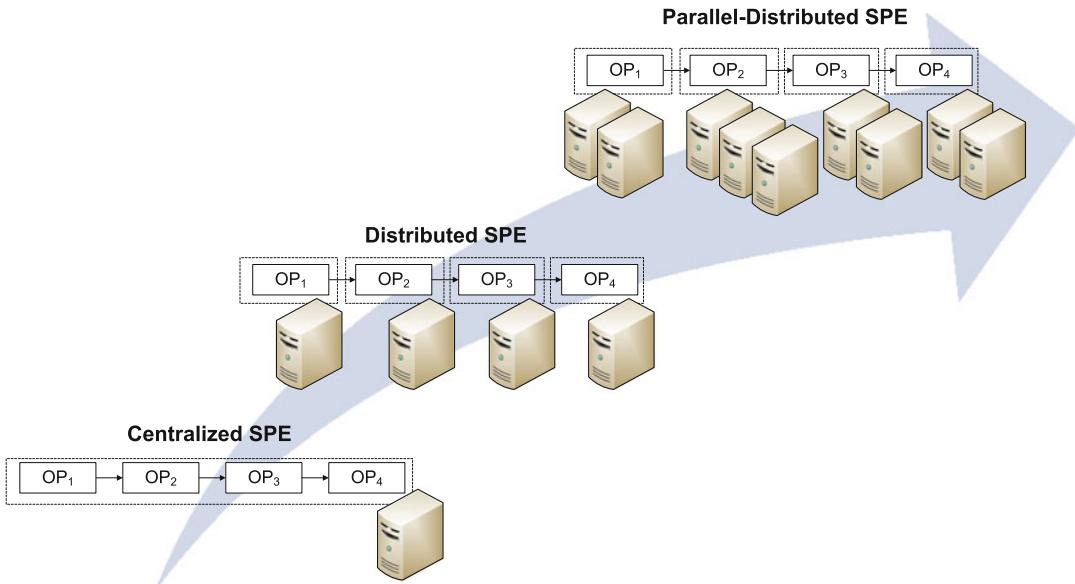

Elastic SPEs are able to dynamically scale up and out (or down and in, respectively) the resources employed to run the existing queries in order to match the needed computational power at each point in time. They can thus benefit of decoupled architectures such as cloud computing ones, and similar metrics for the performance evaluation can be defined (Ilyushkin et al. 2017). The variations in the needed computational power are due to the fluctuating nature

of data streams (both in terms of their volume and their underlying data distribution) and the variable number of queries added and removed over time by users.

Historical Background

Stream processing engines (SPEs) run user-defined continuous queries (or simply queries in the remainder). Each query is a directed acyclic graph of operators that consume and transform tuples coming in from a set of input sources and deliver output tuples to the user at the sink(s). Operators can be stateless, thus not maintaining a state that evolves based on the tuples being processed, or stateful, thus producing output tuples that depend on multiple input tuples. The distinction between stateless and stateful operators plays a significant role in the context of elasticity, as we elaborate in the following.

Since approximately the year 2000, SPEs evolved rapidly from centralized to parallel-distributed ones. As shown in Fig. 1, centralized SPEs, such as the pioneer SPE Aurora presented by Carney et al. (2002), deploy and run all the operators belonging to the same query at one node. Distributed SPEs such as the Borealis SPE, presented by Abadi et al. (2005), allow to run a query over multiple nodes, deploying each operator to exactly one node (i.e., providing inter-operator parallelism). Finally, parallel-distributed SPEs such as StreamCloud, introduced by Gulisano (2012); StreamMine3G, presented by

Elasticity, Fig. 1 Evolution from centralized SPEs to parallel-distributed SPEs, also showing how a sample query composed by four operators can be deployed at

Martin et al. (2014); Apache Spark (<https://spark.apache.org/>); Apache Flink (<https://flink.apache.org/>); or Heron (<https://twitter.github.io/heron/>) allow for individual operators to be run in parallel (i.e., providing intra-operator parallelism).

Before the introduction of elasticity protocols, the resources allocated to an SPE were statically assigned at the time the queries were deployed and their input streams were fed to them. In this case, the SPE running a certain set of queries could either be under-provisioned or over-provisioned.

When under-provisioned, the resources allocated to an SPE can cope with the average computational power needed to run the queries. In the occurrence of a temporary increase in the needed resources, nevertheless, the user will experience higher latency in the delivery of output tuples and might resort to adaptive techniques such as input admission control, as discussed by Balkesen et al. (2013), or load shedding, as discussed by Tatbul et al. (2003). On the other hand, the resources of an over-provisioned SPE are allocated to be able to cope with the highest peak of computational power that would be needed by the user-defined queries.

one or multiple nodes by the different SPEs. The figure is presented by Gulisano (2012) for the StreamCloud SPE

Under-provisioned SPEs are usually not an option when Service Level Agreements (SLAs) are in place, since they might incur monetary penalties. At the same time, over-provisioned SPEs result in wasted resources (and high maintenance costs).

It is important to notice that elasticity should (i) preserve the semantics of the analysis, i.e., not affect the correctness of a query's analysis, and (ii) require as little as possible involvement of the user in the decisions about resources to be provisioned or decommissioned. As we explain in the following, different solutions approach these aspects in different ways (and to different extents).

Foundations

We cover in this section elasticity's core aspects. As discussed by De Matteis and Mencagli (2017) with respect to SASO properties (i.e., stability, accuracy, settling time, and overshoot), elasticity mechanics build on top of contrasting objectives. On one hand, frequent adjustments of resources

to match variations in computational needs are desirable to overcome the limitations of over- or under-provisioned SPEs. At the same time, sporadic reconfigurations result in less overhead and temporary degradation of queries' performance.

For simplicity, we use the term *user* to refer to both who maintains the resources to run the SPE and who defines the queries running on the latter.

Provisioning and Decommissioning

Whenever the allocated resources should be adapted to match computational needs, elasticity can result in the provisioning of new threads or nodes (when more resources than the allocated ones are needed) or the decommissioning of some existing thread or node (when less resources than the allocated ones are needed). A first distinction in the existing elasticity protocols can be made between techniques that can provision (or decommission) one thread or node at a time and techniques that can provision (or decommission) multiple ones.

The solutions presented by Schneider et al. (2009) and Hochreiner et al. (2016), for instance, provide one-at-a-time provisioning and decommissioning of resources. The shortcoming of these techniques is that, in some cases, one extra thread or node might not be enough to match the increase of needed computational power. This is overcome by load-aware elastic techniques such as the ones discussed by Gulisano et al. (2012) and Heinze et al. (2014b). The latter decide how many resources should be provisioned or decommissioned based on the current computational load or the computational load estimated at the end of the elastic reconfiguration. By doing this, they reduce the reconfiguration overhead by encapsulating the provisioning or decommissioning of multiple threads or nodes rather than triggering multiple consecutive reconfigurations.

Load Balancing

Resource provisioning or decommissioning results in temporary performance degradation, while the deployment of queries (and their operators) over the allocated resources is undergoing a change (e.g., when waiting for

a new node to be initialized). Because of this, resources should be provisioned only when allocated ones (as a whole) cannot cope with the current workload. That is, provisioning (and decommissioning) of resources should not be triggered because of an uneven load distribution. This can be prevented by combining load balancing with elasticity.

Load balancing, nevertheless, usually boils down to NP-hard problems such as the bin-packing one, as discussed by Gulisano (2012), Balkesen et al. (2013), Heinze et al. (2013, 2014b), among others. When deciding the best workload repartitioning among allocated resources, it is also of key importance to leverage efficient state transfer techniques, as mentioned by Ding et al. (2015).

Granularity

Since centralized SPEs bound each query to exactly one node, they can only leverage techniques in which nodes are provisioned when a query, as a whole, cannot be run by the allocated ones, as proposed by Loesing et al. (2012).

Differently, distributed SPEs can also benefit of techniques in which operators' responsibility can be shifted between nodes, as proposed by Xing et al. (2005) and Heinze et al. (2013).

Finally, parallel-distributed SPEs can provision (or decommission) threads and nodes to adjust the parallelism degree of individual operators, as discussed by Gulisano et al. (2012), Heinze et al. (2014b), Martin et al. (2014), Castro Fernandez et al. (2013), among others.

Transferring of the responsibility for a whole operator (or part of a parallel one) to a new thread (or node) requires the rerouting of its input tuples to the new thread (or node). For stateful operators, furthermore, it also requires the transfer of its whole state (or part of it for parallel stateful operators).

Triggering Mechanism

A key aspect, besides the mechanics with which an elastic protocol assigns the analysis carried out by the resources before and after the reconfiguration, is the condition upon which such elastic reconfiguration should happen.

In the literature, the triggering conditions are usually based on (i) the threads' and nodes' CPU consumption, as discussed by Gulisano et al. (2012), Martin et al. (2014), Hochreiner et al. (2016), (ii) the operators' latency, as discussed by Zacheilas et al. (2015), De Matteis and Mencagli (2017), or (iii) the operators' queue lengths, as discussed by Kumbhare et al. (2015). An important distinction among the existing protocols can be made between reactive mechanisms and proactive ones. Reactive mechanisms, such as the one proposed by Gulisano et al. (2012), trigger a reconfiguration once a certain condition is met (e.g., when the CPU consumption exceeds a certain threshold). On the other hand, proactive mechanisms actively try to optimize the performance of the running queries (e.g., by constantly minimizing their latency), as for the solution discussed by De Matteis and Mencagli (2017), or predict (rather than observe) when a certain condition will be met, as discussed by Zacheilas et al. (2015).

Determinism

As we mentioned, an elastic reconfiguration can temporarily degrade the performance of an SPE while undergoing a reconfiguration (e.g., a temporary increase in the processing latency while waiting for a new node to be provisioned). Nevertheless, elasticity should not affect the correctness of the analysis. This property is known as determinism.

Determinism has been introduced in the context of parallel-distributed SPEs and in the context of algorithms for parallel data streaming operators, for instance, by Gulisano et al. (2016, 2017). The determinism guarantee states that the results produced by an operator run in parallel by multiple threads or at multiple nodes should produce the same exact results of its centralized counterpart. When all the parallel operators of a query run deterministically, then the query itself enjoys the determinism guarantee.

When elastically reconfiguring the resources allocated to a query, nevertheless, the system undergoes a transition during which the responsibility to process a certain subset of data and the

state currently maintained by stateful operators for such subset is shifted from one thread (or node) to another one. Enforcing determinism in this case implies that the results produced by a system while undergoing elastic reconfigurations are the exact same as the ones produced by a system whose resources are statically allocated. In practice, this means each tuple is processed exactly once, and the state is correctly preserved during each elastic reconfiguration, as we further explain when discussing state transfer.

Determinism is also referred to as *safety* by Hirzel et al. (2014) and *semantic transparency* by Gulisano et al. (2012).

State Transfer

When an elastic reconfiguration is triggered, the responsibility for the input tuples of an operator (a portion of them or all of them) is transferred from thread (or node) A to thread (or node) B . The main idea is to find a point in time P so that the processing of all tuples before P is A 's responsibility, while the processing of tuples coming after P is B 's responsibility.

This is trivial for stateless operators and provided by the protocols as the one proposed by Kumbhare et al. (2015). It is nevertheless challenging for stateful operator when enforcing determinism. The responsibility of the state maintained by A cannot be transferred to B before A is done processing all tuples up to P . A possible way of doing this guaranteeing determinism is by a blocking mechanism in which B cannot start processing tuples until it gets access to A 's state once the latter is done processing all tuples (Gulisano et al. 2012; Martin et al. 2014). When transferring the state by serializing it, sending it between two nodes, and finally deserializing it, nevertheless, the overhead and latency penalty of the reconfiguration can degrade the SPE performance. This can be alleviated by techniques aiming at reducing latency spikes, such as the ones proposed by Heinze et al. (2014a), or at recreating small states at B by sending to the latter previously sent tuples (rather than transferring A 's state).

Syntactic Transparency

Together with determinism, syntactic transparency is another desirable feature to make elastic reconfigurations oblivious to the user. When an SPE is syntactically transparent, the user does not need to trigger reconfigurations manually but can rely on the SPE itself to monitor the resource utilization and adjust the latter depending on the variations of the former. The minimum information provided by the user is the pool from which resources can be provisioned and to which resources can be decommissioned over time.

Further information might be needed depending on the operators deployed by the user. When using the standard operators provided by SPEs, their elastic reconfiguration protocols can handle provisioning and decommissioning without support from the user, as discussed by Gulisano et al. (2012). When relying on user-defined operators, on the other hand, an SPE can provide a general interface to serialize and deserialize the state of stateful operators when a reconfiguration is triggered, as discussed by Martin et al. (2014). Alternatively, an SPE could opt for maintaining operators' state decoupled from the individual operators themselves, exposing it with shared state management primitives, as proposed by Castro Fernandez et al. (2013).

Examples of Applications

In the literature, elasticity has been discussed in relation to many real-world applications. All these applications share data sources with fluctuating input rates that, once fed to the queries run by an SPE, need varying amounts of resources over time in order to cope with the analysis' computational costs.

Gulisano (2012) evaluated the elasticity protocols of the StreamCloud SPE for fraud detection applications (both for credit card transactions and mobile phone networks). Martin et al. (2014) focused on elasticity for clickstream analysis while, Zacheilas et al. (2015) studied the benefit of elasticity in the context of transportation and mobility applications (more specifically, for traf-

fic monitoring of buses in the city of Dublin). Transportation is also discussed by Hochreiner et al. (2016), with a focus on taxi rides, and by Kumbhare et al. (2015), evaluating their solution with the Linear Road benchmark. The benchmark simulates traffic for a set of highways, and the queries are designed to notify drivers of both their variable tolls and of existing accidents, as discussed by Arasu et al. (2004).

Elasticity has also been discussed for applications analyzing social media such as Twitter, by Ding et al. (2015), and applications running financial market analysis, by Gedik et al. (2014), Heinze et al. (2014b), and De Matteis and Mencagli (2017).

Future Directions for Research

Elasticity has been studied extensively in the literature, resulting in many protocols that can cover the presented core aspects to different extents.

New challenges in large distributed architectures such as cyber-physical systems and fog architectures are given by their heterogeneous nature (both in terms of resources and applications). Successful use of elastic protocols will require to properly leverage the computational power of each individual node, that is, to properly scale up before scaling out, as discussed by Gibbons (2015). This can be enabled by elastic protocols that can properly leverage nonhomogeneous hardware, as discussed by Koliousis et al. (2016), and fine-grained synchronization, as discussed by Gulisano et al. (2016, 2017). At the same time, it will require elastic protocols to be application-aware, since SLAs and physical constraints external to SPEs themselves (e.g., the latency incurred when communicating with a certain node) will both affect the elastic reconfigurations triggered by an SPE.

Emerging Hardware Technologies

Xuntao Cheng¹, Cheng Liu², and Bingsheng He²

¹Nanyang Technological University, Jurong West, Singapore

²National University of Singapore, Singapore, Singapore

Definitions

This chapter introduces emerging hardware technologies such as GPUs, x86-based many-core processors, and die-stacked DRAMs, which have significant impacts on big data applications.

Overview

This chapter introduces emerging hardware technologies and their impacts on big data applications. For processors, this chapter includes GPUs, Intel Xeon Phi many-core processors, FPGAs, and specialized processors. This chapter also covers many new memory technologies such as die-stacked DRAMs, storage class memory, etc. At last, we introduce network interconnects.

E

Outline

We introduce emerging hardware including processors, memory, hard disk, and network. On the processors, we focus on many-core processors (GPUs and Intel Xeon Phi), FPGA, and specialized hardware.

Many-Core Processors

GPU

Graphics processing units (GPUs) are specialized processors initially designed to alter memory at a massive scale and fast speed to accelerate the creation of images. They have been redesigned to support programmable shading in 2001 and gradually become general purpose accelerators. A GPU dedicates most of its transistors to simpler and smaller cores with more registers to support massive thread-level parallelism on a large scale of data. The bandwidth of GPU's memory is usually higher than that of the main memory. These features benefit a wide range of big data applications such as business intelligence and data mining (Christoph Weyerhaeuser et al. 2008; Ren Wu et al. 2009).

NVIDIA has proposed the NVLink technology, a high bandwidth, energy-efficient interconnect that enables ultrafast communications between the CPU and the GPU (NVIDIA 2017). The bandwidth of NVLink is 5–12 times faster than that of the PCIe Gen 3. NVLink can also connect multiple GPU cards in a mesh, improving GPUs' capabilities for big data analytics.

Intel Xeon Phi

Intel introduced two generations of x86-based many-core processors branded as Intel Xeon Phi in 2012 and 2016, respectively (Intel 2017f). Xeon Phi tries to offer a general purpose x86-based processor with a high performance that is competitive with tailored accelerators. Important features of the latest Xeon Phi processor include 512-bit vector processing units supporting the AVX-512 ISA (Intel 2017d), die-stacked High Bandwidth Memory (HBM), and up to x86-based 72 cores. Xeon Phi is also binary compatible with Xeon processors, enabling an easy transition for big data applications from multi-core processors to many-core processors.

Intel proposed its Omni-Path Architecture, a high bandwidth low-latency interconnect featuring multiple flow and routing optimizations and aiming at scaling processing units to tens of thousands of cores at a competitive price to support future HPC workload (Intel 2017e). Similar to NVLink, Omni-Path can connect multiple Xeon and Xeon Phi processors to facilitate communications among processors.

FPGA

Field-programmable gate array (FPGA) is an integrated circuit which consists of an array of configurable logic blocks (CLBs) connected via programmable interconnects. It can be reprogrammed and provide application-specific customization for target application. The use of FPGA has been demonstrated to be successful in many applications. This motivates the cloud vendors to integrate FPGAs in the cloud and provide FPGAs as a service (Amazon 2017; Aliyun 2017).

FPGA evolves rapidly over the years, and here are the major features that are worth for highlighting:

- Hybrid system architecture: closely coupled CPU-FPGA architecture such as Intel Xeon-FPGA (Herman and Randy 2016) emerges recently. CPU and FPGA have a shared mem-

ory and coherent cache support facilitating efficient hardware/software co-design.

- Large on-chip resources: By using the latest semiconductor technologies such as 16Fin FET+ process (Xilinx 2017b), stacked silicon interconnect (Xilinx 2017a), and Intel 14 nm Tri-Gate process (Intel 2017c), new generation of FPGAs has much more resources especially DSP slices and on-chip RAM blocks up to 500Mb and allows high-frequency hardware design up to 1 GHz (Intel 2017a). The large amount of on-chip resources exhibit the great potential for compute-intensive and data-intensive applications.
- High bandwidth external memory: High bandwidth memory up to 460GB/s such as HBM (Xilinx 2017c) and HMC (Intel 2017b) is integrated with the FPGAs.
- High performance networking: 100 Gigabit Ethernet or 400 Gigabit Ethernet is provided for high performance interconnection (Intel 2017g).

Specialized Processors

Specialized processors have long been a viable option for conventional processors. Recently, due to the emergence of machine learning, specialized processor is an application-specific integrated circuit (ASIC) developed specifically for neural network and deep learning. Many different specialized processors have been fabricated in the past few years. Google has built TPU for the NN applications in its data center. The first generation of TPU targets NN inference only (Norman et al. 2017). It achieves both high throughput and low latency for inference. The second generation of TPU supports both inference and training (Geoffrey 2017). Huawei has NPU embedded in their mobile phones for faster and more energy-efficient machine learning (Anandtech 2017).

Memory

Die-Stacked DRAM

Die-stacked DRAM is an emerging type of memory that is integrated closely to processing units in

the same package. By stacking multiple layers of DRAMs together in the 3D space, the bandwidth per stack can be increased a lot. For example, the third generation of the High Bandwidth Memory (HBM), a JEDEC standard of die-stacked DRAM, is expected to reach a peak bandwidth of 512 GB/s per module in the near future (JEDEC Solid State Technology Association 2014, 2015). Die-stacked DRAMs can be either interposed by the side of the processor or placed on top of the processor. Although both approaches can achieve a very high bandwidth, the later approach also reduces the memory access latency.

Storage Class Memory

Storage class memory (SCM) is a type of byte-addressable nonvolatile memory that has similar performance with DRAM in terms of latency and similar capacity and economics with the storage (Burr et al. 2008). It is an attractive solution to meet the needs for fast and scalable memory in big data analytics, databases, cloud services, and many other scenarios. By far, candidates for SCM include phase-change memory (PCM), spin-transfer torque memory (STT-RAM), Intel 3D Xpoint, resistive RAM, HP memristors, Samsung V-NAND, and others. SCM has asynchronous read and write latency. For example, the read and write latencies of STT-RAM are 10 ns and 50 ns, respectively. This calls for careful software optimizations.

PIM

Processing in memory (PIM) is a technique that integrates the processing logic with the memory so that the tasks that don't require extensive processing can be done directly within the memory. It avoids the frequent data transfers between the processing units and memory in conventional computing architectures. Thus, it helps to speed up processing, memory transfer rate, and memory bandwidth and decrease processing latency. Centring the PIM concept, a number of PIM architectures have been explored over the years. Some of the researchers proposed to integrate the processing logic with DRAM by leveraging the 3D technologies (Qiuling Zhu et al. 2013). Some of the researchers opted to build processing logic

together with the memory cells based on different memory techniques such as metal-oxide resistive random access memory (ReRAM) (Wong et al. 2012), spin-transfer torque magnetic RAM (STT-RAM) (Adrien et al. 2015), and phase-change memory (PCM) (Geoffrey et al. 2015).

E

Hard Disk

There are recent efforts on improving the hard disk drives (HDD), whose applications have been threatened by its slower bandwidth compared with other emerging memory technologies. A new approach to improve HDDs tries to replace the conventional aluminum substrates with a new prototyping glass substrates. Glass substrates can help in increasing the storage space of a single HDD to about 20 TB (Jon Martindale 2017). This enlarged capacity may improve the storage capability of disks serving big data systems.

Network

Smart NIC

Smart network interface cards (NIC) are NICs equipped with processors to process data while transferring them in the network. These processors can be FPGAs, CPUs, or specifically designed ASICs. Although some computation tasks can be offloaded to conventional NICs, they are usually not complex, such as calculating the checksum. Smart NICs can exploit its processors to support much more complex tasks such as the network functions virtualization (NFV) and more complicated data processing tasks.

RDMA

Remote direct memory access (RDMA) over Converged Ethernet (RoCE) is originally used by the InfiniBand interconnect technology and now applied on Ethernet networks. It allows offloading network transfers from the CPU to RDMA hardware engines, which frees the CPUs for other tasks which in turn increases the performance of tasks. This feature has found very beneficial for big data systems (Lu et al. 2014).

End-to-End Benchmark

Milind A. Bhandarkar
Ampool, Inc., Santa Clara, CA, USA

Synonyms

Deep analytics benchmark; Pipeline benchmark

Definitions

An end-to-end data pipeline benchmark is a standardized suite of data ingestion, data processing, and data queries, arranged in a series of stages, where the output of a previous stage in a pipeline feeds the next stage in pipeline, exercising all the needed system characteristics for commonly constructed data pipeline workloads.

Historical Background

As we witness the rapid transformation in data architecture, where relational database management systems (RDBMS) are being supplemented by large-scale non-relational stores such as Hadoop Distributed File System (HDFS), MongoDB, Apache Cassandra, and Apache HBase, a more fundamental shift is on its way, which would require larger changes to modern data architectures. While the current shift was mandated by business requirements for the connected world, the next wave will be dictated by operational cost optimization, transformative changes in the

underlying infrastructure technology, and newer use-cases, such as Internet of Things (IoT), deep learning, and conversational user interfaces (CUI).

These new use-cases combined with ubiquitous data characterized by its large volume, variety, and velocity have resulted in an emergence of big data phenomenon. Most applications being built in this connected world are based on analyzing historical data of various genres to create a context within which the user interaction with applications is interpreted. Such applications are popularly referred to as data-driven applications. While such data-driven applications are coming into existence across almost all the verticals, such as financial services, healthcare, manufacturing, and transportation, web-based and mobile advertising companies recognized the potential of big data technologies for building data-driven applications and were arguably the earliest adopters of big data technologies. Indeed, popular big data platforms such as Apache Hadoop were created and adopted at web technology companies, such as Yahoo, Facebook, Twitter, and LinkedIn.

Most of the initial uses of these big data technologies were in workloads analyzing large unstructured and semi-structured datasets in batch-oriented Java MapReduce programs or using queries in SQL-like declarative languages. However, availability of the majority of enterprise data on big data distributed storage infrastructure soon attracted other non-batch workloads to these platforms. Massively parallel SQL engines such as Apache Impala and Apache HAWQ that provide interactive analytical query capabilities were developed to natively run on top of Hadoop analyzing data stored in Hadoop Distributed File System (HDFS). Since 2012, cluster resource management, scheduling, and monitoring functionality previously embedded in MapReduce framework have been modularly separated out as a separate component, Apache YARN, in the Hadoop ecosystem. This allowed data processing frameworks other than MapReduce to natively run on Hadoop clusters, sharing computational resources among various frameworks. The last 4 years have seen an explosion of Hadoop-native data processing frameworks

tackling various processing paradigms, such as streaming analytics, OLAP cubing, iterative machine learning, and graph processing, among others.

Flexibility of HDFS (and other Hadoop-compatible storage systems), sometimes federated across a single computational cluster for storing large amounts of structured, semi-structured, and unstructured data, and the added flexibility and choice of data processing frameworks, has resulted in Hadoop-based big data platforms that are being increasingly utilized for end-to-end data pipelines.

Emergence of this ubiquitous new platform architecture has created the imperative for an industry standard benchmark suite that evaluates efficacy of such platforms for end-to-end data processing workloads for consumers to make informed choices about various storage infrastructure components and computational engines.

In this article, we describe an *end-to-end data pipeline* benchmark, based on real-life workloads. While the benchmark itself is based on a typical pipeline in online advertising, it shares many common patterns across a variety of industries that make it relevant to a majority of big data deployments. In the next section, we discuss various previous benchmarking efforts that have contributed to our current understanding of industry standard big data benchmarks. Then we describe the benchmark scenario, at a fictitious Ad-Tech company. The datasets stored and manipulated in the end-to-end data pipeline of this benchmark are discussed along with various computations that are performed on the data in data pipeline. We propose metrics to measure the effectiveness of systems under test (SUT), report based on various classes of benchmarks that correspond to data sizes, and conclude by outlining future work.

Related Work

Performance benchmarking of data processing systems is a rich field of study and has seen tremendous activity since commercial

data platforms were first developed several decades ago. Several industry consortia have been established to standardize benchmarks for data platforms over the years. Of these, Transaction Processing Performance Council (TPC) and Standard Performance Evaluation Corporation (SPEC), both established in 1988, have gained prominence and have created several standard benchmark suites. While TPC has traditionally been focused on data platforms, SPEC has produced several microbenchmarks aimed at evaluating low-level computer systems performance. Among the various TPC standard benchmarks, TPC-C (for OLTP workloads), TPC-H (for data warehousing workloads), and TPC-DS (for analytical decision support workloads) have become extremely popular, and several results have been published using these benchmark suites. The benchmark specifications consist of data models, tens of individual queries on these data, synthetic data generation utilities, and a test harness to run these benchmarks and to measure performance.

Starting late 2011, the Center for Large-Scale Data Systems Research (CLDS) at the San Diego Supercomputing Center, University of California at San Diego, along with several industry and academic partners, established a *Big Data Benchmarking Community (BDBC)* to establish standard benchmarks in evaluating hardware and software systems that form the modern big data platforms. A series of well-attended workshops called *Workshop on Big Data Benchmarking* have been conducted across three continents as part of this effort, and proceedings of those workshops have been published.

Recognizing the need to speed up development of industry standard benchmarks, especially for rapidly evolving big data platforms and workloads, a new approach to developing and adopting benchmarks within the TPC, called *TPC-express*, was adopted in 2014. Since then, two standard benchmarks, TPC-xHS and TPC-xBB, have been created under TPC-express umbrella. TPC-xHS provides standard benchmarking rigor to the existing Hadoop Sort (based on Terasort) benchmark, whereas TPC-xBB provides big data extensions to the data models and workloads

from the earlier TPC-DS benchmarks. TPC-xHS is a microbenchmark, which evaluates the shuffle performance in MapReduce and other large data processing frameworks. TPCx-BB is based on a benchmark proposal named *BigBench* (Ghazal et al. 2013) that consists of a set of 30 modern data warehousing queries that combine both structured and unstructured data. None of the existing benchmarks provide a way to evaluate combined performance of an end-to-end data processing pipelines.

The need for having an industry standard big data benchmark for evaluating performance of data pipelines and conducting an annual competition to rank the top 100 systems based on this benchmark has been described in (Baru et al. 2013). AdBench, the benchmark described in this article, builds upon this deep analytics pipeline benchmark proposal, by extending the proposed user-behavior deep analytics pipeline, to include streaming analytics and ad hoc analytical queries, in the presence of transactions on the underlying datasets.

AdBench represents a generational advance over the previous standardized benchmarks, because it combines various common computational needs into a single end-to-end data pipeline. We note that while the performance of individual tasks in data pipelines remains important, operational complexity of assembling an entire pipeline composed of many different systems adds overheads of data exchange between various computational frameworks. Data layouts optimized for different tasks require transformations. Scheduling different tasks into a single data pipeline requires a workflow engine with its own overheads. These additional data pipeline composition and orchestration are not taken into account by the previous benchmarks that measure effectiveness of systems on individual tasks. We believe that systems that exhibit good-enough performance to implement entire data pipelines are preferred for their operational simplicity, rather than best-of-breed disparate but incompatible systems that may exhibit the best performance for individual tasks, but have to be integrated with external glue code. Thus, our data pipeline benchmarks measure

performance of an end-to-end data pipeline, rather than focus on *hero numbers* for individual tasks.

E

Foundations

Acme is a very popular content aggregation company that has a web-based portal and also a mobile app, with tens of millions of users, who frequently visit them from multiple devices several times a day to get hyper-personalized content, such as news, photos, audio, and video. Acme has several advertising customers (we distinguish between *users*, who browse through Acme's website, from *customers*, who publish advertisements on that website) who pay them to display their advertisements on all devices. Acme is one of the many Web 3.0 companies because they have a deep understanding of their users' precise interests as well as exact demographic data, history of consumption of content, and interactions with advertisements displayed on Acme website and mobile application. Acme personalizes their users' experience based on this data. They have an ever-growing taxonomy of their users' interests, and their advertisers can target users not only by the demographics but also by the precise interests of those users.

Here is Acme's business in numbers:

- 100 million registered users, with 50 million daily unique users
- 100,000 advertisements across 10,000 advertisements campaigns
- 10 million pieces of content (news, photos, audio, video)
- 50,000 keywords in 50 topics and 500 subtopics as user interests, content topics, and for ad targeting

Acme has several hundred machines serving advertisements, using a unique matching algorithm that fetches a user's interests, finds the best match within a few milliseconds, and serves the ad within appropriate content.

Acme has many data scientists and Hadoop expertise that operates a large Hadoop cluster for providing personalized recommendations of content to their users. However, the batch-oriented nature of Hadoop has so far prevented them from using that Hadoop infrastructure for real-time ad serving, streaming analytics on advertisement logs, and providing real-time feedback on advertisement campaign performance to their customers. Also, for their business and marketing analysts, who want to perform ad hoc queries on the advertising data to target a larger pool of users, they have set up a separate data repository away from both the real-time analytics and batch analytics systems. As a result, the operating expenses of their data infrastructure have more than tripled. Worse, they incur a huge overhead, just trying to keep the data synchronized across these three platforms. Since essentially the same data is kept in multiple places, there is a lag and discrepancies in the data and repetitive tasks for data cleansing, ensuring data quality, and maintaining data governance waste more than 80% of precious and valuable time of their data scientists and big data infrastructure specialists.

Acme architects and engineers decided to replace the entire data infrastructure with modern flash- and memory-based architecture. However, because of the high costs of these modern hardware systems, they are unsure whether the return on investment will justify these increased capital expenditures. In addition, they need to consider the engineering costs of rewriting their entire existing data pipelines, written over more than 5 years, for these modern architectures. There are also considerations of having to retrain the data practitioners for utilizing new technologies. Based on process considerations, they decided to do incremental, piecemeal upgrades to their data infrastructure, moving toward a more unified data processing platform from their current disparate systems. However, evaluating modern infrastructures, without having to rewrite the entire data pipeline, would require a standard benchmark that is necessary for Acme to evaluate new systems.

Datasets

There are four important large datasets used in Acme's data analysis pipeline.

User Profiles

User profiles contain details about every registered user. The schema for user profile is as follows:

- UserID: UUID (64–128 bit unique identifier)
- Age: 0.255
- Sex: M/F/Unknown
- Location: Lat-Long
- Registration time stamp: TS
- Interests: Comma separated list of (topic: subtopic:keyword)

Advertisements

This dataset contains all the details about all the advertisements available for displaying within content. The schema for this dataset is as follows:

- AdID: UUID
- CampaignID: UUID
- CustomerID: UUID
- AdType: “banner,” “modal,” “search,” “video,” “none”
- AdPlatform: “web,” “mobile,” “both”
- Keywords: comma separated list of (topic: subtopic:keyword)
- PPC: \$ per click
- PPM: \$ per 1000 ads displayed
- PPB: \$ per conversion

Content Metadata

Content dataset contains all the metadata about the content. The schema for the content dataset is as follows:

- ContentID: UUID
- ContentType: “news,” “video,” “audio,” “photo”
- Keywords: comma separated list of (topic: subtopic:keyword)

Ad Serving Logs

This dataset is streamed continuously from the ad servers. Each entry in this log has the following fields, of which some may be null:

- TimeStamp: TS
- IPAddress: IPv4/IPv6
- UserID: UUID
- AdID: UUID
- ContentID: UUID
- AdType: “banner,” “modal,” “search,” “video”
- AdPlatform: “web,” “mobile”
- EventType: “View,” “Click,” “Conversion”

Computations

The following computational steps are performed on the data in Acme’s advertisement analytics data pipelines.

Ingestion and Streaming Analytics

This phase of the data pipeline is based on a popular streaming analytics benchmark proposed by a large Ad-Tech company. Ad servers produce ad click, view, and conversion events to a message queue, or a staging storage system. Queue consumers consume events continuously from a message queue and process them in a streaming manner using a streaming analytics platform. For every event consumed, the following computations are performed:

1. Parse the event record
2. Extract time stamp, AdID, EventType, and AdType
3. Look up CampaignID from AdID
4. Windowed aggregation of event types for each AdID and CampaignID
5. Store these aggregates in an aggregate dataset
6. Prepare these aggregations for a streaming visualization dashboard for a CampaignID and all Ads in that Campaign

The two output datasets from the streaming analytics stage are:

1. AdID, Window, nViews, nClicks, nCon, \sum PPV, \sum PPC, \sum PPCon
2. CmpgnID, Window, nViews, nClicks, nCon, \sum PPV, \sum PPC, \sum PPCon

Second streaming ingestion pipeline keeps the User Table, Ad Table, and Content Table updated. While the ads are being displayed, clicked, and converted, new users are being registered, and existing users’ information is being updated. New campaigns are created, existing campaigns are modified, new ads are being created, and existing ads are updated. The correct implementation of this data pipeline will allow these inserts and updates taking place concurrently with other stages of the pipeline, rather than periodically, thus introducing transactionality. In this ingestion pipeline also, we use message queue consumers to get insert and update records and apply these inserts and updates to respective datasets in storage in real time. The steps in this pipeline are as follows:

1. Ingest a {user, campaign, ad} {update, insert} event from message queue.
2. Parse the event to determine which dataset is to be updated.
3. Update respective dataset.
4. Keep track of total number of updates for each dataset.
5. When 1% of the records are either new or updated, launch the batch computation stage described below and reset update counters.

Batch Model Building

In this batch-oriented computational stage, we build ad targeting models. The inputs for this pipeline are the user dataset, ad dataset, and content dataset. And outputs of this pipeline are two new datasets:

1. ($UserID$, $AdID_1$, $weight_1$, $AdID_2$, $weight_2$, $AdID_3$, $weight_3$)
2. ($ContentID$, $AdID_1$, $weight_1$, $AdID_2$, $weight_2$, $AdID_3$, $weight_3$)

These datasets represent the top 3 most relevant ads for every user and for every content. These datasets are then used for the ad serving systems, such that when a user visits a particular content, the best match among these ads is chosen, based on one look up each in the user dataset and content dataset.

Relevance of an ad for a user or a content is determined by cosine similarity in the list of keywords, topics, and subtopics. This model building pipeline, built using batch-oriented computational frameworks, has the following steps:

1. Extract the relevant fields from user dataset and ad dataset, and join based on topics, subtopics, and keywords.
2. Filter the top 3 matching keywords, and compute the weights of ads for those keywords using cosine similarity.
3. Repeat the steps above for the content dataset and ad dataset.

Interactive and Ad Hoc SQL Queries

The interactive and ad hoc queries are performed on varying windows of the aggregates for campaigns and ads using an interactive query engine (preferably SQL-based). Some examples of the queries are:

1. What was the {per minute, hourly, daily} conversion rate for an ad? For a campaign?
2. How many ads were clicked on as a percentage of viewed, per hour for a campaign?
3. How much money does a campaign owe to Acme for the whole day?
4. What are the most clicked ads and campaigns per hour?
5. How many male users does Acme have aged 0–21 or 21–40?

The results of these queries can be displayed in a terminal, and for the queries resulting in time-windowed data, visualized using BI tools.

Various stages of computations in the Ad-Bench data pipeline and dataflow among them are shown in Fig. 1.

Scale Factors and Metrics

When compared to microbenchmarks or benchmarks that consist of a fixed set of queries representing similar workloads, performed on a single system, an end-to-end data pipeline with mixed workloads poses significant challenges in defining scale factors and metrics and reporting benchmark results. In this section, we propose a few alternatives, with reasoning behind our choice.

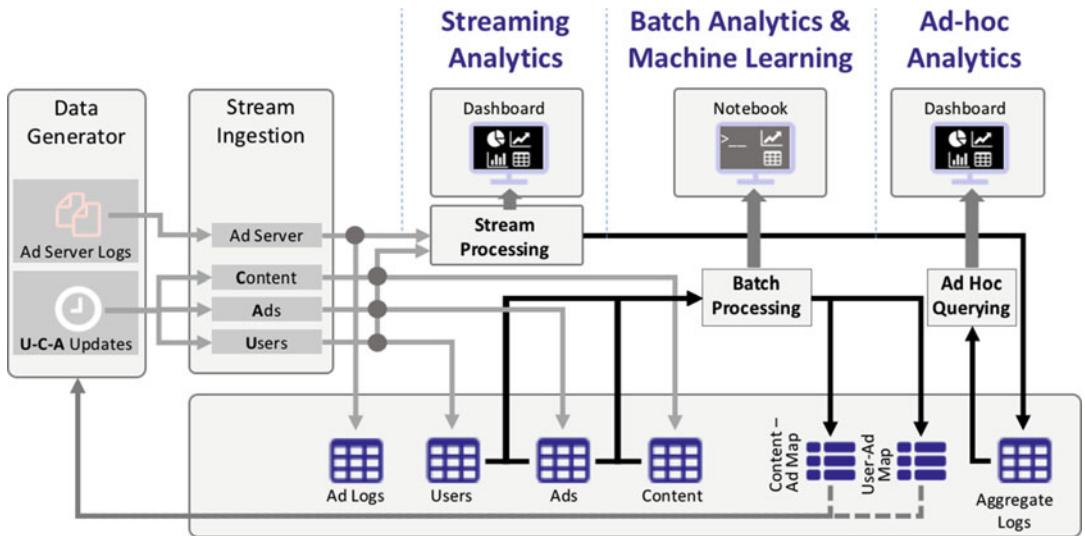

Scale Factors

Across different verticals, the number of entities and thus the amount of data and data rates vary widely. For example, in financial institutions, such as Banks providing online banking, the number of customers (users) is between a few tens of thousands and millions, the number of advertisements that correspond to the number of different services (such as loans, fixed deposits, various types of accounts) is tens to hundreds, the number of content entities is equivalent to the number of dashboards (such as account transaction details, bill pay), and the data rates tend to be in low tens of thousands per minute even during peak times. These scales are very different than a content aggregation website or mobile application. To address these varying needs for various industries, we suggest the following scale factors:

Class	Users	Ads	Contents	Events/second
Tiny	100,000	10	10	1,000
Small	1,000,000	100	100	10,000
Medium	10,000,000	1,000	1,000	100,000
Large	100,000,000	10,000	10,100	1,000,000
Huge	1,000,000,000	100,000	100,000	10,000,000

Metrics

Since the benchmark covers an end-to-end data pipeline consisting of multiple stages, measures of performance in each of the stages vary widely. Streaming data ingestion is measured in terms of number of events consumed per second, but due to varying event sizes, amount of data ingested

End-to-End Benchmark, Fig. 1 Dataflow across AdBench data pipeline

per second is also an important measure. Streaming data analytics operates on windows of event streams, and performance of streaming analytics should be measured in terms of window size (amount of time per window, which is a product of number of events per unit time, and data ingestion rate). Because of the latency involved in ingestion of data and output of streaming analytics, the most relevant measure of performance of streaming analytics is the amount of time between event generation and event participation in producing results.

Batch computations, such as machine-learned model training (of which recommendation engine is a representative example), the amount of time needed from the beginning of the model training, including any preprocessing of raw data, to the upload of these models to the serving system, need to be considered as performance measure.

Similarly, for ad hoc and interactive queries, time from query submission to the production of results is the right performance measure.

While most of the benchmark suits attempt to combine the performance results into a single performance metric, we think that for an end-to-end data pipeline, one should report individual performance metrics of each stage, to enable choice of different components of the total technology stack. For a rapidly evolving

big data technology landscape, where a complete data platform is constructed from a collection of interoperable components, we encourage experimentation of combining multiple technologies to implement end-to-end data pipeline, and stage-wise performance metrics will aid this decision.

In order to simplify comparisons of environments used to execute these end-to-end pipelines, initially, a simple weighted aggregation of individual stage's performance is proposed as a single performance metric for the entire system, with weights explicitly specified. There is anecdotal evidence to suggest that the business value of data decreases as time between production and consumption of data increases. Thus, one might be tempted to give higher weight to the streaming computation performance than to the batch computation performance. However, it also might be argued that approximate computations in real time are acceptable, while batch computations need exact results, and therefore faster batch computations should be given higher weightage. We propose that determining appropriate weights for individual stages should be an active area of investigation and should be incorporated in the metrics based on the outcome of this investigation.

In addition to performance metrics, the complexity of assembling data pipelines by

combining multiple technologies must be taken into account by the architects of these pipelines. Skills needed to effectively use multiple technologies and operational complexity of these data pipelines tend to be some of the important factors in choosing such systems. These are reflected in the total cost of ownership (TCO) of the system under test. We recommend that metrics such as time and manpower required to develop the pipeline, time to deployment, management, and monitoring tools for operationalizing data pipelines should be reported.

Synonyms

Energy-efficiency benchmarking; Power benchmarking

Definitions

Software that utilizes standard applications, or their core routines that focus on a particular access pattern, in order to measure the power

consumption or energy efficiency of single or multiple servers or storage systems.

Overview

Energy benchmarks are useful tools to analyze the power consumption and efficiency of IT equipment. This chapter will provide historical context for energy benchmarking, brief descriptions of the most commonly used benchmarks, current research findings, and future research challenges.

Historical Background

In 1996, one of the earliest works on an energy-efficiency metric was published by Gonzalez and Horowitz (1996) in which the authors proposed the energy-delay product as the metric of energy-efficient microprocessor design. Almost a decade later, January 2006, the SPECpower Committee (<https://www.spec.org/power>) was founded and started the development of the first industry-standard energy-efficiency benchmark for server-class compute equipment.

The SPECpower Committee developed the SPEC PTDAEMON (http://www.spec.org/power/docs/SPEC-PTDaemon_Design.pdf) interface which offloads the details of controlling a power analyzer or temperature sensor, presenting a common TCP/IP-based interface that can be readily integrated into different benchmark harnesses.

The Power and Performance Benchmark Methodology (https://www.spec.org/power/docs/SPEC-Power_and_Performance_Methodology.pdf) was created by the SPECpower Committee for performance benchmark designers and implementers who want to integrate a power component into their benchmarks. This public document also serves as an introduction to those who need to understand the relationship between power and performance metrics in computer systems benchmarks. Guidance is provided for including power metrics in existing benchmarks, as well as altering existing benchmarks and

designing new ones to provide a more complete view of energy consumption.

In 2007, the research benchmark JouleSort (Rivoire et al. 2007) was released and later that year, the industry standard SPECpower_ssj2008 benchmark (http://spec.org/power_ssj2008), which exercises the CPUs, caches, memory hierarchy, and the scalability of shared memory processors on multiple load levels (Lange 2009). The benchmark runs on a wide variety of operating systems and hardware architectures. 2008 marks the first release of the SPC Energy specifications (<http://spcresults.org/specifications>) and the TPC-Energy specification ([http://www\(tpc.org/tpc_energy/default.asp](http://www(tpc.org/tpc_energy/default.asp)), which utilizes the SPEC PTDaemon.

The SPECpower Committee augmented the SPECpower_ssj2008 benchmark with multi-compute node support in 2009 and started the work on the SERT (<https://www.spec.org/sert>) suite by designing the Chauffeur (<https://www.spec.org/chauffeur-wdk>) framework, followed with the implementation of the workload, automated HW and SW discovery, and GUI.

Several enhancements and code changes to all SPECpower_ssj2008 benchmark components were included in subsequent releases in 2011 and 2012. SPEComp2012 (<https://www.spec.org/omp2012>) and the vendor-based benchmarks VMmark (<https://www.vmware.com/products/vmmark.html>) and SAP (<https://www.sap.com/about/benchmark.html>) were also released in 2012, utilizing the SPEC PTdaemon and the SPEC benchmark methodology.

After a series of successful alpha and beta test phases, the SERT suite was released in 2013 and 2 months later, the US Environmental Protection Agency (EPA) adopted the SERT suite for their ENERGY STAR for Server Certification program. Over the years, four SERT upgrades were released in order to further enhance the usability and to increase its platform support. SPECvirt_sc2013 (https://www.spec.org/virt_sc2013) was also released that year replacing its predecessor, SPECvirt_sc2010.

The Chauffeur framework from SERT is made available as the Chauffeur Worklet Development Kit (WDK). This kit can be used to develop new

workloads (or “worklets,” in Chauffeur terminology). Researchers can also use the WDK to configure worklets to run in different ways, in order to mimic the behavior of different types of applications. These features can be used in the development and assessment of new technologies such as power management capabilities. The first version of the Chauffeur WDK was released in 2014, and succeeded by releases in 2015 and 2017.

For the SERT suite 2.0, one of the main focuses was the reduction of its run time and improvements on the automated hardware and software discovery, in order to save the user testing time and costs. The support of additional power analyzers and interfaces was adopted as well in order to provide wider choices for users. Also, some major improvements of the memory subsystem worklets for more accurate characterization of memory were implemented. Simultaneously to these efforts, the SPECpower Committee, in collaboration with the more academic-focused SPEC Power Research Group (<https://research.spec.org/working-groups/rg-power.html>), conducted large-scale experiments in order to determine the server efficiency metric (<https://www.spec.org/sert2/SERT-metric.pdf>) for SERT Suite 2.0, which enabled its release on March 28, 2017.

Foundations

Energy benchmarks are useful tools to analyze the power consumption and efficiency of IT equipment. They execute standard applications or specialized micro-workloads to stress a system, enabling measurement of the system’s power consumption. Workloads used within an energy benchmark can be adopted from existing benchmarks. Specific to the energy benchmarks are measurement methodologies regarding power measurement and metrics that combine the energy measurement result with the primary performance metric of the underlying benchmark.

An energy benchmark measurement methodology defines, among other things, the point

at which energy is measured. This point is usually the entire system for application benchmarks, but may be specifically instrumented system components for micro- or component-benchmarks. System component instrumentation is rare. Most benchmarks instrument the entire system under test, as it enables comparison of different system architectures and require the least constraints on internal system structure for the benchmark. To further improve the comparability of measurement results, power benchmark measurement methodologies may impose restrictions and requirements on the accuracy of power measurement devices to be used in the benchmark (e.g., the SPEC Power and Performance Methodology (https://www.spec.org/power/docs/SPEC-Power_and_Performance_Methodology.pdf) requires a maximum measurement uncertainty of 1% for all used power measurement devices).

In addition to defining how power is measured, an energy benchmark often defines a performance measure and measurement method. This performance measure usually is intended to be used in conjunction with the power measurements in order to derive an efficiency metric. For this context, *throughput* has established itself as the go-to metric. Throughput defines itself as the number of completed work units per time:

$$\text{Throughput} = \frac{\text{Completed Work Units}}{\text{Measurement Time}} \left[\frac{1}{\text{s}} \right]$$

As work units vary between different workloads, throughput is often normalized by comparing it to the throughput of a reference system.

Energy efficiency is computed using an energy-efficiency metric, which constructs a ratio of power consumption and performance, such as

$$\text{Efficiency} = \frac{\text{Performance}}{\text{Power Consumption}}$$

Alternatively, efficiency may be a ratio of work performed, which is often (depending on the concrete metric) mathematically equivalent to performance per power consumption:

$$\text{Efficiency} = \frac{\text{Work performed}}{\text{Energy expended}}$$

Using throughput as the performance metric, energy efficiency is the ratio of throughput and power consumption in Watts. This is mathematically equal to the alternative efficiency ratio, as work units per time divided by power equals work units divided by energy:

$$\begin{aligned} \text{Efficiency} &= \frac{\text{Throughput}}{\text{Power Consumption}} \left[\frac{\text{s}^{-1}}{\text{W}} \right] \\ &= \frac{\text{Work Units}}{\text{Energy expended}} \left[\frac{1}{\text{J}} \right] \end{aligned}$$

Energy benchmarks can be used to provision Big Data systems with hardware or/and underlying software stack that reduces operational costs and meets environmental criteria.

The following are descriptions of the most common energy benchmarks and energy benchmark specifications:

JouleSort is probably the oldest energy-efficiency benchmark, which is also intended for use with large-scale server systems, as employed in Big Data environments. It was released in 2007 and rates energy efficiency by measuring the total energy consumed while sorting a large array of fixed sizes. It features three workload classes, which differ in the size of the array to be sorted (10 GB, 100 GB, and 1 TB).

SPECpower_ssj2008 is the first industry-standard benchmark for server energy efficiency. It measures the energy efficiency of an emulated transactional enterprise application. SSJ's innovation is the measurement of energy efficiency at multiple load levels. It computes energy efficiency by dividing its normalized throughput (transactions per second) by power consumption. The final score is the sum of the separate load level scores. SSJ is relevant for Big Data, as its methodology has been adopted by many of the following benchmarks.

SPC Energy Specifications are specifications for the benchmarks of the Storage Performance Council (SPC). These benchmarks test the

performance of storage systems (SPC-1 and SPC-2) and storage systems components (SPC-1C and SPC-2C). The energy specifications specify modes of benchmark execution for which power consumption is measured. Power consumption is measured at three loads (idle, mid, and high) and reported with the performance results of the regular benchmark run.

TPC Energy Specification features explicit rules for energy measurement as part of the TPC-C, TPC-E, TPC-H, and TPC-DS benchmarks. TPC energy requires measurement of power consumption of the entire system under test and then computes an efficiency metric corresponding to each benchmark's performance metric. Analogue to the TPC's pricing metrics, the efficiency metric divides power consumption by performance, i.e., computing the inverse metric to the regular efficiency metric used by other benchmarks.

SERT is the Server Efficiency Rating Tool developed by SPEC to evaluate the energy efficiency of servers. The SERT suite is a suite of 12 “worklet” modules that stress different system components and measure performance as well as the power consumption of the system. These worklets stress the CPU, memory, and disk I/O subsystem at various target load levels just as well as one hybrid worklet that stresses a series of complex CPU and memory access patterns. The SERT suite utilizes the Chauffeur harness and is configurable so individual worklets or categories of worklets can be run.

SPECvirt_sc2013 measures the server consolidation aspect of virtualized environments, replacing the SPECvirt_sc2010 benchmark. Its workload is comprised of components from the SPECweb2005, SPECjAppserver2004, SPECmail2008, and SPEC CPU2006 benchmarks. The benchmark reports the performance (SPECvirt_sc2013); performance/power for the system under test including storage (SPECvirt_sc2013_PPW); and performance/power for the server-only (SPECvirt_sc 2013_ServerPPW).

SPEComp2012 is a benchmark package developed by the Standard Performance Evaluation

Corporation (SPEC) to provide a comparative measure of compute-intensive performance across the wide practical range of HPC platforms. The benchmark uses 14 workloads developed from real-world programs from a variety of application areas, including molecular dynamics, fluid dynamics, physics, weather-forecasting, imaging, and computer development. The SPEComp2012 benchmark reports performance in SPECcompG_base2012/SPECcompG_peak2012 (the normalized geometric mean of all 14 workloads) and energy in SPECcompG_energy_base2012/SPECcompG_energy_peak 2012.

VMmark is a benchmark from VMware used to measure the performance of multi-node VMware environments. It introduced power measurement with version 2.5 and utilized the SPEC PTDaemon as the interface between the power analyzer and the benchmark harness. VMmark's workload leverages components from several application areas (Exchange 2007, Olio, DVD Store 2, and a standby mode) in order to stress the system with common virtualization procedures, e.g., virtual machine relocation, relocation, cloning, deployment, and load balancing. VMmark reports the power consumption in power-per-kilowatt (PPKW).

SAP is a benchmark from SAP SE used to measure the performance of SAP application environments. In 2009, the SAP server power benchmark was added to the SAP Standard Application Benchmark Suite. It reports performance in SAP Application Performance Standard (SAPS) and energy efficiency as a key performance indicator (kpi), representing the amount of power consumption per 1000 SAPS (W/kSAPS).

Key Research Findings

A significantly large class of research in Big Data, such as the research in Mashayekhy et al. (2015), focuses on placement of jobs (usually MapReduce jobs) on servers. This kind of

research can utilize energy benchmark results for the information that it provides on the systems in question.

Other research focuses on energy management of the servers themselves when running Big Data applications (Chen et al. 2014). Energy benchmarks are used for evaluating the management mechanisms that result from such research.

Research on the benchmarks themselves has been conducted with focus on workloads and load levels. Load levels have been introduced with the SPECpower_ssj2008 benchmark and have since been implemented in the SPEC SERT suite as well. As load levels are intended to increase the relevance of the energy benchmarks using them, research on these levels has focused on the relevance aspect. In addition, research has investigated the reproducibility of load level implementations. An analysis in Kistowski et al. (2016) showed that the load level mechanism of SPECpower_ssj2008 and SERT allows for a high reproducibility regarding measurement re-runs. Workloads, on the other hand, are usually application specific, but the investigation in Kistowski et al. (2015) demonstrated explicitly that benchmark suites that employ multiple workloads can provide more information for server characterization. This analysis also investigated the information gain that can be achieved by increasing the number of load levels. Similarly, results from multiple micro-benchmarks have been used by researchers for the creation of system models (Bellosa 2000), which, in turn, can be used for energy management research.

Future Directions for Research

Reproducibility is a significant challenge for energy benchmarks, as these benchmarks require both the performance results, as well as the power measurements to be reproducible. However, it was shown that power measurements of nominally identically servers, using hardware with the same nameplate information and configuration, can differ for as much as 15% (Chen et al. 2014). This difference is due primarily to differences in semiconductor quality within the hardware itself.

Future research on energy-efficiency benchmarks must find answers on how to deal with this spread of results.

Energy Efficiency in Big Data Analysis

Carmela Comito
CNR-ICAR, Rende, Italy

Overview

Data generation has increased drastically over the past few years. Processing large amounts of data requires huge compute and storage infrastructures, which consume substantial amounts of energy. Moreover, another important aspect to consider is that more and more the data is analyzed on-board battery operated mobile devices like smart-phones and sensors. Therefore, data processing techniques are required to operate while meeting resource constraints such as memory and power to prolong a mobile device network's lifetime. This chapter reviews representative methods used for energy efficient Big Data analysis, providing first a generic overview of the issue of energy conservation and then presenting a more detailed analysis of the issue of energy efficiency in mobile and sensor networks.

Energy-Aware Big Data Analysis: Approaches and Trends

Distributed data analysis strategies are widely adopted to cope with huge volumes of data and to provide fast response times. Usually distributed

data analysis is performed on computer clusters composed by thousands of computers and hosted in large data centers. While such facilities enable large-scale online services, they also raise economical and environmental concerns. Indeed, a large-scale data center can draw tens of megawatts of electricity to operate, and it can cost millions of US dollars per year in terms of energy expenditure. Therefore, an important problem to address is how to reduce the energy expenditure of data centers. Obviously, a possible solution to these challenges consists in designing more energy-efficient data centers, which consume less energy and, consequently, pollute and cost less. In the past, a large part of the energy consumption of a data center could be accounted to inefficiencies in its cooling and power supply systems. However, many companies already adopt state-of-the-art techniques to reduce the energy wastage of such systems, leaving little room for more improvements in those areas. Indeed, the energy consumption of a state-of-the-art data center would be reduced by less than 24% if all the overheads in its cooling and power supply systems were eliminated. Therefore, new approaches are necessary to mitigate the environmental impact and the energy expenditure of data centers.

This section reports the main approaches proposed to reduce energy consumption of big data analysis frameworks, by differentiating among the hardware and software solutions. At the end of the section, the few initiatives that have been done in the DBMS community are outlined.

Hardware Approaches

The energy expenditure of data centers can be mitigated by reducing the energy consumption of the computing resources. In fact, most of the existing research work in the area of energy-aware systems concerns hardware-based techniques focused on reducing the energy consumption of the processor. Among those techniques, turning off idle components is widely adopted (Li et al. 1994). In particular, CPUs are the most energy-consuming component in servers dedicated to query processing, accounting for 40% of total energy consumption when a server is idle and for

66% of total energy consumption when it is fully utilized.

Dynamic Voltage and Frequency Scaling (DVFS) is another hardware-based technique for energy conservation, allowing for simultaneously varying the processor voltage and frequency as per the energy performance level required by the tasks (Zhuo and Chakrabarti 2005; Aydin et al. 2004; Seth et al. 2003). In fact, higher core frequencies mean faster computations but higher power consumption, while lower frequencies lead to slower computations but reduced power consumption. However, arbitrary slowing down the CPU can yield significant performance degradation especially during compute-bound application phases: low frequencies entail longer query processing times that may be unacceptable for the users.

Another important aspect that can be exploited to reduce the energy consumption of a server is the fact that users can hardly notice response times that are faster than their expectations. Therefore, sometimes it is not necessary to process queries faster than user expectations, and based on this observation, Catena and Tonellootto (2017) proposed the Predictive Energy Saving Online Scheduling Algorithm (PESOS) to select the most appropriate CPU frequency to process a query on a per-core basis. PESOS aims at process queries by their deadlines and leverage high-level scheduling information to reduce the CPU energy consumption of a query processing node. PESOS bases its decision on query efficiency predictors, estimating the processing volume and processing time of a query.

Uni-processor energy-aware scheduling algorithms have been developed to make an efficient use of hardware-based energy management techniques. An energy-aware scheduling algorithm, proposed in Weiser et al. (1996), orders task execution such that different components of a mobile computing device can have longer idle periods to be shut down. Several energy-saving scheduling (e.g., Zhang et al. 2002; Luo and Jha 2000) algorithms for multi-processor distributed systems are focused on architectures with dynamic voltage scaling or dynamic power management capabilities.

Software Approaches

Among software-based energy-aware techniques, remote execution provides that a device with limited energy transfers a computational task to a nearby device which is more energy powerful (Rudenko et al. 1998; Li et al. 2001). Software-based energy management emerged as a key topic for resource management in distributed cluster-based systems (Bianchini and Rajaniony 2004; Lefurgy et al. 2003). The use of virtualization for consolidation is presented in Petrucci et al. (2009), which proposes an approach for power optimization in virtualized server clusters through an algorithm that dynamically manages the virtualized servers. Following the same idea, Liu et al. (2009) aims to reduce the power consumption in virtualized data center by supporting task migration and task placement optimization. Verma et al. (2008) also propose a virtualization-aware adaptive consolidation approach, measuring energy costs executing a given set of applications and using correlation techniques to predict usage. PARM (Mohapatra and Venkatasubramanian 2003) is a distributed power-aware middleware framework consisting of several distributed servers (service providers), proxy servers, metadata repositories (directory services), and mobile clients. The framework adapts to the diminishing power availability of the devices over time, by dynamically off-loading expensive middleware components to a proxy.

Energy-aware task scheduling is another software method where the scheduling policy aims at optimizing the energy consumption. Alsalih et al. (2005) proposed an energy-aware dynamic task allocation algorithm over mobile networks. They adopt an objective function that minimizes the energy consumption in the network. The solution proposed in Alsalih et al. (2005) does not address the communication aspects of the system; it considers only the local computation issues and works at a node level without taking into account the workload in the rest of the network.

DBMS Approaches

With the rising energy costs and energy-inefficient server deployments, it is key for

DBMSs to evolve and to consider energy efficiency as a main goal (Lang et al. 2011).

Processing the query as fast as possible is not the most energy-efficient way to operate. First, typical servers often run at low utilization. This opens the opportunity to execute the query slower, if the additional delay is acceptable. For example, this situation may occur if the service-level agreement (SLA) permits the additional response time penalty. Since typical SLAs are written to meet peak or near-peak demand, SLAs often have some slack in the frequent low utilization periods, which could be exploited by the DBMS. Second, components on modern server motherboards offer various power/performance states that can be manipulated from software. Of these components, the CPU is currently the most amenable for transitioning between such power/performance states. Based on these observations, in Lang et al. (2011) is proposed a novel framework where the query optimization problem is to find and execute the most energy-efficient plan that meets the SLA. To enable this framework, existing query optimizers have been extended with an energy consumption model, in addition to the traditional response time model. With these two models, the enhanced query optimizer can generate a structure that details the energy and response time cost of executing each query plan at every possible power/performance state under consideration.

Lang and Patel (2009) proposed the ecoDB project whose goal is to investigate energy-efficient methods for data processing in distributed computing environments, proposing two mechanisms that can trade energy for performance. The first mechanism, called Processor Voltage/Frequency Control (PVC), lets the DBMS explicitly change the processor voltage and frequency parameters. Processors can take commands from software to adjust their voltage/frequencies to operate at points other than their peak performance. The second mechanism is at the workload management level. It is referred to as the Explicit Query Delays (QED) approach where queries are delayed and placed into a queue on arrival. When the queue reaches a certain threshold, all the queries in the

queue are examined to determine if they can be aggregated into a small number of groups, such that the queries in each group can be evaluated together. Evaluating this workload can trade average query response time for reduced overall energy consumption. Single group queries can be run in the DBMS at a lower-energy cost than the individual queries.

In Roukh et al. (2016) is proposed an energy-aware query optimizer framework, called EnerQuery, which leverages the PostgreSQL query optimizer by integrating the energy dimension. EnerQuery is built on top of a traditional DBMS to capitalize the efforts invested in building energy-aware query optimizers. Energy consumption is estimated on all query plan steps and integrated into a mathematical linear cost model used to select the best query plans.

E

Energy-Efficient Data Analysis on Mobile Computing

The increasing power of wireless devices is opening the way to support analysis and mining of data in a mobile context (Wang et al. 2003).

Mobile data analysis and mining may include different scenarios in which a mobile device can play the role of data producer, data analyzer, client of remote data miners, or a combination of them. Accordingly, an increasing number of smartphone and PDA-based data intensive applications have been recently developed (Kargupta et al. 2002, 2003; Wang et al. 2003). Examples include smartphone-based systems for body-health monitoring, vehicle monitoring, and wireless security systems.

A key aspect that must be addressed to enable effective and reliable data mining over mobile devices is ensuring energy efficiency, as most commercially available mobile devices have battery power which would last only a few hours (Comito et al. 2011, 2012).

In Bhargava et al. (2003), based on the experimental energy consumption data collected for several popular data analysis techniques, it has introduced energy efficiency as a novel criterion

to evaluate algorithms intended to run on mobile and embedded platforms. The authors characterize and compare the energy consumed by data mining applications implemented onboard a device with the energy costs for sending the data to a remote site. The obtained results show that for low-bandwidth lossy networks, the high energy costs of communication often make local onboard data mining a more energy-efficient choice.

The work in Comito and Talia (2017) enables energy-efficient execution of data mining algorithms on mobile devices, making them lightweight in terms of resource utilization. To achieve this purpose, the approach is to act on data dimensionality according to the fact that mining algorithms are data intensive. Therefore, in order to identify the key factors in the data complexity in Comito and Talia (2017), an experimental study of the energy consumption characteristics of representative data mining algorithms running on mobile devices is performed. The performance analysis depends on many factors encompassing size of data sets, attribute selection, number of instances, number of produced results, and accuracy. To carry out the performance evaluation, an Android application has been developed allowing users to execute data mining algorithms over Android smartphones by tuning a set of parameters. The energy characterization outcomes have been then exploited to predict the energy costs of data mining algorithms running on mobile devices. Specifically, in Comito and Talia (2017) is designed and implemented a machine learning-based framework to predict, from a set of mobile devices and set of data mining tasks, the resulting energy consumption of such tasks over the mobile devices. A supervised approach has been used where the main idea is to exploit examples of cases from past system behavior to construct an energy model that is able to predict the class of new examples.

Many emerging context-aware mobile applications involve the execution of continuous queries over sensor data streams generated by a variety of onboard sensors on multiple personal mobile devices. To reduce the energy overheads,

the work in Yang et al. (2013) introduces CQP, a collaborative query processing framework that exploits the overlap across multiple smartphones. The framework automatically identifies the shareable parts of multiple executing queries and then reduces the overheads of repetitive execution and data transmissions, by having a set of “leader” mobile nodes executing and disseminating these shareable partial results. To further reduce energy, CQP utilizes lower-energy short-range wireless links to disseminate such results directly among proximate smartphones.

Efficient resource allocation and energy management can be achieved through clustering of mobile nodes into local groups. In Comito and Talia (2014) is proposed a clustering scheme where mobile devices are organized into local groups (clusters or mobile groups). Each cluster has a node referred to as cluster head that acts as the local coordinator of the cluster. The focus of the approach is building and maintaining a cluster structure in a network of cooperating mobile devices. The problem of assigning devices to clusters has been formulated as a multicriteria decision-making problem based on the weighted-sum approach. A multi-objective cost function is defined where the aim of the optimization is to maximally extend the network lifetime and the mobility similarity of the devices within a group. Depending on the specific application scenario, the weights associated to the two costs can be properly tuned. This way optimal decisions may be taken in the presence of trade-offs between the two objectives. A weighted metric that combines the effect of energy and mobility of nodes is also introduced to select suitable cluster-head nodes.

In Comito et al. (2017) is proposed an energy-aware (EA) scheduling strategy for allocating computational tasks over a wireless network of mobile devices. In such a network, the devices are clustered into local groups, named *clusters*. Generally, geographically adjacent devices are assigned to the same cluster. To make the most of all available resources, the EA strategy tries to find a suitable distribution of tasks among clusters and individual devices. Specifically, the

main design principle of the strategy is finding a task allocation that prolongs the total lifetime of the wireless network and maximizes the number of alive devices by balancing the energy load among them. To this end, the EA scheduler implements a two-phase heuristic-based algorithm. The algorithm first tries to assign a task locally to the cluster where the execution request has been generated, so as to maximize the cluster residual life. If the task cannot be assigned locally, the second phase of the algorithm is performed by assigning the task to the most suitable node all over the network of clusters, maximizing this way the overall network lifetime. The energy model takes into account the energy costs of both computation and communication.

Energy-Efficient Query Processing in Sensor Networks

Query processing has been studied extensively in traditional database systems. However, few existing methods can be directly applied to wireless sensor database systems (WSDSs) due to their characteristics, such as decentralized nature, limited computational power, imperfect information recorded, and energy scarcity in individual sensor nodes. Moreover, traditional database systems result in high energy consumption and low energy efficiency due to the lack of consideration of energy issues and environmental adaptation in the design process. In this section, representative recent efforts on this issue, with a focus on energy-aware query optimization and energy-efficient query processing, are reported.

In Guo et al. (2017) is proposed a method of modeling energy cost of query plans during query processing based on their resource consumption patterns, which helps predict energy cost of queries before execution. Using the cost model as a basis, the evaluation model can utilize the trade-offs between power and performance of plans and helps the query optimizer select plans that meet performance requirements but result in lower-energy cost. Finally, a green database framework integrated with the two above models is proposed to enhance a commercial DBMS.

Experimental results reveal that, with reliable and accurate statistical data, the framework proposed in this study can achieve significant energy savings and improve energy efficiency.

Query for sensor networks should be wisely designed to extend the lifetime of sensors. In Sun (2008) is presented a query optimization method based on user-specified accuracy item for wireless sensor networks. When issuing a query, user may specify a value/time accuracy constraint according to which an optimized query plan can be created to minimize the energy consumption. At each single sensor node, instead of direct delivery of each reading, algorithms are proposed to reduce both data sensing and data transmission.

In Rosemark et al. (2007), a query optimizer for sensor networks whose key component is a cost-based analysis to estimate the overall energy consumption associated with a given query plan over the lifetime of a query is presented. By utilizing this estimation technique, the query optimizer compares the desirability of several candidate plans for a given query and chooses a plan that is likely to utilize the least energy for execution. Simulation results show that the query plan chosen by such query optimizer consumes significantly less energy than the state-of-the-art query processing engine for sensor networks. In Alwadi and Chetty (2015), an energy-efficient data mining approach to characterize and classify large-scale physical environments based on a combination of feature selection and single mode/ensemble classifier techniques is introduced.

By approaching the complexity of WSN/SN with a data mining formulation, where each sensor node is equivalent to an attribute or a feature of a data set, and all the sensor nodes together forming the WSN/SN setup equivalent to multiple features or attributes of the data set, it is possible to use powerful feature selection, dimensionality reduction, and learning classifier algorithms from data mining field and come up with an energy-efficient automatic classification system. Here, minimizing the number of sensors for energy-efficient control is very similar to minimizing the number of features with an optimal feature selection scheme for the data mining problem.

Conclusion and Future Direction

This chapter presented a survey of some of the most representative initiatives that have been done in the field of energy-efficient big data analysis. On top of the current approaches described above, there is a need for new methods and concepts in order to optimize the processing of big data analysis and improve the associated energy efficiency. Three main promising topics can be then considered:

- approximate computing
- quantum technologies
- low-energy processors

In light of the need for new innovations to sustain these improvements, approximate computing plays a key role. Approximate computing has recently emerged as a promising approach to energy-efficient design of digital systems. It relies on the ability of many systems and applications to tolerate some loss of quality or optimality in the computed result. By relaxing the need for fully precise or completely deterministic operations, approximate computing techniques allow substantially improved energy efficiency. The objective here is not to describe this concept in detail; nevertheless the main research topics can be mentioned:

- Approximate circuits: Components like approximate adders, multipliers, and other logical circuits can significantly reduce hardware overhead. For example, an approximate multi-bit adder can ignore the carry chain and, thus, allow all its sub-adders to perform additional operation in parallel.
- Approximate storage: Instead of storing data values exactly, they can be stored approximately, or another method is to accept less reliable memory. In general, any error detection and correction mechanisms should be disabled. Software-level approximation: There are several ways to approximate at software level like memorization, iterations of loop deletion, some tasks skipping, etc.

- Approximate system: Here, different subsystems of the system such as the processor, memory, sensor, and communication modules can be approximated to obtain a much better than the one reached at sub-system level.

Quantum computing studies computation systems that make direct use of quantum mechanical phenomena, such as superposition and entanglement, to perform operations on data. As of 2017, the development of actual quantum computers is still in its infancy, but experiments have been carried out in which quantum computational operations were executed on a very small number of quantum bits. Both practical and theoretical research continues, and large-scale quantum computers would theoretically be able to solve certain problems much more quickly than any classical computers that use even the best currently known algorithms. That implies a more efficient way to compute and will lead to a better efficiency.

Finally, low-energy processors will also play an important role in the energy efficiency and optimization battle. This domain helps design CPUs that perform tasks efficiently without overheating which is a major consideration of nearly all CPU manufacturers to date. Some CPU implementations use very little power; CPUs in mobile phones often use just a few watts of electricity, while some microcontrollers used in embedded systems may consume only a few milliwatts or less. In comparison, CPUs in general-purpose personal computers, such as desktops and laptops, dissipate significantly more power because of their higher complexity and speed. For all the manufacturers, the final objective is so to reduce the power consumption. This can be done in several ways, from voltage, frequency, capacitance reduction, or recycling some of the energy stored in the capacitors rather than dissipating it as heat in transistors.

As a highlight with these three examples, diminishing benefits from technology scaling have pushed designers to look for new sources of computing efficiency. These are part of our near future; nevertheless, as energy efficiency is becoming a major challenge for the computing

industry, progresses in the domain will continue and new concepts will emerge.

Definitions

Data storage, communication, and processing consume energy, and big data requires a correspondingly big energy budget, necessitating more attention and effort to ensure energy efficiency.

Overview

Until fairly recently, developments in the field of computer architecture (Parhami 2005) were focused around computation running time and hardware complexity and how the two can be traded off against each other in various designs. With the advent of mobile devices and terascale, petascale, and, soon, exascale computing, energy consumption emerged as a major design

factor that overshadowed the older concerns to some extent. Key driving forces for research into energy efficiency were battery life in compact mobile devices with smallish batteries, energy costs for operators of supercomputer centers, and the difficulties of heat dissipation in both mobile devices and mainframe/data-center installations. We are thus motivated to seek extreme energy economy measures to make the processing of large data sets feasible within power budgets that are practical for both cloud data centers and mobile devices used at the cloud's edges.

Energy-Efficiency Trends

Early digital computers of the 1940s performed about one operation per Watt-hour (Wh) of energy consumed. Those machines, which resembled factory equipment, were bulky, unreliable, and user-unfriendly, problems that overshadowed their energy inefficiency. The exponential decline of the per-computation energy requirement, or exponential rise of the number of operations performed per unit of energy (Denning and Lewis 2017), over the decades is known as Koomey's law (Koomey et al. 2011). The exponential rise of computational capability per kWh of energy is depicted in Fig. 1.

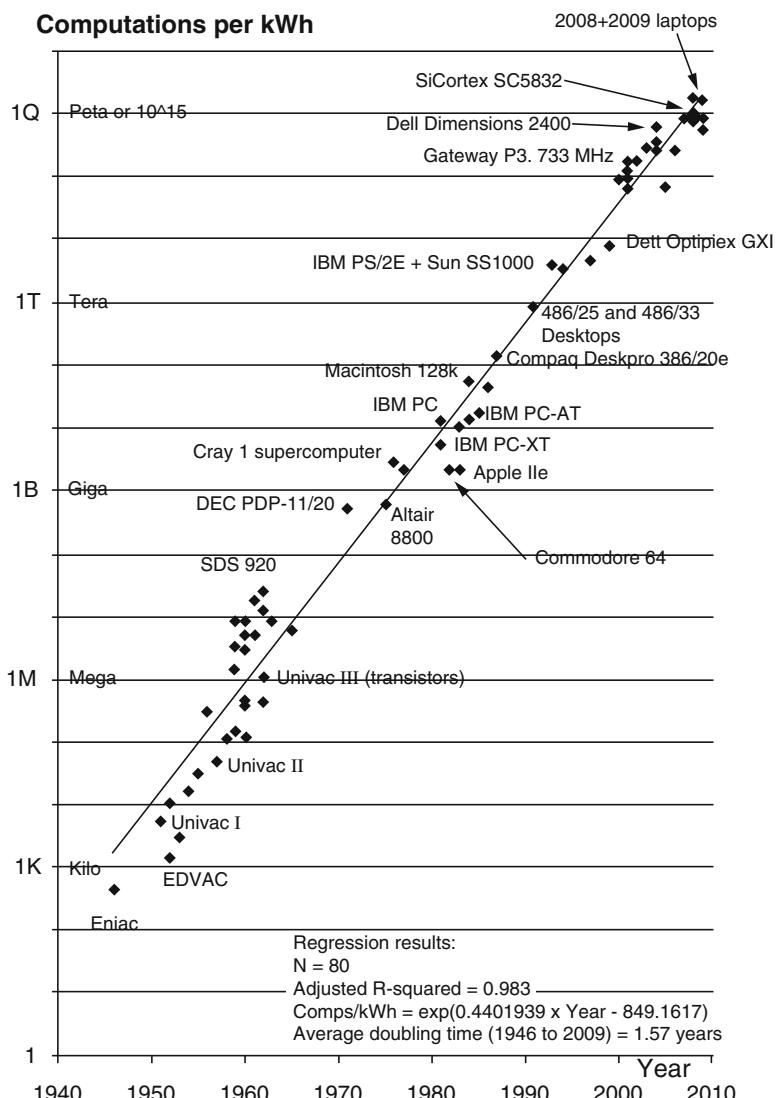

A simple back-of-the-envelope calculation based on the expected 10^{25} bytes of data produced per day by 2020 leads to the conclusion that even at the optimistic 10^{18} computations per kWh, energy requirements of big-data processing will be prohibitive.

Causes of Energy Dissipation

As energy efficiency of mainstream processors that control servers, desktops, laptops, and smartphones has improved, research into ultralow-power digital circuits has paved the way for even greater reduction in energy requirements per computation. Physical laws dictate that any nonlinear transformation of the kinds performed by standard AND/OR logic

Energy Implications of Big Data, Fig. 1

Trends in energy efficiency, expressed as computations per kWh (Koomey et al. 2011)

gates must necessarily expend energy, and a lower bound for this energy is known to be on the order of kT , where $k \approx 1.38 \times 10^{-23}$ is the Boltzmann constant and T is the operating temperature in Kelvin (Landauer 1961). This lower bound has come to be known as Landauer's principle (Bennett 2003). Although, in principle, this minimum should be reachable, current computing devices are a great deal less efficient in the amount of energy they dissipate.

The energy used by a computing device is the product of average power drawn and the computation time. This relationship suggests two

ways of reducing the energy consumption: Using lower-power technologies (e.g., Jaberipur et al. 2018) and using faster algorithms. Use of faster algorithms is, of course, highly desirable, as it has performance implications as well. So, there is a great deal of ongoing research to find ever-faster algorithms for computational problems of interest. Power consumption per device has been going down due to Dennard scaling, a law devised in 1974 that maintains the relative constancy of MOSFET power density, as transistors get smaller, a trend predicted by Moore's law (Brock and Moore 2006; McMenamin 2013).

The power dissipated by computing devices consists of static and dynamic components. Static power is the power used by devices that are in the off state and ideally should not be drawing any power; however, leakage and other factors lead to some power waste, which is increasing in significance as we use smaller and denser circuits. Dynamic power (Benini et al. 2001) is proportional to the operating voltage squared, the operating frequency, circuit capacitance, and activity (prevalence of signal-value changes). Low-voltage circuits use much less power, but the closer we get to the threshold voltage, the slower and less reliable circuit operation becomes (Kaul et al. 2012). Thus, there is a limit to power savings by reducing the operating voltage.

Reasons for energy waste include glitching (Devadas et al. 1992), unnecessary signal-value transitions that can be avoided by suitable encodings (e.g., Musoll et al. 1998), and not clocking the circuitry that is not involved in performing useful computations (Wu et al. 2000). Practical notions in this regard include energy-proportional computing, that is, the desirable property that the energy used is commensurate with the amount of useful work performed (Barroso and Holzle 2007), and dynamic frequency AND/OR voltage scaling (Nakai et al. 2005) in an effort to save energy when application requirements do not demand the highest performance level.

A data center's energy efficiency is influenced by three factors attributed to the facility, server conversion efficiency, and efficiency at the level of circuits and devices (Barroso et al. 2013). Only about a third of the energy is used for productive computation (Holzle 2017). Generally speaking, large-scale installations provide more opportunities for energy fine-tuning, thus underlining the importance of data centers and cloud-computing in handling big-data loads. More on this later.

Near-Threshold Multi-core Computing

Parallel processing is nearly a necessity for handling of large data volumes, on performance

grounds. It is also helpful for reducing power consumption. Using m processors/cores, each with $1/m$ the speed, is more energy-efficient than using a single high-performance processor. Thus, if an application offers enough parallelism to use multiple processors/cores efficiently, it will lead to higher performance AND/OR lower energy consumption. Beginning with dual-core chips in the mid-2000s, multi-core chips (Gepner and Kowalić 2006) have allowed performance scaling to continue unabated, despite Moore's Law, in its original formulation, becoming invalid (Mack 2011).

While use of a large number of simple cores carries energy-efficiency benefits, one must also pay attention to the effect of inherently sequential parts of a computation which give rise to speedup limits predicted by Amdahl's law (Parhami 1999). Perhaps a judicious mix of powerful or "brawny" and simple or "wimpy" cores (Holzle 2010) in a multi-core chip, possibly also including application-specific performance boosters (Hardavellas et al. 2011), can help mitigate this problem.

The ultimate in energy efficiency is achieved when the processors/cores operate very near the threshold voltage (Dreslinski et al. 2010; Gautschi 2017; Hubner and Silano 2016). As operating voltage is scaled down, performance is reduced nearly linearly, whereas active energy dissipation goes down quadratically. Therefore, performance per unit of energy improves. When the static or leakage power is taken into account, the savings become less pronounced but still significant. Near-threshold computing has pitfalls in terms of computation stability and system reliability, so there is a sensitive trade-off to be performed. There is also the issue of giving up too much in sequential performance in the hopes of regaining some of it via parallel processing (Mudge and Holzle 2010).

Memory/Storage Energy Requirements

Dynamic random-access memory (DRAM) chips account for a significant fraction of the power

used in a computer's electronic parts. Static RAM (SRAM) is even more energy-intensive, but because SRAM sizes tend to be relatively much smaller, they do not contribute as much to the energy budget of a system. Precise modeling of DRAM energy consumption has been attempted in an effort to determine the exact share of power used; importance of power dissipation within the memory cells vs. peripheral circuitry for decoding, access, and content refreshing; and expected changes as DRAM technology is scaled down and goes through other generational changes (Vogelsang 2010). These methods will guide energy reduction in main memories in the near future. For the longer term, a variety of main memory technologies, some of which enable inherently lower-power operation, are being investigated (Xie 2011).

Disk memories are both slow and energy-intensive but have the advantage of permanence, low cost per bit, and nonvolatility. For small to modest memory sizes, replacement of disks with solid-state memories is feasible, but for very large data volumes, such a replacement is still impractically expensive. So, in the short term, we have to live with disk memory shortcomings. Even though a single disk unit has a long mean time to failure (MTTF), when many thousands of disks are involved in a storage warehouse, failures are inevitable. Modern data storage facilities make use of redundant arrays of independent disks, RAID for short (Schroeder and Gibson 2007), to mitigate the slowness and low reliability of disk units. A variety of methods have been devised to make disk memories and attendant units, such as disk caches and RAID controllers, that make a disk array look like a single disk and reconstruct damaged or lost data upon disk failures, more energy-efficient (Pinheiro and Bianchini 2014).

As storage devices are increasingly networked to gain the reliability, availability, and scale benefits of distributed access, communication overhead and its attendant energy requirements must be factored in when comparing different organizations with regard to energy efficiency.

Communication Energy Requirements

Like computation and storage, communication also dissipates energy. In fact, one of the most challenging aspects of managing big-data applications is to decide how the energy budget should be allocated to the three aspects of computing, storage, and communication. Data replication often reduces communication costs during access but may impose a nontrivial overhead for keeping replicas consistent, and storage of previously computed results may obviate the need for re-computation.

Reducing communication costs has been studied extensively in connection with energy-limited mobile and sensor networks (Heinzelman et al. 2000), but many of the techniques are applicable more broadly. For example, expending local computation to aggregating data before transmitting a smaller volume of data is a generally useful method (Krishnamachari et al. 2002).

Given their current prevalence and future importance, energy efficiency consideration for on-chip networks and those used in data centers are of paramount importance. Networks-on-chip (Benini and De Micheli 2002; Pande et al. 2005) are key components of modern multi-core chips, and their importance will increase as the number of cores is scaled up. Data-center networks have been subjects of numerous studies, given their role in the energy costs of a typical data center (Hammadi and Mhamdi 2014). One example consists of the proposal for energy-proportional data-center networks (Abts et al. 2010).

Beyond networks-on-chip and data-center networks, we must also be concerned with energy efficiency in broad-area networks, the Internet in particular (Bolla et al. 2011). Whereas the introduction of low-power techniques in the design of routers and other electronic units is necessary for energy-efficient networking, it is not enough. We also need energy savings at the physical network layer and in the algorithms and protocols used for computation, routing, resource management, testing, and fault tolerance.

Energy Considerations in the Cloud

The cloud consists of computational, storage, and communication resources. Yet, to achieve energy efficiency in the cloud, we must go beyond separate energy optimizations for the aforementioned components. Such optimizations are challenging, given the scale of the cloud (Assuncao et al. 2015; Feller et al. 2015). As of 2017, servers collectively use about 200 TWh of energy, which is comparable to energy use in all of Mexico. Google alone uses as much energy as the city of San Francisco. As large as this value is, it is dwarfed compared with the energy required by users' laptops or other computing equipment at the edges of the cloud.

As for the energy used in data-center installations, it consisted until fairly recently of three nearly equal parts devoted to mechanical cooling, IT equipment, and everything else (lighting, backup power supply, etc.). So, the energy used for the actual computation was multiplied by a factor of 3.0, implying a 200% overhead. More efficient modern data centers reduced this factor to 1.8, for an overhead of 80%. Now, we can go as low as 10% overhead through a variety of energy-saving schemes, including the application of machine learning to adjust a building's cooling strategy based on information about the applicable parameters (Holzle 2017).

Servers have undergone similar efficiency improvements. Earlier, some 50% of energy went to waste, even before power got to the actual circuits. By eliminating this waste, we are now at about 10% overhead relative to the actual energy used by the circuits. The circuit energy has been going down by 20% per year in recent years (post-Moore's Law era). Factors leading to this reduction are smaller circuits, clock-gating (disabling the parts of the circuits not in use, so that they don't draw energy), frequency scaling, and specialization (tailoring the circuits to computations). In the latter domain, Google's hardware optimized for machine learning uses 0.2 MW of power, compared with 2.5 MW needed by a general-purpose supercomputer doing the same job (Holzle 2017).

As a whole, the IT industry uses about 2% of the world's energy, which is of the same order as the amount used by airlines. Because modern data centers are way more efficient than local server installations, moving to the cloud will reduce the energy consumption associated with computations by some 87%. Operating data centers with exclusive use of renewable energy is now possible, which constitutes a major benefit. The lower hardware redundancy needed to ensure reliable operation also saves energy. For example, Gmail uses 1% redundancy in hardware resources, whereas a typical local e-mail server installation needs at least duplication to avoid service disruptions. This makes the user-side energy consumption even more important. Fortunately, with the move away from desktops and laptops to tablets and smartphones, user-side energy consumption is also plummeting.

Future Directions

Work is proceeding in improving energy efficiency in all aspects of the big-data environment discussed in the preceding sections. At the circuit and chip levels, ultralow-power technologies are being devised and evaluated. Examples are found in the fields of optical, biologically inspired, adiabatic, and reversible circuits. The ultimate goal might be doing away with batteries and other power sources altogether (Eisenberg 2010), for a large fraction of the big-data ecosystem. Significant reduction in the dissipated energy will also obviate the need for complex cooling strategies and their associated hardware and software costs (Kaushik and Nahrstedt 2012).

The future of big data is closely tied to the future of cloud computing, as the economy of scale provided by the cloud is necessary for the successful deployment of big-data applications (Hashem et al. 2015; Wu et al. 2013). A promising direction in energy monitoring and optimization, with no need for human intervention, is the use of machine learning strategies. Such techniques have already been applied to power management at the circuit level (Dhiman and Rosing

2006) and to data-center climate control systems (Holzle 2017), but a great deal more can be done.

Definitions

ETL is short for Extract-Transform-Load. The ETL process extracts data from operational source systems, transforms the data, and loads the data into a target. The transformations to perform on the data can involve a plethora of different activities, e.g., filtering, normalization or de-normalization to a desired form, joins, conversion, and cleansing to remove bad or dirty data. In the ELT variant, the data is extracted from the source systems, loaded in its raw form into the target, and then transformed.

Overview

The term ETL process has traditionally been used for a process that populates a data warehouse (DW) managed by a relational database management system (RDBMS). As pointed out by Simitsis and Vassiliadis (2017), the basic concept of populating a data store with data reshaped from another data store is, however, older than data warehousing. The ETL process can be hand-coded or made with a designated ETL tool where the developer typically uses graphical constructs to define the ETL process. With the emergence of cheap technologies for capturing and processing Big Data, the requirements to ETL tools have increased. First, new types of data sources have appeared, for example, NoSQL systems, files in the Hadoop Distributed File System (HDFS), and streams from Apache Kafka. Second, the target to load data into may be something different from a DW managed by an RDBMS. Organizations with very big amounts of data are now using many clusters of commodity computers (or clouds in case the machines are virtual) for data processing and data analytics. In such a case, the ETL process, for example, has to load the data into HDFS files.

Both commercial and open source ETL tools now typically provide support for Big Data sources. It varies from tool to tool exactly which types of sources are supported, but reading data from HDFS files is very widely supported. This kind of support thus enables extracting existing data from a Big Data system. Querying and transformation of such data are also supported by varying degrees. Basic support includes the execution of a predefined task on a Big Data processing platform. Such a task could, for example, be a HiveQL query on Hive, a MapReduce job on Hadoop, or a file operation on HDFS. More advanced ETL tools in addition support that the developer uses the ETL environment and its transformations to define an ETL flow which then automatically is translated into a native program (e.g., Spark or MapReduce) that can be executed on a Big Data

processing platform. The same ETL flow can then be used both for testing and development on a stand-alone machine with little data and for production on a cluster with large amounts of data. Tools supporting this are typically based on the visual paradigm where the developer connects boxes representing transformations with lines representing dataflow. Much development of ETL flows for Big Data is, however, done by manual programming of Spark programs or the like. This allows the developer to easily integrate with the existing tool chain and to use the quickly evolving functionality of the data processing platform. Databricks report that the most widely used language for ETL programming on Spark is Python (No matter if visual or code-based ETL flow definitions are used, the use of a massively parallel system like Spark enables processing of larger and more complex datasets than can be handled in more traditional setups with a single ETL server. The transformed and cleaned data can then be loaded into a traditional DW managed by an RDBMS, or it can be stored directly in files (e.g., in ORC or Parquet format) in HDFS to enable analysis from tools like Hive and Spark. In the latter case, it is often necessary to also use data residing in a relational database. To support the need for efficient bulk transfers between Hadoop and relational databases, the open source and command-line-based tool Sqoop (<http://sqoop.apache.org/>) was created.

With the advent of cloud computing platforms available on demand (such as Amazon Web Services and Google Cloud Platform) and data warehousing solutions for them (such as Amazon Redshift (Gupta et al. 2015), Snowflake (Dageville et al. 2016), and Google BigQuery (Tigani and Naidu 2014)), on-demand ETL services have also appeared recently. Examples include Matillion, Attunity Compose, and AWS Glue. With such services, the user pays for the use of the ETL software and the hardware it is running on based on how long the software is running. This thus makes it possible to start using the ETL services with very low upfront payment and to scale to larger hardware when needed.

Key Research Findings

Cloud computing gained momentum in the 2000s, and this opened possibilities for collecting and analyzing big datasets. In 2004, Google published a paper about their MapReduce framework (Dean and Ghemawat 2004) which soon became very popular. It offered an easy way to make a highly scalable and fault-tolerant program for a cluster of hundreds or thousands of computers. The developer only had to define two functions – *map* which processes different parts of the input in parallel and produces intermediate key/value pairs and *reduce* which for a given intermediate key and all its values produces a result. Open source versions of MapReduce and its distributed file system were implemented in Apache’s Hadoop and HDFS, respectively, as well as in other frameworks. MapReduce was not only used for analysis of data but also preprocessing of data such as cleansing and transformations. IBM reported that many customers used MapReduce to preprocess data before loading it into DW managed by the DB2 DBMS (Özcan et al. 2011). While MapReduce conceptually is simple, there are still many technical aspects to pay attention to when using it and the developer uses a general-purpose programming language (such as Java for Apache Hadoop) to express what to do. Further high-level functionality (such as joins) is not built-in. It can thus be tedious and error prone to write MapReduce programs. As a remedy, Facebook proposed Hive (Thusoo et al. 2009) where the user can use the high-level SQL-like HiveQL language. HiveQL queries are then compiled into MapReduce jobs by Hive’s query compiler. Hive also supports so-called external tables with data written to files by other applications and can be extended to read other input formats. It can also use user-defined functions (UDFs) written in Java. It is thus possible to use Hive to do much ETL/ELT processing of data.

Another abstraction on MapReduce is Pig (Olston et al. 2008) where the developer specifies sequences of transformations in a high-level procedural language called Pig Latin. Pig is made for parallel data processing and can operate on rela-

tional, nested, and unstructured data. It has built-in functionality for joining, grouping, ordering, filtering, etc. and can also be extended by UDFs. Pig thus also became popular for transforming and cleaning data in ETL flows. Pig can now execute on MapReduce as well as other platforms. Sawzall (Pike et al. 2005) is a similar tool created by Google.

ETLMR (Liu et al. 2013) was proposed as a high-level dimensional ETL tool which loads data into a traditional relational database. It executes on MapReduce but hides the complexity of MapReduce. The developer writes Python code to specify sources, targets, and transformations. ETLMR has built-in DW-specific support for handling dimension tables and fact tables. The developer can thus, for example, find changes and possibly insert a new version of a member in a slowly changing dimension (Kimball 2008) with a single method call. With ETLMR, dimension processing is always done first followed by fact processing. The developer can choose between different dimension processing schemes deciding how dimension data is partitioned between different reducers. CloudETL (Liu et al. 2014) has a similar approach but is aimed at loading data into Hive. The developer defines the ETL flow by high-level constructs in Java, and the system will then handle the parallelization. It remedies that it is hard to do dimensional ETL processing in Hive and Pig which are made for batch processing and not individual look-ups or inserts and which do not support UPDATEs such that slowly changing dimensions are very difficult to implement, although they are widely used in traditional DWs. For big dimensions (i.e., dimensions with many members), CloudETL also supports a map-only job where data locality in the distributed file system is exploited to avoid the need of shuffling of data from mappers to reducers.

Many other cluster computing frameworks have been proposed after MapReduce. Recently, Spark (Zaharia et al. 2012) has become very popular, and it is now a very active Apache project. Spark can keep datasets in memory as the so-called resilient distributed datasets (RDDs) between jobs and avoids expensive I/O which MapReduce has to do. Spark does not

use MapReduce but is closely integrated with Hadoop and works with HDFS. Spark has APIs for different languages including Scala, Java, and Python and gives the developer much flexibility in creating transformations. With the Spark SQL module (Armbrust et al. 2015), it is possible to manipulate data using both procedural and relational APIs. The relational API, however, enables richer optimizations and works both with Spark's RDDs and external data sources. To enable better optimizations, the use of the relational operations in Spark SQL builds a logical plan which first is executed when data must be output. The relational operations can be expressed in a domain-specific language. To perform the optimizations, Spark SQL provides a relational optimizer named Catalyst which is extensible such that support for new data sources and optimization rules as well as user-defined functions and data types can be added.

With the Dataflow model, Google introduced a high-level simple programming model for scalable parallel data processing with “the ability to dial in precisely the amount of latency and correctness for any specific problem domain given the realities of the data and resources at hand” (Akidau et al. 2015). In the model, data is not viewed as anything that eventually will be complete, and the same operators can thus be used for bounded data and unbounded streaming data. The physical execution engine is abstracted away under the programming model, and different execution engines can thus be used. Apache Beam (<https://beam.apache.org/>) is an open source version of Dataflow and does also support a number of different execution engines.

BigDansen (Khayyat et al. 2015) is a data cleansing system for Big Data. The user expresses a logical plan by means of five logical operators which are UDFs allowing great expressibility. The operators are defined at the finest unit of the input data (e.g., rows for relational data and triplets for RDF) to allow highly parallel execution of the operators. BigDansen translates a logical plan into an optimized physical plan which in turn is translated into an execution plan for a specific execution engine such as MapReduce or Spark. The user does thus only specify the

UDFs in Java code and does not need expertise on the specific execution engine.

It is generally known that it is very time-consuming to transform and clean data to prepare it for analysis. Traditionally such preprocessing has been done by specialized IT staff when creating the ETL flow. In the Big Data context where new and complex data sources often must be explored and used, this is impractical. Wrangler (Kandel et al. 2011) is an interactive system where the user can be a business analyst rather than an IT professional. The user specifies transformation scripts in an interactive way by selecting data and choosing among suggested, configurable transforms and immediately review the results. When the necessary transformations have been defined, a Wrangler script can be exported to MapReduce and Python programs. Wrangler has been commercialized by the product Trifacta which also works with cloud platforms. In early 2017, the service Google Dataprep was launched to allow users to prepare data visually. It is based on Trifacta's software.

Another interesting system which is not oriented toward specialized IT staff is Data Tamer (Stonebraker et al. 2013) (commercialized as Tamr). Data Tamer uses machine learning and statistics to do schema integration and entity consolidation (i.e., deduplication). Only when needed, a human expert is asked. The human expert is a business user and not a programmer. By using automation, Data Tamer avoids the need for human specification of complex rules and can scale to a huge amount of data sources as present in the Big Data era.

Examples of Application

Organizations often have to deal with large amounts of complex and dirty data to be prepared for analysis. With the large amounts of data, dirty data is the norm, and the data is often semi-structured or unstructured. The data can, e.g., be open data from publicly available web sources, data harvested from social media, licensed commercial data, log data about page views or ad clicks, and sensor data from IoT

devices. ETL pipelines are used to cleanse such data and integrate it with existing data to enable analysis. The ETL pipelines can be created in an ETL tool but are often made of homegrown solutions exploiting a variety of other Big Data tools such as Pig, Spark, etc.

Future Directions for Research

At the time of this writing, a number of Big Data ETL tools are available. Optimization and automatic tuning of ETL pipelines for Big Data is an area for further research. There will most likely be an increasing demand for ETL tools for Big Data which are efficient and also easy to use for less technically inclined users to enable self-service. Supporting the user in discovering relevant datasets and structures of complex, dirty data is another area. As web data often changes structure, the development of self-repairing ETL flows is also an interesting direction.

Event Log Cleaning for Business Process Analytics

Andreas Solti

Vienna University of Economics and Business,
Vienna, Austria

Synonyms

[Event log preprocessing](#); [Event log repair](#)

Definitions

Event log cleaning is a data preparation phase that turns event data into event logs to enable or improve the quality of business process analytics methods like process mining, model enrichment, and conformance checking. Event data might have to be collected from different sources and formats, filtered, transformed, and assigned to the corresponding processes and cases.

Overview

The goal of business process analytics projects is to gain insights into the execution of business processes. It can help to know which questions should be answered by the analysis. Some typical questions are *what* is done (activities), *when* is it done or how long does it take (time

stamps), in which *order* (relations), and by *whom* (resources). In contrast to traditional questionnaires, the process participants do not need to be personally asked about their perception of the process. In business process analytics, the event logs containing process execution data are directly analyzed (Dumas et al. 2013).

The quality of the underlying event logs is decisive for the success of any process analytics project. In personal interviews, the experience and insights of a person, as well as their honesty and willingness to answer questions, influence the analysis results. “Asking the data” might seem to be a less complicated task at first leading to objective analytics results. However, as experiences in process mining show, “most real-life logs tend to be incomplete, noisy, and imprecise” (Bose et al. 2013). Failing to address the data quality issues of an event log can compromise the validity of the analytics results. Rendering all the analytics efforts mute. Therefore, it is crucial to be aware and address event log quality issues before conducting any analytics. This chapter highlights typical quality issues of event logs, offers general solution strategies, and points to exemplary solution approaches available in literature.

Event Log Quality Issues

Before starting any cleaning procedure, the analysts need to understand the nature of the given event logs. To that end, a model of data quality is helpful. Different models of data quality exist in the literature that look at the dimensions of accuracy, completeness, and consistency of data, cf. (Suriadi et al. 2017, Section 2.2). To get a better understanding in the process analytics context, it is helpful to distinguish *inherent* characteristics of the business process and *system-dependent* characteristics that appear in the recorded data (International Organization for Standardization 2011).

Process Characteristics

When looking at the business process itself, the following list of challenges and solution

approaches help cleaning event logs and preparing them for analytics.

Volume. The simplest reason for large sizes of event logs is the high number of cases that are processed in large organizations. Certain log cleaning approaches perform costly operations and can take a lot of time to run.

Strategies: Divide and conquer. Stream processing.

Approaches: Scalable approaches need to be chosen for handling large event logs. At times, the available implementations of an approach are not optimized for handling huge event logs, as they require to load the event log into computer memory. In these cases, approaches with implementations that rely on divide and conquer and stream processing technologies are preferable, e.g., Leemans (2017).

Variability. Many process execution environments require a certain degree of flexibility to perform the tasks at hand. For example, doctors need to react and decide which action they need to do next based on a case by case basis. This flexibility can create a high variability in the event log, which needs to be taken into account for analytics and when cleaning the event logs (Reichert and Weber 2012). Variability can occur on the case level, that is, a lot of different paths are taken to reach one business objective. Variability can also occur in the number of different activities that can be performed.

Strategies: Divide and conquer. Clustering behavior. Focusing on frequent behavior–infrequent behavior in the event log, however, is not always irrelevant and can be separately analyzed.

Approaches: Trace clustering is proposed in Greco et al. (2006) and applied in complex and variable processes in Mans et al. (2008) to analyze the clusters separately with process mining. A more recent approach specifically addressing high variability is taking the divide and conquer approach to the limit by focusing on individual cases (Diamantini et al. 2016).

Veracity. The process of recording events in a business process can itself be subject to errors.

Examples of erroneous event log data appear due to human recording of events, due to noisy sensors tracking the progress in a process. The problem of stripping noisy and irrelevant data from event logs is one of the most important challenges in cleaning event logs for process analytics.

Strategies: Remove outliers. Repair data (with or without external knowledge). Store raw data for other analyses.

Approaches: Under the assumption that noisy data is less frequent than regular data, the events can be filtered by frequency. The concept of anomaly detection is applied to single cases in an event log in de Lima Bezerra and Wainer (2013). Here, mainly frequencies are used, as also in Conforti et al. (2017). If a process model exists, the event log can be aligned to it to identify and correct unforeseen behavior (de Leoni et al. 2015) effectively making the log fit into the model with minimum corrections.

Change. Business processes can be subject to evolution or sudden changes to adapt to changing environments. The phenomenon is also called *concept drift* in data mining (Gama et al. 2014). Undetected and untreated, different variants of a single process over time can lead to overly complex process models and faulty analysis results.

Strategies: Divide and conquer. Partition event log based on underlying process.

Approaches: To partition the event log correctly, the concept drifts need to be localized first. One of the first attempts to detect concept drifts in business processes is Bose et al. (2014). By analyzing event logs and statistically comparing the relations between events in two adjacent sliding windows, significant differences can be detected and concept drifts can be detected. More advanced methods to detect process changes over time are described in Ostovar et al. (2017).

Event Log Characteristics

Besides the process characteristics, the circumstances of recording process execution data, as well as the extraction of data from systems, affect

the event log. Thus, the nature of event logs and their generation must be well understood to select and apply the appropriate event log cleaning techniques.

Different Processes. When extracting process data from information systems, the extracted event logs can contain events from different processes or different process variants.

Strategies and Approaches: See point *Variability* in Sect. 1.

Different Sources. Real business processes are often supported by multiple different IT systems. Hence, the number and heterogeneity of sources from which data is integrated in the event log can complicate the analysis (Song et al. 2016). Dealing with multiple sources can create temporal inconsistencies, semantic ambiguities, or also different levels of granularity of recording. Because each of these issues can also occur with only a single event source, they are listed as separate points.

Strategies: Awareness of potential issues. Apply tailored data cleaning solution.

Approaches: The unification of different sources is largely a manual and time-consuming task. This is an ongoing research challenge, and mostly partial solutions to subproblems exist. The analyst needs to pick the appropriate techniques to transform the different sources into a common format. Approaches exist in the domain of schema matching (Rahm and Bernstein 2001).

Time stamps. When event logs are integrated from different sources, inconsistencies can be caused by the clocks of different systems being out of sync. Untreated, these temporal issues may lead to incorrect ordering of events in a unified event log. Currently, this problem requires the analyst to investigate potential time differences within systems and apply a correction to restore synchronicity. If the systems are spread over different time zones, additional complexity in harmonizing the time stamps stems from different treatment of daylight savings time.

Strategies: Detect anomalies. Repair data.

Approaches: Correct time stamps based on rules. Inconsistencies can be detected by anomaly detection methods (e.g., using probabilistic models (Rogge-Solti and Kasneci 2014) or temporal constraints (Song et al. 2016))

Correlation. Typically, events of a single business case can be identified by a correlating attribute. For example, the “order id” of a customer order identifies the case, and all related events carry this information as attribute. In some cases, however, this information is missing, and it can be unclear how to correlate events in an event log.

Strategies: Find correlation anchors (the correlation anchor can change within a case). Repair data.

Approaches: In the simpler case, correlation is possible through attributes. An approach to identify correlation attributes is Nezhad et al. (2011). It can be used for correlating events belonging to the same cases. In the more complicated case, such attributes cannot be found. Even then, there are attempts to solve this problem (Bayomie et al. 2016; Pourmirza et al. 2017). Latter techniques work with dependencies between activities and try to find a mapping between cases and events that is consistent (Bayomie et al. 2016) or even optimal with respect to the temporal variations in the process (Pourmirza et al. 2017).

Completeness. Completeness issues can appear on different aggregation levels, meaning that entire cases, single events, or also event attributes can be missing from an event log.

Strategies: Impute missing data. Remove incomplete cases.

Approaches for missing cases: It can happen that entire cases are missing from event logs. The detection of missing cases is nontrivial, however. A chance to detect missing cases is by carefully analyzing idle times of resources for patterns of successive idleness. These “blank spots” in the schedules could indicate a missing case. Further indications might be found in cross-checking the event log records with other sources (e.g., the accounting books).

Approaches for missing events: If single events are missing from an event log, causal relations between events can be used to deduce which events are missing. For example, a case with a “leave room” event, but without a logically preceding “enter room” event, points at a missing record. Logic-based missing event completion techniques are used in Bertoli et al. (2013) and Francescomarino et al. (2015). Also process models can be used to fill in the blanks (de Leoni et al. 2015; Wang et al. 2016).

Approaches for missing attributes: The problem of missing attributes is especially common, when the event documentation is done by humans. Two approaches are common: the minimum change principle (Song et al. 2016; Mannhardt et al. 2016a) or the maximum likelihood principle (Rogge-Solti et al. 2013; Yakout et al. 2013).

Granularity. There is not always a 1:1 relationship between events in an event log and business activities that analysts are interested in. Events can be recorded in a higher frequency than required. Also the contrary can be the case. For example, temporal information can be cloaked or recorded on a daily granularity only.

Strategies: Group low-level events to higher level activities. Infer relations.

Approaches:

- (a) Dealing with the event granularity mismatch.

A bridge between the low-level events to the high-level business events needs to be built by establishing a mapping. Rule-based approaches were the first to address the problem of n:m relations between events and activities (Baier et al. 2014). If low-level events follow a certain structure, a pattern-based mapping is possible between low-level events and high-level events (Mannhardt et al. 2016b). Also works based on raw sensor data exist that convert location data into process instances by solving an optimization problem and taking potential

process knowledge into account (e.g., temporal, resource assignments, precedes relationships) (Senderovich et al. 2016).

- (b) Dealing with the attribute granularity mismatch. When time stamps are coarse grained such that the order of events cannot be inferred by looking at the time stamps, events need to be treated as *partially ordered*. One idea is to guess the order of events by exploiting ordered information from other cases within the event log (Lu et al. 2014).

Ambiguity. Event labels can be ambiguous, and the relation between business activity in a process model and event is unclear. For example, two events with the same label (or name) can indicate different activities in a process depending on their context.

Strategies: Relabel ambiguous terms.

Approaches: Semantic ambiguities are a highly complex problem, and only specific solutions exist, but techniques to relabel certain activities with the same label based on their context greatly facilitate the process mining and analytics part (e.g., Song et al. 2009; de San Pedro and Cortadella 2016).

Further Reading

In this handbook, a condensed view on event log cleaning methods is provided. Deeper insights can be retrieved from the text book on process mining (van der Aalst 2016, Chapter 4). Additionally, the *process mining manifesto* emphasizes the need for handling of event log quality issues to improve process analytics results. It defines a five-level maturity model for the assessment of event logs. The scale ranges from “★” lowest quality (e.g., paper-based medical records) to “★★★★★” highest quality (e.g., semantically annotated logs of BPM systems) (van der Aalst et al. 2011).

A collection of so-called event log *imperfection patterns* lists common problems that occur in real projects and also provides recipes

to overcome these problems (Suriadi et al. 2017). Another related work specifically addresses the preprocessing of event logs required for process mining (Bose et al. 2013). Last, the approach proposed in (de Leoni et al. 2016) can solve data cleaning problems on the basis of data mining tools by projecting event logs into data tables. This approach enables a large share of data manipulation and analytics tool set of the data mining field (Han et al. 2011) in the process mining context.

Conclusion

The quality of an event log is of utmost importance for accurate process analytics. Data cleaning needs to be done with care, and each performed step needs to be documented. Furthermore, access to the raw event data can help to evaluate the effect of the data cleansing steps and enables analysts to replace certain cleaning approaches. Automatically handling different quality issues is an active research field with more and more novel and improving approaches appearing recently.

Definitions

As the expansion of nano-devices, smartphones, 5G, tiny sensors, and distributed networks evolve, the IoT is combining the “factual and virtual” anywhere and anytime. Subsequently, it is attracting the attention of both “maker and hacker.” However, interconnecting many “things” also means the possibility of interconnecting many diversified threats and attacks. For example, a malware virus can easily propagate through the IoT at an unprecedented rate. In the four design aspects of the smart IOT, there may be various threats and attacks; they are:

- (a) Data perception and collection: In this aspect, typical attacks include data leakage, sovereignty, breach, and authentication.
- (b) Data storage: The following attacks may occur – denial-of-service attacks (attacks on availability), access control attacks, integrity attacks, impersonation, modification of sensitive data, and so on.
- (c) Data processing: In this aspect, there may exist computational attacks that aim to generate wrong data processing results.

- (d) Data transmission: Possible attacks include channel attacks, session hijacks, routing attacks, flooding, and so on. Apart from attenuation, theft, loss, breach, and disaster, data can also be fabricated and modified by the compromised sensors.

Health-related and medical data is one of the sensitive application paradigms, where smart healthcare IoT deals with voluminous and meaningful data. As health data are highly critical for personal privacy and relevant regulations such as HIPAA (Lever et al. 2015) must be conformed to, the uploaded data need to be encrypted. The privacy of the communication link between smartphones and cloud servers can be protected by underlying media access control (MAC) protocols. A straightforward method is to encrypt uploaded data with off-the-shelf methods such as block ciphers, for example, AES or KASUMI (Ould-Yahia et al. 2017; Li et al. 2015). However, this may not be suitable and applicable in smartphones, because smartphones usually have energy constraints. Moreover, smartphones may be misused, lost, stolen, or hacked by attackers; thus privacy protection itself should be robust. Therefore, it is a critical challenge to design a lightweight and robust method to protect privacy.

As all the phases of data transmission of IoT involves substantial amount of threat and vulnerability, hence therefore trust and authentication in smart system have become crucial. Specifically, we envisage the smart health sector, where the medical data and health data is deployed through various involvement and stages influenced by human factors (e.g., doctors, patients, several medical agencies, diagnostic centers). The categories of known and unknown attacks improvise to develop more adaptive and self-organized system, which could foster into embedded smart applications. Conventional techniques like encryption and security protocol may not provide adequate security support. Typically, secure embedded systems are guided by the factors, e.g., small form factor, high performance, low energy consumption (Urien 2016), and robustness to attacks. The prediction, decision planning, and action can be

synchronized in these sections of health centric IoT application.

This proposal explores the possibilities and realization of computational intelligence techniques in terms of empowering trust, authentication, and residence mechanism. The desired objective is to configure the trusted and secure elements for smart IOT by using fuzzy logic, Bayesian attack graphs, intelligent learning, hybrid intelligent methods (e.g., combining fuzzy and neural network), and natural computing (like specifically through ant colony, bee colony optimization, swarm intelligence). The highlight of computational intelligence is to provide the security measures and action plan against unknown and uncertain threats and attacks considering the design constraints of secure elements (low energy consumption and high performance). The level of trust can be measured and data mined from different profile of users, contexts, and places of application deployment. However, depending on the design and adaptability of applications, even one or more intelligent techniques can be embedded in the design of single secure elements. The level of secure elements can also be ranked depending on the deployment intelligent techniques from lower to higher security levels. Till this novel article is formulated, there was no documented chronological survey available of such prototypes available.

State-of-the-Art & Contemporary Applications

As mentioned, there are many existing research and industrial applications to counter different security attacks for connected objects. However, most of them are dependent either on conventional cryptography or on secured protocol design (Zhao 2013; Bao and Chen 2012; Lize et al. 2014; Yan et al. 2014). However, there are few approaches, where fuzzy logic has been used for trust management and access control (Mahalle et al. 2013). Still, commercialization of those intelligent security measures is not directly implemented with IoT and smart applications (WhitePaper 2017). Interestingly, there is good

zero-day safety matrix proposed to rank the degree of vulnerabilities (Wang et al. 2014). This mapping also can be made predictable. The present proposal emphasizes on the aspect of prediction and configuring a decision support system. In addition, it will be worthy to scan the detailed applications or products that exist with respect to relevant industrial perspective. The next section elaborates this issue.

Subsequently, there is substantial scope to configure and customize the existing suit of Smart IoT protocols. Considering the low energy consumption as prime criteria, out of the followings, some of them can be focused for intelligent algorithm and customization.

- CoAP: Constrained Application Protocol.
- MQTT: Message Queue Telemetry Transport.
- XMPP: Extensible Messaging and Presence Protocol.
- RESTFUL Services: Representational State Transfer.
- AMQP: Advanced Message Queuing Protocol
- Websockets

Computational Intelligence: A Road Map for Security in IoT and Connected Systems

The road map of using computation intelligence in this proposal could be as follows:

Fuzzy Logic-Based Trust and Authentication System

While developing a trust and authentication matrix using *Fuzzy Logic* (where uncertainty about the trust focused on the user can be measured and discrete value of trust can be evaluated. Embedded software for secure elements can be developed by embedded programming environment), the embedded fuzzy program with fuzzy operators can work on user behavior and profile data and can aggregate a discrete decision from fuzzy referral index, known as membership function. The secure elements realized as secure microcontrollers with low power consumption(<200 mW) and a

crypto processor that accelerates cryptographic processing. However fuzzy logic-driven secure elements can be positioned with Datagram Transport Layer Security (DTLS) or Transport Layer Security (TLS) stacks. The trust application can be scripted in *Python Data gram Transport Layer Security* (<https://pypi.python.org/pypi/Dtls>) and as a whole is well supported by SSL. However, for secure elements, JAVACARD Syntax is popularly used, which is a subset of JAVA language (Javaid et al. 2016).

E

Concept of Attack Graph for Interconnected Systems

Generation of attack graph is recently used to assess the risk of interconnected networks (Lever et al. 2015), applying *Bayesian attack graphs* at real time on secure elements to calculate the probability that an attacker can reach each state (condition) in the graph. Instead of attempting to rank unknown vulnerabilities, the proposed BAG metric counts how many such vulnerabilities would be required for compromising network assets (Wang et al. 2014); a larger count implies more security since the likelihood of having more unknown vulnerabilities available, applicable, and exploitable all at the same time will be significantly lower. Categorically, the IoT malware families, e.g., BASHLITE and Mirai, can be analyzed to determine common properties which can be used for detection through probability values of BAG. Even an attribute data base can be prepared offline for other IoT malware families such as Hajime, NyaDrop, and LuaBot, this will assist to classify the types of malware attacks on line. The malware mentioned is also known as botnet of IoT: BAG algorithm can be developed and emulated through observe-orient-decide-act (OODA) to match the requirements of smart healthcare applications. This will be a decision dashboard, and it assists IoT management. Finally, a security risk measure matrix can be evaluated, and based on the recommendation, OODA can be triggered. High-level programming description will be sufficient.

Hybrid Model and Intelligent Learning

In this paradigm of computational intelligence, more than one intelligent model can be combined to ensure the detection of malware, attack-prone component, and intrusion. For example, artificial fish swarm algorithm (Lin et al. 2014) can be implemented with analyzing various features of possible intrusion. This could be distance, vision, neighbor, center, crowded degree, and maximum iterations. Here, considering (support vectors can be used for classifying new data) F_i represents fish i and C_i represents the center of F_i , then the embedded applications for configuring secure elements are:

- Initialization
- Fitness Evaluation
- Movement dynamics of fish swarms

At first, a feature subset is randomly assigned to N fishes. All parameters including vision, maximal crowded degree, and maximal trial number are defined. For example, if eight fishes were initiated, each fish has its own feature, and the circle represents the vision of fish i . The next step is to evaluate the classification value as a fitness value of the feature subset of each fish.

Starting with the first fish, follow step is implemented. If follow is successful, optimal value of fitness of fish demonstrates highly secured indicator; for example, in Fig. 1, the fitness value of fish i is 55; by contrast, the best fitness neighbor exhibits a value of 80. Thus, the best fitness neighbor demonstrates a superior fitness value, indicating that a superior fish is located in the vision of fish i . Therefore, the follow step is successful, and fish i moves to the location of best fitness neighbor and can be declared as secure zone in real time (Refer Fig. 1).

Trusted and low power objects ideally be based on Linux operating system, for example, Raspberry Pi board with DEBIAN distribution. Here, through middleware, the proposed algorithm could be developed (Beal et al. 2015; Viroli et al. 2016) by a recent emerging technique known as “Aggregate Programming” (Beal et al. 2015). Potential attack can be detected and

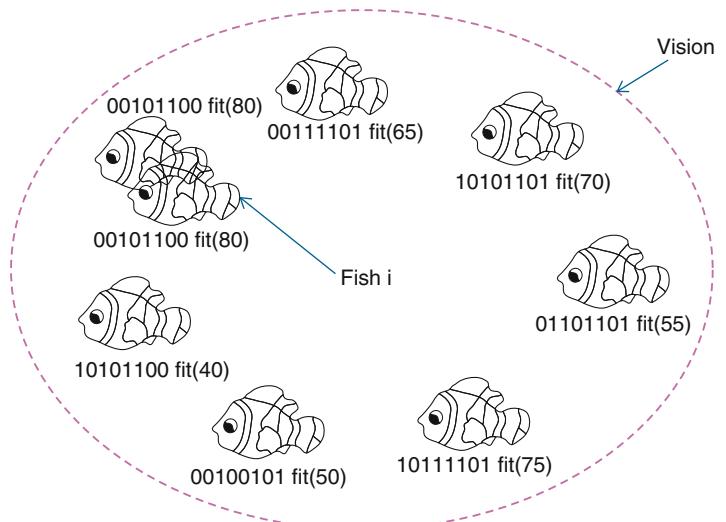

warnings disseminated robustly with just a few lines of Protelis code dynamically deployed and executed on individual devices by a middleware application. This short program is resilient and adaptive, enabling it to effectively estimate for identifying the prone to attacks (could be partitioned in several fuzzy values like low, moderately low, depending medium, very high, etc.) and distribute warnings while executing on numerous mobile devices. Mobile Python could be ideally chosen for embedding the application for secure elements.

Natural Computing for Resilience and Self-Organized Mechanism

The vertical applications of natural computing are driven by social insects like ants, bees, or swarms. Modeling of ant colony system (ACS) under random undirected graph can also define IoT configuration and empirical measurement of trust and security. Measured values are evaluated from topological mapping of pheromone communication of ants across the graph of interconnected sensors (Ould-Yahia et al. 2017). In the dynamic contexts of sensors (in case of body wearable sensors), it will be more appropriate to quantify contextual or referential intelligence according to the locations of the sensors. The degree of security or trust can vary with respect to the sensors’ locations.

Computational intelligence can be plugged into smart health security. Smart health of interconnected devices often needs intelligent control policies (Ayala et al. 2012) to manage different contexts of IoT sensors to sense. Examples of such capabilities are control policies for managing a self-controlled swarm of IoT devices (Viroli et al. 2016) (hierarchical vs. collaborative control strategies) or context-aware control of devices and adaptation of their behavior according to the environment. The mobile wireless body sensor and participatory sensing. Mobile WBSN comprises multiple sensor nodes that are implanted (or attached) into (or on) a human body to monitor health or EEG physiological indicators, such as electrocardiogram (ECG electroencephalography), glucose, toxins, blood pressure,

Exploring Scope of Computational Intelligence in IoT Security Paradigm, Fig. 1
Dynamic movement of fish for connected systems.
 (Scheme Courtesy Lin et al. 2014)

E

and so on. Data usually need to be uploaded to a central database (e.g., a cloud computing server) instantly so that doctors or nurses can remotely access them for real-time diagnosis and emergency response. As most persons possess a smartphone and customized applications can be installed on it, it is convenient and economical to use a smartphone as a gateway between WBSN and cloud servers. Participatory sensing also follows the suitable authentication scheme, and here the self-organized swarms can be programmed to deploy for access control of the application. Conventionally, one-time mask (OTM) scheme and one-time permutation (OTP) scheme both are reasonably efficient from energy consumption of view of IoT system, to protect the data of WBSN. However, as an additional security cover, swarm agents are used to anticipate the sensing scheme. Based on the design of swarm control, these encryption schemes can be functional.

Currently, there are agent technologies that can be embedded in devices of the IoT, such as Jade-Leap and Agent Factory Micro Edition (Muldoon et al. 2006). The embedded development may consider multiple agent technologies, like Jade (Muldoon et al. 2006), Jadex, Jade-Leap, and Mobile Agent Platform (Bellifemine et al. 2001). In this case, the agents are the managers of the sensors and make these data available to the IoT. Thus they can be adapted to

new devices (i.e., Symbian, Android, Sun SPOT, Libelium) and network technologies (i.e., WiFi, Bluetooth, ZigBee, XBee, NFC) and extended with additional features, such as goal orientation (Aiello et al. 2011) and self-management (Ayala et al. 2013).

Conclusion and Scope of Future Research

The paradigm of interconnected devices, sensors, and IoT improvises manifold applications with the requirement of substantial security cover to facilitate the big data-driven interactions. Static measures and conventional form of security, e.g., cryptography, may not be effective. Hence, different dimensions of computationally intelligent systems can be deployed in IoT environment, and importantly, the approaches are well supported with embedded system components for IoT. Approximation measures (fuzzy logic-based system and attack graphs), automated learning, and social insect-driven approaches are already been implemented, and thus new generation of IoT can be more dynamically secured and protected from different anticipated security breaches. At present, more machine learning-based methodologies like deep learning (Javaid et al. 2016;

Li et al. 2015) are planned to be incorporated with malicious code detection in IoT applications.

School of Computing, Informatics, and Decision
Systems Engineering, Arizona State University,
Tempe, AZ, USA

²Clari Inc., Sunnyvale, CA, USA

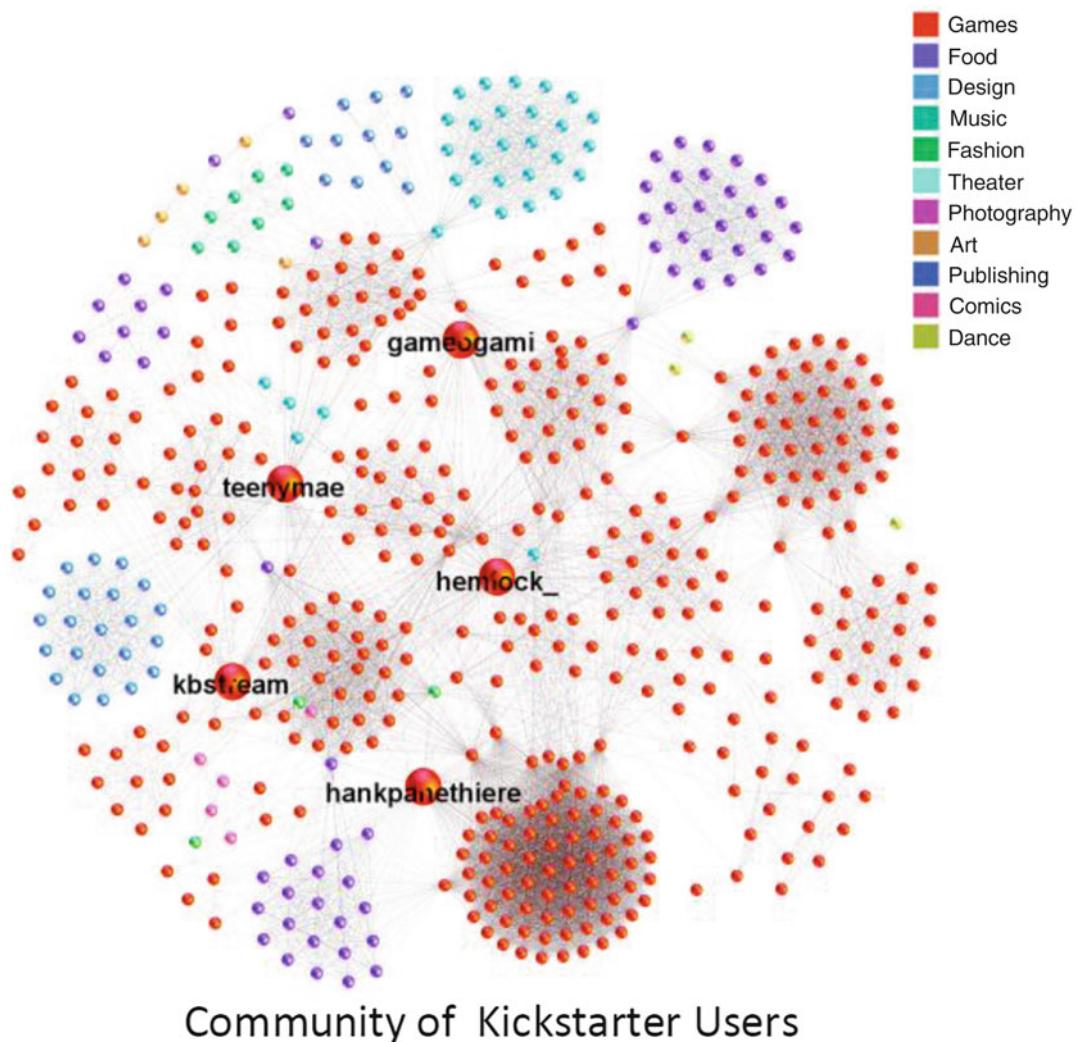

Overview

The rapid evolution of social network platforms such as Twitter, Facebook, and Instagram has resulted in heterogeneous networks with complex social interactions. Despite providing a rich source of information, the dimensionality of features in these networks poses several challenges to machine learning tasks such as personalization, prediction, and recommendation. Therefore, it is important to ask the question “how to capture such complex interactions between users in simplified dimensions?”. To answer this question, this entry explores network representation learning (NRL), where the objective is to model the complex high-dimensional interactions between nodes in a reduced feature space while simultaneously capturing the neighborhood similarity and community membership.

Information in the modern world flows in the form of graphs such as social networks, biological networks, and World Wide Web. These

graphical structures reveal many intriguing characteristics about the individuals and the structure of their communities. Figure 1 shows an example of a network that is composed of Twitter users who tweet about crowdfunding projects from Kickstarter (www.kickstarter.com). The colors in this graph indicate different communities that pertain to the category of projects like games, technology, art, etc. Communities are also known as *clusters* or *groups* (Jones et al. 2015), and they reveal several interesting properties of social networks such as homophily, cohesiveness, and structural holes. Consequently, the research on learning graph representations (or embedding) has gained significant attention in recent years where the objective is to represent the vertices of the graph in a low-dimensional vector space which embeds structural, semantic, and relational information.

Learning graph representations possesses two main challenges, namely, *heterogeneity* and *scalability*. Modern social networks are highly heterogeneous where interaction between the users cannot be measured using simple features (Tang et al. 2008). For instance, in Twitter, a user could interact with another user because both users follow the same celebrity or political figure (i.e., entity-centric interaction); in YouTube, the interaction between users might be due to their mutual interest in a video (i.e., content-centric interaction); and in location-based social networks such as Foursquare, interaction could be due to geo-location proximity between the users (i.e., location-centric interaction). Therefore, it is

Feature Learning from Social Graphs, Fig. 1 A Twitter-based community formed by the backers of Kickstarter (Rakesh et al. 2015). The colors represent

topical categories of communities, and the names denote the top users of the community

essential to develop models that can embed different layers of information in a condensed feature space. The second challenge is the scalability of models. Although various methods of graph embeddings have been proposed in the field of machine learning (Belkin and Niyogi 2002; Tenenbaum et al. 2000), these methods are suitable only for small networks with few thousand nodes and edges. Modern social networks on the other hand typically contain millions of nodes and billions of edges. For example, as of 2017, the popular social networking website Facebook has over 330

million users, while the microblogging website Twitter has over 2.7 billion users (www.statista.com). Therefore, it is extremely important to develop algorithms that scale to networks of this size.

To overcome the aforementioned challenges, researchers have proposed different algorithms that are highly effective in representing very large networks in a condensed feature space (Newman 2006b; Tang and Liu 2009; Perozzi et al. 2014; Grover and Leskovec 2016; Tang et al. 2015). This entry focuses on explaining three

most popular models, namely, SocDim (Tang and Liu 2009), DeepWalk (Perozzi et al. 2014), and node2vec (Grover and Leskovec 2016), that have become the state-of-the-art techniques in the field of network representation learning (NRL). These algorithms have proven to be highly scalable in capturing the latent representations from large graphs while simultaneously encoding the social similarity and community membership.

Definitions

The graph notation: A graph is denoted by $G = (V, E, F, Y)$, where $v \in V$ are the nodes (or actors), E are the edges of the network, $F \in \mathbb{R}^{|V| \times f}$ are the attributes, and f is the size of the feature space for each attribute and $Y \in \mathbb{R}^{|V| \times y}$ are the labels and y is the size of each label vector.

Random walks: Originally known as *Brownian motion* in space, the random walk is named after the botanist Robert Brown (www.wikipedia.org/wiki/Brownian_motion) who in 1826 peered at a drop of water using a microscope and observed tiny particles (such as pollen grains and other impurities) in it performing strange random-looking movements. A random walk on a undirected graph $G = (V, E)$ can be perceived as a stochastic process that starts from a given vertex and then selects one of its neighbors uniformly at random to visit. The transition probability from vertex v_i to v_j is defined as follows:

$$p(v_i, v_j) = \begin{cases} \frac{1}{Odeg(v_i)}, & v_j \text{ neighbor of } v_i \\ 0, & \text{otherwise} \end{cases} \quad (1)$$

where $Odeg(v_i)$ signifies the out-degree of node v_i . A random walk rooted at node v_i is denoted by W_{v_i} . Random walks are popular techniques for detecting the community and social structure of a network (Zafarani et al. 2014). In the subsequent sections, this entry will demonstrate how NRL algorithms utilize this technique to obtain representative samples of a large graph.

Key Research Findings

The Social Dimension Model

One of the earlier works on NRL was proposed by Tang and Liu (2009) to extract the latent dimensions (or features) that are indicative of the homophily in the network. To achieve this, the authors propose a model called SocDim that performs two separate functions: (a) extract latent social dimensions based on network connectivity and (b) construct a discriminative classifier that uses the latent features for predicting the node labels. Since the main focus of this entry is on network representation learning, the classifier part is excluded from the description. When developing algorithms for learning graph representations, it is important to make sure that the latent features capture the following properties:

- **Informative:** The social dimensions should be indicative of affiliations between actors.
- **Plural:** The same actor can get involved in multiple affiliations, thus appearing in different social dimensions.
- **Continuous:** The actors might have different degree of associations to one affiliation. Hence, a continuous value rather than a discrete $\{0, 1\}$ is more favorable.

Algorithm 1: SocDim(A,g,m)

```

1 Input: interaction matrix A, node degree g , number
   of edges m
2 Output: latent feature matrix  $\phi \in \mathbb{R}^{|V| \times d}$ 
3  $B = \text{GetModularityMat}(A, g, m)$ 
4  $\mathcal{E} = \text{GetTopEigenVec}(B)$ 
5 for each  $v \in V$  do
6   |  $\phi(v) = \text{GetLatentSocDim}(\mathcal{E}, v)$ 
7 end
```

Essentially, clustering techniques such as graph partitioning (Karypis and Kumar 1998), spectral clustering (Von Luxburg 2007), and block models (Nowicki and Snijders 2001) are the classic strategies for learning the latent representations of nodes in the network. However, these algorithms tend to ignore the

scale-free property (Chakrabarti and Faloutsos 2006) of large-scale social networks. To overcome this problem, SocDim uses the popular graph clustering algorithm called the Modularity (Newman 2006b) that explicitly takes degree distribution into consideration. Basically, modularity measures how far the interaction deviates from a uniform random graph with the same degree distribution. The objective is to divide a matrix A of v vertices and m edges into c nonoverlapping communities. For two nodes v_i and v_j with degree g_i and g_j , respectively, the modularity score is defined as follows:

$$Q = \frac{1}{2m} \sum_{ij} \left[A_{ij} - \frac{g_i g_j}{2m} \right] \delta(s_i, s_j) \quad (2)$$

where s_i and s_j denote the community membership of nodes i and j , respectively, and $\delta(s_i, s_j) = 1$ if $s_i = s_j$ and 0 otherwise. The term $\frac{g_i g_j}{2m}$ indicates the expected number of edges between these two nodes in a uniform random graph model. A positive Q value indicates that a cluster is able to capture the community structure, while a negative value indicates that the vertices are split into bad clusters. Therefore, the objective is to find a community structure such that Q is maximized. Maximizing the modularity over hard clustering is proven to be NP hard (Brandes et al. 2006); consequently, a soft clustering method is adopted. It is important to note that the adoption of soft clustering not only solves the problem efficiently but also generalizes well to the real-world scenario. That is, in real-world networks, users are not confined to one single community; instead, they have affiliations with different communities. The soft clustering is achieved by relaxing the notion of the community membership. Let $\mathbf{g} \in \mathbb{Z}_+^n$ be the degree of each node, and $S \in \{0, 1\}^{n \times k}$ be a community indicator matrix defined as follows:

$$S_{ij} = \begin{cases} 1 & i \text{ belongs to community } j \\ 0 & \text{otherwise} \end{cases} \quad (3)$$

The modularity matrix is defined as

$$B = A - \frac{\mathbf{g}\mathbf{g}^T}{2m} \quad (4)$$

using the above equation, the modularity can be reformulated as follows:

$$Q = \frac{1}{2m} \text{Tr}(S^T B S) \quad (5)$$

by relaxing S to be continuous, it can be shown that the optimal S is the top-k eigenvectors of the modularity matrix (Newman 2006a). Finally, there is one last bottleneck in solving the above equation, i.e., the modularity matrix B is dense and cannot be computed and held in memory when the number of nodes are large. To circumvent this issue, Lanczos method is used to calculate the top eigenvectors since it relies only on basic operation of matrix-vector multiplication. For further details on this method, readers are suggested to refer to Tang and Liu (2009). Algorithm 1 describes the three main steps of the SocDim model (lines 3–7), where line 3 uses Eq. 4 to obtain matrix B . The latent dimensions of nodes can be extracted using the top eigenvectors of the modularity matrix B .

The DeepWalk Model

The DeepWalk (Perozzi et al. 2014) is a popular model for network representation learning that excels in mapping large and complex graphs to a low-dimensional feature space. The algorithm begins by obtaining samples from a large graph using short random walks and then applies a neural language model over the samples to learn their latent representations. These latent representations are learned in such a way that the following characteristics are satisfied:

- **Evolution of networks:** The model should capture the continuously evolving nature of social networks.
- **Community aware:** The distance between latent dimensions should represent the social similarity between the members of the network.

- **Community membership:** The latent representations should model partial community membership in a continuous space.

One of the most interesting aspects of DeepWalk is the utilization of the *SkipGram* model (Mikolov et al. 2013) from the natural language processing (NLP) domain to capture the graph representations. The SkipGram tries to maximize the probability of observing a word w_n from a given sequence of words $\{w_0, w_1, \dots, w_{n-1}\}$. In other words, the algorithm tries to maximize the co-occurrence probability among the words that appear within a window w . A direct analogy can be established between SkipGram and NNL; i.e., given a node v_i , the objective is to maximize the likelihood of co-occurrence $p(v_i|(v_1, v_2, \dots, v_{i-1}))$. However, contrary to the SkipGram model, the primary objective of DeepWalk is not to estimate the likelihood of node co-occurrences but to capture the complex relationships between nodes in a low-dimensional feature space. To achieve this, DeepWalk introduces a subtle modification to the likelihood function. First, every node is represented by a real valued latent vector with a mapping function $\phi : v \in V \rightarrow \mathbb{R}^{|V| \times d}$, where d is the size of the latent dimension. Second, the objective is viewed as a problem of *predicting the whole context using a single missing word*. Therefore, the modified likelihood is written as follows:

$$\min_{\phi} \log Pr(\{v_{i-w}, \dots, v_{i-1}, v_{i+1}, \dots, v_{i+w}\} | \phi(v_i)) \quad (6)$$

To achieve this objective, DeepWalk uses a combination of truncated random walks and a neural language model shown in Algorithm 2. There are two main steps to this process. First, given a graph $G(V, E)$, at each vertex v_i , the algorithm begins by exploring its neighbors using a random walk of length ℓ (i.e., lines 5–8), and this procedure is repeated K times (the outer loop from lines 4–9). After generating a random walk $|W_{v_i}|$ of size ℓ , the algorithm then

Algorithm 2: DeepWalk(G, w, d, k, ℓ)

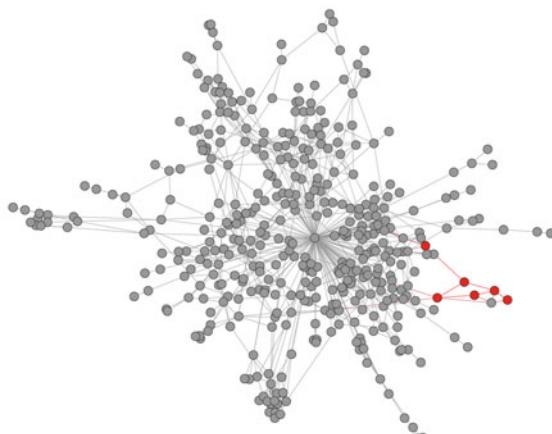

```

1 Input: graph  $G(V, E)$ , window size  $w$ , embedding size  $d$ 
2 # walks per node  $K$ , walk length  $\ell$ 
3 Output: latent feature matrix  $\phi \in \mathbb{R}^{|V| \times d}$ 
4 for  $i=0$  to  $K$  do
5   for each  $v_i \in V$  do
6      $\mathcal{W}_{v_i} = \text{RandomWalk}(G, v_i, \ell)$ 
7      $\text{SkipGram}(\phi, \mathcal{W}_{v_i}, w)$ 
8   end
9 end
10 SkipGram ( $\phi, \mathcal{W}_{v_i}, w$ )
11   for each  $v_j \in W_{v_i}$  do
12     for each  $\mu_k \in W_{v_i}[j-w:j+w]$  do
13        $J(\phi) = -\log Pr(\mu_k | \phi(v_j))$ 
14        $\phi = \phi - \alpha * \frac{\partial J}{\partial \phi}$ 
15     end
16   end
17 end

```

F

calls the *SkipGram* method in line 7. In the second step, the SkipGram procedure (line 10 in Algorithm 2) takes the random walk sample W_{v_i} as input, and for each node v_j , it iterates over all possible collocations of window length w in lines 11–12. These two steps are visually represented in Fig. 2a, b. Now, given the latent representation $\phi(v_j)$, the objective is to maximize the probability of obtaining a node μ_k from the neighborhood of v_j (line 13). However, this posterior is intractable to compute due to the marginalizing factor. To overcome this problem, a hierarchical softmax approximation technique is introduced. It works by constraining u_k to the number of nodes in the path from v_j to the leaves of the binary tree. This reframes the optimization problem into the task of maximizing the probability of a specific path in the tree; thereby, reducing the complexity of calculating the posterior from $O(|V|)$ to $O(\log|V|)$. This step is depicted in Fig. 2c. It should be noted that although the objectives of SocDim and DeepWalk are similar, they take very different approaches to learning the graph representations. The former directly optimizes for the modularity metric, while the latter first extracts random walk samples and then applies SkipGram to extract the latent dimensions.

(a) Random walk generation.

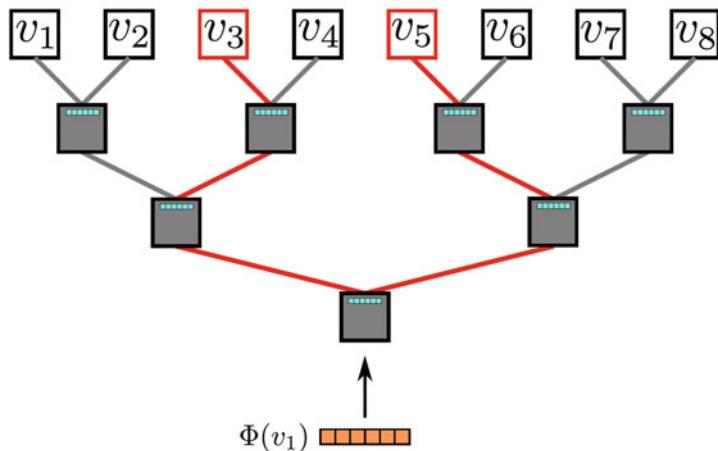

$$\mathcal{W}_{v_4} = \begin{matrix} 4 \\ 3 \\ 1 \\ 5 \\ 1 \\ \vdots \end{matrix}$$

$$u_k \begin{bmatrix} 3 \\ 1 \\ 5 \\ 1 \\ \vdots \end{bmatrix} v_j \longrightarrow \Phi(v_j)$$

Φ

The diagram illustrates the representation mapping step. It shows a vector u_k (represented by a column of numbers) being multiplied by a matrix v_j (represented by a row of numbers) to produce a latent feature vector $\Phi(v_j)$, which is represented as a grid of size $d \times j$.

(b) Representation mapping.

(c) Hierarchical Softmax.

Feature Learning from Social Graphs, Fig. 2 Shows the three main steps of DeepWalk algorithm where (a) denotes a random walk sample \mathcal{W}_{v_4} rooted at node v_4 , (b) shows the neighborhood window of node v_1 and the latent feature mapping $\phi(v_1)$ and (c) the hierarchical

softmax approximation technique which reduces the computational complexity of the posterior $Pr(v_j | \phi(v_1))$ by restricting the co-occurrence probability of v_1 to just v_3 and v_5 (Image Courtesy of Perozzi et al. 2014 and Perozzi 2016)

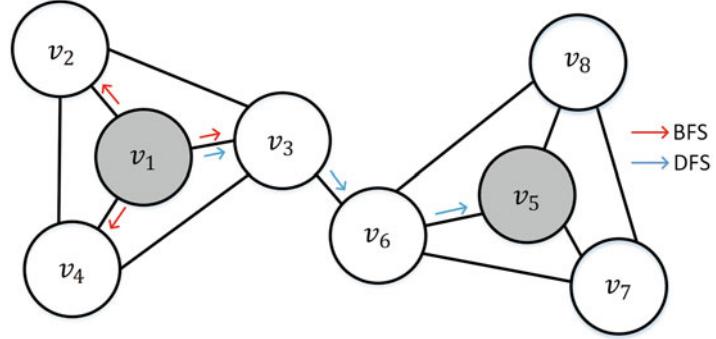

The node2vec Model

Similar to DeepWalk, the node2vec (Grover and Leskovec 2016) is another recent technique that learns representations of network by maximizing the likelihood of co-occurrence between a node and its neighborhood. An important drawback of DeepWalk is its sampling technique, which

is insensitive to the network connectivity patterns. To be more specific, the random walk method adopted by this model fails to capture community-specific properties such as *homophily* and *structural equivalence*. For example, Fig. 3 shows that node v_1 forms a tightly knit community with v_2, v_3 and v_4 (i.e., homophily) and node

Feature Learning from Social Graphs, Fig. 3

Example of BFS and DFS exploration strategies on a network exhibiting homophily and structural equivalence

F

v_5 forms a community with v_6 , v_7 , and v_8 . On the other hand, although v_1 and v_5 are from two distinct communities, they share the same structural equivalency by acting as hub nodes. Therefore, to capture such community-specific properties, the node2vec algorithm *defines a biased form of random walk* that aims to maximize the likelihood of preserving network neighborhood of nodes.

Given a node $v \in V$ and its neighbors $N_S(v) \subset V$ generated using a sampling strategy S , the nod2vec model aims to optimize the following function:

$$\max_{\phi} \sum \log Pr(N_S(v)|\phi(v)) \quad (7)$$

The above equation is very similar to the objective of the DeepWalk model (Eq. 6). Nonetheless, contrary to DeepWalk, which models the neighborhood $N_S(v)$ using a sliding window over consecutive nodes, the node2vec does not restrict the samples to the immediate neighbors of v . Instead, it allows to extract many different structures depending on the sampling strategy S .

Flexible biased random walk: As stated earlier, the aim of node2vec algorithm is to create sampling techniques that can capture both the structural equivalence and homophily in graphs. This is achieved using a combination of breadth-first search (BFS) and depth-first search (DFS) graph exploration strategies. BFS captures the structural equivalence by sampling the immediate neighbors of the given source node, while DFS captures the homophily between the nodes by sequentially sampling nodes at increasing distances from the source node. For example, in Fig. 3, for a

source node v_1 and neighborhood size $w = 3$, the BFS samples nodes v_2 , v_3 , v_4 and DFS samples v_3 , v_6 , v_5 . Furthermore, since BFS samples a very small section of a neighborhood, the nodes tend to repeat themselves in multiple neighborhood sets; consequently, this reduces the variance in characterizing the distribution of 1-hop nodes with respect to the source nodes. Contrary to this technique, the DFS samples neighborhood on a macro-level by exploring large parts of the network that results in capturing the homophily between the nodes.

Inspired by the above graph exploration strategies, the node2vec proposes a second-order random walk with a transition probability π that facilitates *smooth transitions between BFS and DFS*. The transition probability between nodes v_1 and v_2 is defined as follows:

$$\pi(v_1, v_2) = \begin{cases} \frac{1}{p} & \text{if } d_{v_1, v_2} = 0 \\ 1 & \text{if } d_{v_1, v_2} = 1 \\ \frac{1}{q} & \text{if } d_{v_1, v_2} = 2 \end{cases} \quad (8)$$

where d_{v_1, v_2} denotes the shortest path between v_1 and v_2 . Parameters p and q control how fast the walk explores and leaves the neighborhood of the starting node; in other words, they allow the search procedure to interpolate between BFS and DFS. The working of node2vec is illustrated in Algorithm 3. Similar to DeepWalk, the algorithm begins exploring its neighbors using a random walk of length ℓ , and this procedure is repeated K times (i.e., lines 7–11). The novelty of node2vec is described by the function *node2vecWalk* that

Algorithm 3: node2vec(G, d, K, ℓ, p, q)

```

1 Input: graph  $G(V, E)$ , latent dimension  $d$ , # walks
   per node  $K$ , context window  $w$ 
2 walk length  $\ell$ , return parameter  $p$ , In-out parameter
    $q$ 
3 Output: latent feature matrix  $\phi \in \mathbb{R}^{|V| \times d}$ 
4  $\pi = \text{GetTransitionProb}(G, p, q)$ 
5  $\text{walks} = []$ 
6  $G' = (V, E, \pi)$ 
7 for  $i=0$  to  $K$  do
8   for each  $u \in V$  do
9      $\text{walk} = \text{node2vecWalk}(G', u, \ell)$ 
10    Append  $\text{walk}$  to  $\text{walks}$ 
11  end
12   $\phi = SGD(w, \text{walks}, d)$ 
13 end
14  $\text{node2vecWalk}(G', u, \ell)$ 
15    $\text{walk} = [u]$ 
16   for each  $l \in \ell$  do
17      $cur = \text{walk}[-1]$ 
18      $V_{cur} = \text{GetNeighbors}(cur, G')$ 
19      $\text{sample} = \text{FlexRanWlk}(V_{cur}, \pi)$ 
20     Append  $\text{sample}$  to  $\text{walk}$ 
21   end
22   return  $\text{walk}$ 
23 end

```

Feature Learning from Social Graphs, Table 1
 Important differences between SocDim, DeepWalk, and node2vec models. Both DeepWalk and node2vec are highly scalable, but the latter is more sensitive to parameter changes

Model	Method	P-Sensitivity	Scalability
SocDim	Eign + Modularity	d	Limited
DeepWalk	Rwalk + SkipGrm	ℓ, d	High
node2vec	Rwalk* + SGD	ℓ, d p, q	High

performs the biased second-order random walk in line 19. After sampling several walks, the latent representation of nodes is learned using stochastic gradient descent (SGD) in line 12.

Table 1 delineates the key differences between the three models that were discussed in this entry. Here, $Rwalk$ and $Rwalk^*$ indicate the random walk and the modified random walk that is used by DeepWalk and node2vec, respectively. To conclude, the algorithm of SocDim is very different from both DeepWalk and node2vec since it gen-

erates the latent representation R^d from the top- d eigenvectors (Eign) of B and the modularity matrix of G . Contrary to this, both DeepWalk and node2vec first perform a random walk, obtain samples from a large graph, and then apply some form of feature learning such as SkipGram or stochastic gradient descent (SGD). In addition to this, all algorithms are relatively sensitive to the number of latent dimensions d , but the node2vec has additional function parameters p and q , which requires proper tweaking.

Examples of Application

NRL with Content Information: Since DeepWalk purely relies on structural relationships between the nodes, a logical extension to this algorithm is to incorporate content information into the feature learning process. Chang et al. (2015) propose a deep embedding algorithm called heterogeneous network embedding (HNE) that captures the complex interactions between nodes with different edge types. HNE considers both the content and the relational information of nodes to create heterogeneous embeddings.

Deep NRL Models: Some researchers use a mixture of different deep learning techniques to capture the latent representations of graphs. For instance, in Cao et al. (2016), the graph representation is learned using a three-step framework. First, it captures the structural information from weighted graphs using a random surfing model to create a probabilistic co-occurrence matrix. Second, it uses a modified pointwise mutual information (PMI) over this matrix to create a PPMI matrix, and third, a stacked denoising autoencoder is used to learn the low-dimensional vertex representations. The main advantage of this model over DeepWalk is the ability to directly obtain a probabilistic co-occurrence matrix without the need for random sampling.

NRL for Recommender Systems: Recommending suitable answers to user queries, the Q&A domain is a challenging task due to

the sparsity of links between questions and answers. However, modern Q&A websites such as Quora and Stack Exchange provide additional information in the form of user communities where a reliable user may be followed by other users. Therefore, in Fang et al. (2016), the authors use DeepWalk to extract the social information of users to solve the sparsity problem and combine it with a deep recurrent neural network which models the textual contents of questions and answers. In Chen et al. (2016), the authors propose a heterogeneous preference embedding approach (HPE) for music playlist recommendation. The input to the HPE model is a graph that is composed of users, songs, and playlists, and the output is a low-dimensional embedding of user preference vector. This preference vector is then used for recommending songs and playlists to users.

Future Directions for Research

This entry presents some recent trends in network representation learning by introducing three popular algorithms, namely, SocDim, DeepWalk, and node2vec. Future improvements and extensions to these algorithms can be categorized into the following research directions: (a) extending the model for multiple types of vertices, (b) embedding explicit domain-specific features of nodes and edges into a latent space, (c) modifying (or replacing) the feature learning process with recent techniques from deep neural networks, and (d) extending the models for signed networks.

Synonyms

Federation of SPARQL endpoints; SPARQL federation

Definitions

Federated RDF query processing is concerned with querying a federation of RDF data sources where the queries are expressed using a declarative query language (typically, the RDF query language SPARQL), and the data sources are autonomous and heterogeneous. The current literature in this context assumes that the data and the data sources are semantically homogeneous, while heterogeneity occurs at the level of data formats and access protocols.

Overview

In its initial version, the SPARQL query language did not have features to explicitly express queries over a federation of RDF data sources. To support

querying such a federation without requiring the usage of specific language features, the following assumption has been made throughout the literature: The result of executing any given SPARQL query over the federation should be the same as if the query was executed over the union of all the RDF data available in all the federation members.

Formalization of SPARQL Over Federated RDF Data

To capture this assumption formally (Stolpe 2015), it is necessary to introduce a few basic concepts first: The core component of each SPARQL query is its query pattern. In the simplest case, such a query pattern is a so-called *triple pattern*, that is, a tuple $tp = (s, p, o)$ where s and o may be either a URI, an RDF literal, or a variable, respectively, and p may be either a URI or a variable. Multiple triple patterns can be combined into a set, which is called a *basic graph pattern (BGP)* and resembles the notion of a conjunctive query. In addition to such BGPs, several other features are possible in SPARQL query patterns (e.g., UNION, FILTER). For the complete syntax refer to the SPARQL specification (Harris et al. 2013).

The expected result of any given SPARQL query is defined based on an evaluation function $\llbracket \cdot \rrbracket_G$ that, given an RDF graph G , takes a SPARQL query pattern and returns a set (or multiset) of *solution mappings*, that is, partial functions that associate variables with RDF terms (i.e., URIs, literals, or blank nodes). For instance, for a triple pattern tp , the result $\llbracket tp \rrbracket_G$ contains every solution mapping whose domain is the set of all variables in tp and replacing the variables in tp according to the mapping produces an RDF triple that is in G . The evaluation function $\llbracket \cdot \rrbracket_G$ is defined recursively over the structure of all query patterns (Pérez et al. 2009).

To capture the aforementioned assumption and, thus, define SPARQL over a federation of RDF data sources (rather than over an RDF graph), it is possible to introduce another evaluation function $\llbracket \cdot \rrbracket_F$ where F is a given federation. Formally, such a federation may be captured as a tuple $F = (E, d)$ where E is the

set of all data sources in the federation and d is a function that associates every source $e \in E$ with the RDF graph that can be accessed via e . Then, the new evaluation function $\llbracket \cdot \rrbracket_F$ can be defined in terms of the standard evaluation function $\llbracket \cdot \rrbracket_G$ as follows: For every SPARQL query pattern P , $\llbracket P \rrbracket_F$ is a set of mappings such that $\llbracket P \rrbracket_F = \llbracket P \rrbracket_G$ where G is the RDF graph that is the (virtual) union of the graphs of all federation members; i.e., $G = \bigcup_{e \in E} d(e)$.

Types of RDF Data Sources

Note that the aforementioned definition is deliberately generic in what it considers to be possible federation members. Most of the current solutions for federated query processing over RDF data have focused on federations of SPARQL endpoints. Nonetheless, federations of RDF data sources may be composed of other types of sources including RDF documents or Triple Pattern Fragments.

Federation of SPARQL Endpoints. SPARQL endpoints are Web services that allow for querying RDF datasets online using the SPARQL protocol (Feigenbaum et al. 2013). Such an endpoint has a URI as its address and is, in theory, capable of evaluating any given SPARQL query over its internal RDF dataset. Therefore, SPARQL endpoints are considered RDF querying interfaces with a high expressive power. The concept of querying SPARQL endpoints has even been integrated into the latest version of the SPARQL language. That is, SPARQL 1.1 comes with an extension (Prud’hommeaux and Buil-Aranda 2013) that introduces the notion of a SERVICE clause that can be used as part of a SPARQL query pattern. This new clause has the form `SERVICE c P` where c is a URI and P is a (sub-)pattern (note that, by the SPARQL 1.1 standard, c may even be a variable, but the existing formal definition of this case (Aranda et al. 2013) is not part of the standard). Then, assuming URI c is an address of a SPARQL endpoint, the SERVICE clause means that the evaluation of P has to be delegated to this endpoint. The resulting solution mappings returned from the endpoint have to be combined

with the result of the rest of the query pattern in which the SERVICE clause is contained.

Federation of RDF Documents. This type of federation composes a Web of (Linked) Data in which the federation members are RDF documents that can be retrieved by URI dereferencing. In URI dereferencing, clients use URIs (typically found in the data) to perform HTTP requests which result in retrieving documents that contain a set of RDF triples. The process of evaluating queries over a federation of RDF documents is referred to as *Linked Data query execution* (Hartig 2013) and URI dereferencing is a core task of this process. Hartig (2012) has shown that by using this process, producing the complete query result as defined by the aforementioned evaluation function $\llbracket \cdot \rrbracket_F$ cannot be guaranteed and that there exist more restrictive approaches to define an evaluation function that can be computed completely over a federation of interlinked RDF documents.

Federation of Triple Pattern Fragments. Triple pattern fragments (TPFs) is an alternative interface for providing access to RDF data (Verborgh et al. 2016). TPF sources are able to evaluate SPARQL triple patterns over their internal RDF dataset. The result of such an evaluation is a sequence of RDF triples that match the given triple pattern; this is called a fragment. Given that some fragments may contain a large number of triples, fragments are partitioned into fragment pages that contain a fixed maximum number of triples. Then, to retrieve an entire fragment, clients must traverse the TPF pages. The expressive power of TPFs is higher than URI dereferencing, but notably lower than SPARQL endpoints. To execute an arbitrary SPARQL query using TPFs, the query engine has to decompose the query into a series of TPF requests.

Query Processing

Conceptually, the processing of queries in a federated setting can be separated into three tasks:

(i) query decomposition and source selection, (ii) query optimization, and (iii) query execution. This section provides an overview of existing approaches to tackle these tasks. To this end, the tasks are considered separately, one after another, which is also the most common approach to perform them in many RDF federation engines. However, some engines intertwine the tasks (at least partially) to account for changing data sources and runtime conditions.

Query Decomposition and Source Selection

To execute a query over a federation, the query first has to be decomposed into subqueries that are associated with data sources (federation members) selected for executing the subqueries. Essentially, the result of this step resembles a rewriting of the query into a SPARQL query with SERVICE clauses, and the objective is to achieve a complete query result with a minimum number of SERVICE clauses. An important notion in this context is the relevance of data sources for triple patterns; that is, a data source d is *relevant* for a triple pattern tp if the evaluation of tp over the data of d is nonempty; i.e., $\llbracket tp \rrbracket_{ep(d)} \neq \emptyset$.

An initial, not necessarily optimal approach to decompose a given SPARQL query is to treat each triple pattern in the query as a separate subquery and to associate each such subquery with all the data sources that are relevant for the respective triple pattern. A common improvement of such an initial decomposition is to merge subqueries that are associated with the same single data source; such merged subqueries are called *exclusive groups* (Schwarte et al. 2011).

Note that the results of the different subqueries have to be combined to produce the result of the given SPARQL query. It is possible, however, that for any of the (relevant) data sources associated with a subquery, the subquery result obtained from that source may give an empty result when combined with the results of some of the other subqueries. Hence, that subquery result does not contribute to the overall query result produced in the end. Based on this observation it is possible to prune some of the data sources associated with subqueries if there is evidence that the subquery

results from these data sources can be safely ignored without affecting the completeness of the overall query result. Source selection approaches that apply such a pruning are called *join-aware* (Saleem and Ngomo 2014).

Table 1 lists the approaches for query decomposition / source selection as proposed in the SPARQL federation literature. The main difference between these approaches (in addition to join awareness) is in the information they require about the federation members and the point at which they obtain this information. There exist approaches that rely solely on some type of *pre-populated data catalog* with (approach-specific) metadata about the federation members. Other approaches do not assume such a catalog and, instead, identify relevant federation members by querying all federation members *during the source selection process*. A third type of approaches are *hybrids* that employ a pre-populated data catalog in combination with runtime requests to the federation members. The approaches that employ a catalog (with or without

additional runtime requests) can be distinguished further based on what type of metadata and statistics they capture in their catalog. Both Görlitz and Staab (2011a, Sec.5.3.2) and Oguz et al. (2015, Sec.3.1–3.2) provide a more detailed overview of existing approaches.

Query Optimization

The optimizer devises a plan that encodes how the execution of the query is carried out. The objective of the optimizer is to devise an execution plan that minimizes the cost of processing the query decompositions. In federated scenarios, both the number of intermediate results as well as the communication costs impact on the query performance.

Cost Estimation for Plans. To estimate the cost of plans in federated SPARQL query processing, Görlitz and Staab (2011b) propose a cost model that accounts for communication costs and estimates the cardinality of SPARQL expressions. Regarding the communication costs, this model assumes that all the responses from the sources require the same number of packages to be transmitted over the network and that the solution mappings have the same average size. Furthermore, this cost model relies on exact cardinalities for triple patterns with bound predicates and estimations for other variations of triple patterns, graph patterns, and joins. Nonetheless, in federated query processing where sources are autonomous, it is not always possible to collect sufficient statistics from the data sources to estimate cardinalities accurately. Therefore, some SPARQL federation engines (Acosta et al. 2011; Schwarte et al. 2011) implement heuristic-based optimization techniques that estimate the cost of subqueries based on the number of triple patterns and the number of variables in each triple pattern.

Plan Enumeration. To explore the space of query plans, optimizers of current SPARQL federation engines implement different search strategies that devise different tree plan shapes: (left-) deep plans and bushy plans. In contrast to deep plans, bushy trees are able to reduce the size of intermediate results in SPARQL queries (Vidal

et al. 2010) and enable parallel execution of independent sub-plans. One common strategy used in traditional query processing is dynamic programming, which is able to enumerate all join plans while pruning inferior plans based on the estimated cost. This strategy is implemented by SPLENDID (Görlitz and Staab 2011b) and LHD (Wang et al. 2014) to devise bushy tree plans. The main advantage of dynamic programming is that it produces the best possible plans under the assumption that cost model is accurate. However, the time and space complexity of dynamic programming is exponential, and thus this strategy does not scale for queries with a large number of subqueries. To overcome this limitation, the federated engines FedX (Schwarte et al. 2011) and ANAPSID (Acosta et al. 2011) implement heuristics to devise reasonable effective plans quickly. The heuristics implemented by FedX enumerate left-deep plans, while ANAPSID heuristics are able to devise bushy tree plans.

Further Optimization Techniques. In traditional query processing, the optimizer considers pushing down filters in the query plan which, in turn, allows for reducing the amount of intermediate results produced during query execution. Following this technique, ANAPSID (Acosta et al. 2011) implements heuristics to (i) push down filter expressions in the query plan and (ii) decide whether the filter is evaluated at the query engine or at the endpoint. In case that the filter expression contains variables that are resolved by the same source, ANAPSID ships the evaluation of the filter to the endpoint thus reducing the amount of data transmitted over the network. Other optimization techniques split composed filter expressions into sub-expressions such that each sub-expressions can be pushed down in the query plan (Görlitz and Staab 2011b).

Query Execution Techniques

During query execution, the engines evaluate the plan devised by the optimizer. In this task, the engine contacts the members of the federation identified as relevant and combines the retrieved data to produce the final query result. In federated

SPARQL query processing, physical operators and adaptive query processing techniques have been proposed to efficiently combine the intermediate results.

Physical Operators. In terms of Nested Loops Join, Görlitz and Staab (2011a) and Schwarte et al. (2011) have proposed join operators that reduce the number of requests submitted to the sources by grouping several bindings into a single request. The *distributed semi-join* (Görlitz and Staab 2011a) buffers the solution mappings in FILTER expressions using the logical connectors \wedge (when mappings contain several variables) and \vee (for grouping several mappings). In contrast, the *bound join* (Schwarte et al. 2011) groups a set of solution mappings in a single subquery using SPARQL UNION constructs. Furthermore, ANAPSID (Acosta et al. 2011) provides non-blocking join operators *agjoin* and *adjoin* that efficiently combine solution mappings able to produce results as soon as the data arrives from the endpoints.

Adaptive Query Processing. Most of the current federated SPARQL query engines follow the optimize-then-execute paradigm. In this paradigm the plan devised by the optimizer is fixed. Nonetheless, the optimize-then-execute paradigm is insufficient in federated scenarios in which the optimizer is not able to devise optimal plans due to misestimated statistics or unpredictable costs resulting from network delays or source availability. To overcome the limitations of the optimize-then-execute paradigm, some SPARQL federation engines implement adaptive query processing techniques (Deshpande et al. 2007) to adjust their execution schedulers according to the monitored runtime conditions. ANAPSID (Acosta et al. 2011) is an adaptive engine that flushes solution mappings that have matched a resource to secondary memory, in cases when the main memory becomes full. Solution mappings in secondary memory are re-considered to produce new solutions when the endpoints become blocked. The query execution techniques implemented by ANAPSID are tailored to cope

with network delays and to handle a large number of intermediate results produced by arbitrary data distributions. Another federated engine that implements adaptivity during query execution is ADERIS (Lynden et al. 2010, 2011). ADERIS is able to re-invoke the query optimizer at execution time after all the data is retrieved from the endpoints. The optimizer then changes the join ordering to devise a new efficient query plan given the current runtime conditions.

Open Research Challenges

The open research challenges can be organized in two parts. The first set of challenges are in the context of the Semantic Web. The second set of challenges extend known issues in federated query processing on relational databases.

Challenges of Using the Semantic Web as a Federation

Reasoning: RDF and SPARQL are part of a larger set of Semantic Web technologies standardized by the W3C. An important standard is the Web Ontology Language (OWL), which is a knowledge representation and reasoning language based on Description Logics. RDF systems may implement reasoners which enables inferring new data based on the input data and ontologies. A federated query processing system on RDF data coupled with OWL ontologies must be extended to support the following: (i) understanding different entailment regimes (Glimm and Ogbuji 2013) that a federation member is able to support (e.g., RDF entailment, RDFS entailment, OWL2 direct semantics entailment) and (ii) reasoning with alignments between different OWL ontologies used across different federation members. Early approaches that have taken first steps to integrate ontology alignments into federated query processing are ALOQUS (Joshi et al. 2012) and LHD-d (Wang et al. 2014).

Unboundedness: Existing approaches to federated RDF query processing assume that the complete federation is known beforehand. However,

in the context of the Semantic Web, this may not be the case. An initial set of data sources (federation members) may be known, but it is possible that all the sources are not known initially. Hence, the total number of sources that can contribute to the answer of a given query may be unbound. This unboundedness has implications in query processing, namely, in the query decomposition and source selection step.

Completeness: Recall that the result of executing any given SPARQL query over the federation should be the same as if the query was executed over the union of all the RDF data available in all the federation members. Therefore, completeness of a SPARQL query over the federation depends on knowing all the federation members. Per the unboundedness challenge (see above), if the sources are not known, then this notion of completeness should be relaxed. The implication of this challenge is to understand a tradeoff between soundness and completeness versus precision and recall of answering a query in a federation.

Dynamicity: The data of some federation members may change frequently (e.g., streams, social media). It has to be studied how such dynamicity affects the results of queries over a federation and how the dynamicity can be taken into account during federated query processing.

Challenges of Extending Federated Query Processing

Access Control: Within federated database systems, access control is a mechanism to check whether a query issued by a user is allowed or not. Given that each federation member is autonomous and has its own access control, conflicts may arise when data sources are combined in a federation. This challenge is further increased with the presence of ontologies and reasoning capabilities at the federation members. The inferred data needs to be checked with respect to the access control.

Heterogeneity: Although all the federation members are assumed to use a common data model (RDF), the members can be heterogeneous at different levels: (i) members may be using different ontologies to model data, (ii) different versions of SPARQL and different query capabilities (e.g., SPARQL endpoints vs. TPF) may have an impact on the type of queries that members are able to answer, (iii) depending on which entailment regimes are supported, a member can infer different types of answers.

Source Selection: The challenge of decomposing a query into subqueries that are associated with data sources is increased when the following additional constraints are considered. Given that data sources are autonomous, they can: (i) have different timeouts, (ii) put a limit on the number of results a query can return, (iii) support different version of SPARQL or even support subsets of SPARQL only, (iv) be of different types, such as SPARQL endpoints, RDF documents, or TPF interfaces, (v) support different entailment regimes. Therefore, a federated query processing system should take into account these constraints during the source selection.

Query Results: An important challenge in federated query processing is to associate provenance with the query results in order to understand where an answer is coming from. When sources that support reasoning such that they are able to infer new data, this adds to further explanations in the provenance of the answers.

Definitions

Water is one of the vital substances for life, which occupies two-thirds of the earth's surface. For the survival of living beings, water management is critically important. One of the most common sources of its heavy wastage is flood. Conventional methods of disaster management have improved at large extent. Similarly, flood prediction, localization, and recovery management mechanism have been upgraded from manual reporting to advanced sensor-based intelligent systems. Additionally, data from social media big data streams appeared as a main source of information flow for ordinary events as well as for emergency situations. Millions of images along with text streams, audio clips, and videos are uploaded from different corners of the world. Data from social media is then processed to gain various socioeconomic benefits including weather prediction, disaster awareness, and so on. The aim of this chapter is to discuss and evaluate state-of-the-art computer vision and natural language techniques for flood detection using social media big data streams.

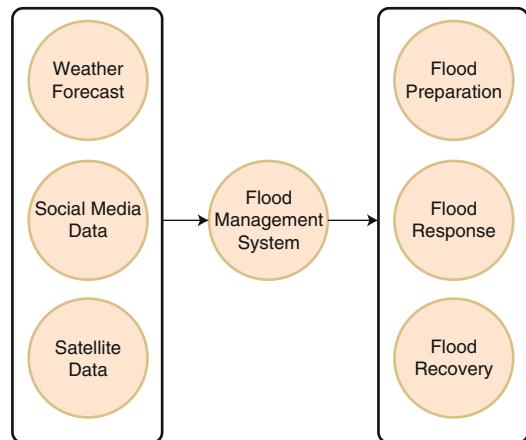

Overview

This chapter provides comprehensive review of the state-of-the-art natural language processing

(NLP), machine learning (ML), and deep learning (DL) technologies for flood detection. This chapter also summarizes the performances of several ensemble techniques where floods are predicted using the combination of meta and visual data.

Introduction

Hydroinformatics helps to effectively manage water resources of the world, by utilizing information and communication technology (Abbott et al. 1991). Conventional methods of hydroinformatics have entirely changed with the advent of technological advancement. Traditionally, gauging machines were used to manage flood detection by examining the level of water. Floods are usually caused by overflowing of river, more rainfall than available drainage system, sudden breach of protection made against it, or unexpected opening of hydropower (Jongman et al. 2015). In case of weak protective measures, floods may create dangerous situation for living beings. Mostly, valuable economical resources are also highly affected by floods. The strong defensive measures are directly linked with the information regarding the flood. The strong flood response system performs its function on the basis of the data collected from different sources including weather forecast, social media contents, and data collected from satellite system, as shown in Fig. 1. The information helps to indicate time, location, causes, and impact of the flood. Flood management system makes preparation as a response to any possibility of the flood. The response includes relief during the event. While recovery starts after the end of the emergency, to overcome the situation (Jiang et al. 2013; Chen and Han 2016; Jongman et al. 2015), there are various resources, from which useful information is generated to overcome the situation, which includes social media contents, satellite data, and weather management data. On the basis of these information resources, flood management system performs the responsibilities of preparation, response, and recovery, as shown in Fig. 1.

Flood Detection Using Social Media Big Data Streams, Fig. 1 Flood management system

The omnipresent nature of Internet has provided social interactivity pathway to the users. Moreover, social media has provided the opportunity of rapid interaction to its users and effortless sharing of text, images, audio, and video as well as any of their combination. Various social media giants are competing to attract maximum users, and Facebook tops the list. As per an official announcement, Facebook has achieved the target of 2 billion users by June, 2017. Big data collected from social media can be used for the well-being of the society and different situational awareness analysis. Specially, people use social media during emergency situations like storms and floods, to spread awareness among people of the surrounding vicinity, authorities, and humanitarian organization so that the situation may be tackled appropriately. Along with the data from social media, satellites are also used for the prediction and detection of flooding events (Pohl et al. 2012, 2016; Fohringer et al. 2015).

The massive quantity of disaster-related information is regularly collected from social media and satellite. These huge datasets require advanced storage and processing technologies. The term “big data” is used to denote complex and huge datasets, which cannot be captured, stored, and processed by normal computing technologies including big data analytics and cloud computing (Shamsi et al. 2013). The big data techniques

create patterns by exploring huge amount of data. This motivates usage of big data techniques in disaster management systems, especially in flood management (Eilander et al. 2016; Chen and Han 2016). The main aim of this chapter is to discuss the existing challenges for flood detection using social media big data streams. This chapter will also provide comprehensive review of the state-of-the-art natural language processing (NLP), machine learning (ML), and deep learning (DL) technologies for flood detection.

Literature Review

Most awful situations are faced by the countries with scarcity of resources. They are unable to handle floods properly. Consequently, humanitarian organizations play their role to handle the situation. Moreover, countries having a larger area are also facing troubles in protecting larger region from flooding events. Also, there is a lack of proper intercommunication mechanism between countries to share the experiences and knowledge regarding flood management. Flooding events in Pakistan and Philippines are analyzed to explore the timing of occurrence of flood, mapping of its location, and understanding of its impact (Jongman et al. 2015). Data has been gathered by using organizations of disaster response, Global Flood Detection System (GFDS) satellite signals, and information from Twitter accounts. It was observed that GFDS satellite information is appropriate to produce better results in case of larger floods while less appropriate for flood with smaller duration. It also has a drawback, as it produces errors while calculating data in coastal areas, so it is more suitable to be used in regions of delta or islands. Moreover, Twitter information analysis for flood exploration can produce fruitful results in handling flood of any size. However, it has challenges of finding the appropriate location of event. Additionally, Twitter population is limited in rural areas, which hinders the accurate and timely information (Jongman et al. 2015).

In an experimental research study (Imran et al. 2016), a huge corpus of 52 million Twitter messages has been gathered during the period

of 2013–2015. Dataset was collected from different parts of the world, during 19 different incidents of crises including earthquakes, floods, landslides, typhoons, volcanos, and airline accidents. Artificial Intelligence for Disaster Response (AIDR), an open source platform, is used for the collection and classification of the messages. Additionally, the platform provides easy method to collect tweets from specific regions with particular keywords. Messages are categorized according to their contents as injured and dead people, missing people, damaged infrastructure, volunteer services, donations, sympathy, and emotional support. Before classification, stop-words and uniform resource locators (URLs) are removed from the data; both of them have no or less role in classification. Moreover, Lovins stemmer is used, which removes the derivational part of the word to make it more clear like “flooding” will be replaced by “flood.” Unigram and bigram words are defined as features. However, the information gained is used to select the top 1000 effective features. After the selection of features, multiclass categorization is performed by using support vector machine (SVM), random forest (RF), and Naïve Bayes (NB) algorithms. Evaluation of trained models is performed by tenfold cross validation, and largest word embedding on the topic of crisis management has been developed (Imran et al. 2016).

Another research (Nguyen et al. 2016) has explored stochastic gradient descent and proposed online algorithm using deep neural network (DDN). This algorithm is aimed to perform identification and classification of significant tweets. For identification, informative effectiveness of each tweet is investigated, and as a result, two categories were formed which were tagged as “informative” and “non-informative.” Informative tweets contains indication regarding the category of destruction due to disaster. Furthermore, the tweets are categorized according to their contents, as tweets containing an indication of loss of infrastructure are placed in a different category, while tweets with information regarding deceased and injured persons are placed in a separate category. Convolutional neural network

Flood Detection Using Social Media Big Data Streams, Table 1 Some public datasets for disaster event

Media	Samples	Algorithm	Duration	Disaster event
Twitter, satellite (Jongman et al. 2015)	7.6 million	–	2014–2015	Flood
Twitter (Imran et al. 2016)	52 million	NB, RF, SVM	2013–2015	Flood, earthquake
Twitter (Nguyen et al. 2016)	0.11 million	DNN	2015	Earthquake

(CNN)-based model is trained and tested for multiple six classes, including “donation and volunteering,” “sympathy and support,” and so on (Nguyen et al. 2016). Some public datasets for disaster events are shown in Table 1.

The severity of flood is diverse for different parts of the world. Few countries are significantly affected, as in Malaysia 40% of the total damage is caused by floods. The flood prone region of Terengganu, Malaysia, has been mapped by implementing support vector machine (SVM). The flood event took place in this area in November, 2009. Flood locations were detected by the method of texture analysis, and 181 flood-affected locations were recorded. The quantity of 70% locations was selected as training set and remaining 30% as testing set. Availability of flood or its absence is verified by binary classification with the help of various mathematical functions called kernels. This approach has used sigmoid (SIG), radial basis function (RBF), linear (LN), and polynomial (PL) kernel functions. Results were compared with the popular method of frequency ratio; it is found that SVM linear and SVM polynomial achieved success rate of 84.31% and 81.89%, respectively, while 72.48% by frequency with ratio method (Tehrany et al. 2015).

Efficient Natural Language Processing (NLP) Techniques for Flood Detection Using Social Media Big Data Text Streams

Natural language processing (NLP) plays a vital role in progressing artificial intelligence (AI) research in many practical areas of life. There are many several challenges in the NLP realm to be resolved such as natural language generation, natural language understanding, dialog

systems, speech generation, and recognition systems to name a few. Major fields that support NLP research are computer science, artificial intelligence, and computational linguistics. On the Internet 80% of user-generated contents are in textual form, and the potential of this huge knowledge resource is still to be explored. Internet with its recent advancement in real-time interactive user-/social group-generated textual content and readership offers new potential applications in the area of real-time event-based information processing and management. The NLP-based applications generally have a preprocessing pipeline for processing of textual features into more meaningful units. There can be parsing of lexeme from text, stemming/lemmatization, statistical, or counting of features. During the US presidential election of 2016, Twitter proved to be the largest and powerful source of breaking news, with 40 million election-related tweets posted by 10 PM on election day. Social media platforms, including Twitter, have been used and analyzed for use in disasters and emergency situations. Kaminska and Rutten (2014) identified the main uses of social media across the four pillars of the disaster management cycle being prevention and mitigation, preparedness, response, and recovery. Following are the three main areas where these platforms can be very helpful (Dufty et al. 2016).

- public information
- situational awareness
- community empowerment and engagement

Natural language processing (NLP) is a significant research area, which aims to achieve computational language processing mechanism, similar to human beings. Various desired tasks may be accomplished through NLP, including translation of text from one language to another,

paraphrasing, summarization, informational retrieval, and so on. Nowadays, social media contents are a huge source of information; hence appropriate processing could reveal valuable outcomes. The text available in social media is in raw format and needs preprocessing. Various techniques are used for preprocessing including stemming and lemmatization. Stemming is a process of finding the root or the main word from its derived word. For example, if stemming is applied on word flooding and storming, they will be reverted to their root words as “flood” and “storm,” respectively. Lemmatization removes unnecessary part of the word and provides root word, which must be a dictionary word with proper meaning (Bramer 2007; Eilander et al. 2016).

Challenges in NLP

Social Media Challenges

The information available in the form of social media contents is unreliable in various aspects. The creators of the information are not experts of the field; this inexperience may result in wrong judgment. Moreover, there are no restrictions on the usage of slang language. As the word flood may be used to indicate a huge quantity of people or things arriving at some place. Additionally, information mentioned on social media could indicate past experiences, rather than current situations (Eilander et al. 2016).

Challenges of Using Tweets for Disaster Response System

Twitter is an important part of social media, where the user may upload text up to 140 characters. Usage of data collected from tweets for crisis management faces various challenges due to the informal and restrictive nature of Twitter. The major drawback is unintentional spelling mistakes due to negligence of user. Additionally, due to the restriction of fewer words, the user may intentionally use formal or informal abbreviations of the words as; “Govt.” or “gov” instead of “government” and “2morrow” instead of “tomorrow.” Sometimes, the user faces inputting the whole idea in a restrictive space and removes spaces between words and write them

together, as “floodingEvent” instead of “flooding event,” which creates ambiguity (Imran et al. 2016; Nguyen et al. 2016).

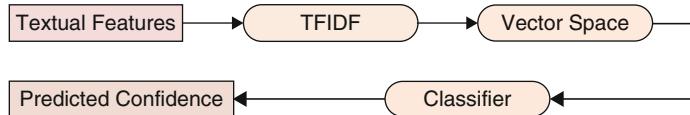

Machine Learning and NLP

Naïve Bayes (NB) and Multinomial Naïve Bayes

Naïve Bayes algorithm is highly simple and efficient. It uses probability theory for predicting the class for the given instance. The algorithm assumes that attributes of the instances are independent from each other (Bramer 2007). The process of text classification considers each word appearing in the document as a separate attribute; hence Naïve Bayes is an appropriate option to process them. Initially, multivariate Bernoulli model of Naïve Bayes classifier is proposed. It creates a binary vector form of document; each instance of the vector indicates availability or unavailability of particular word in that document. This model is more applicable to text classification with constant number of attributes. It lacks in counting the frequency of words appearing in the document. To address this issue, multinomial Naïve Bayes (MNB) is introduced. It counts the frequency of each word appearing in the document (Jiang et al. 2013).

Deep Neural Network (DNN)

In contrast to manual feature extraction, deep neural network (DNN) automatically extracts the abstract features from the data, which helps in the construction of effective classes. The network is mostly trained by using online algorithms, which is a favorable feature to be used for disastrous situations. The adaptive nature of deep neural network (DNN) attracts its usage in crisis management. The model can be trained earlier, while in case of a newly available dataset, it can work fine in the classification of newly arrived datasets, which is ideal for a crisis situation where real-time data needs rapid processing (Nguyen et al. 2016). Figure 2 shows the flow diagram for metadata feature processing using TF-IDF. Naive Bayes and support vector machines are the most popular classifiers in NLP Systems.

Flood Detection Using Social Media Big Data Streams, Fig. 2 Data flow diagram for metadata feature processing using TF-IDF

Flood Detection Using Social Media Big Data Streams

Table 2 Some state-of-the-art NLP techniques for flood detection using social media text data stream

Technique	Dataset	Evaluation measure	Performance
Relation networks (Nogueira 2017)	MediaEval	Average precision (Top 480)	77.0
Logistic regression, multinomial Naïve Bayes, random forest (Tkachenko et al. 2017)	MediaEval	Average precision (Top 480)	66.0

Latent semantic analysis (LSA) (Basnyat et al. 2017)	Twitter	Accuracy	94.0%

State-of-the-Art NLP Systems for Flood Detection Using Big Data Streams

Recently, various novel systems have been proposed to detect flood through text analysis of social media big data streams (Bischke et al. 2017; Hanif et al. 2017; Ahmad et al. 2017b,a; Avgerinakis et al. 2017; Nogueira 2017). Most of these approaches are evaluated on standard public dataset from Multimedia Satellite Task at MediaEval, 2017. This dataset consists of metadata of images uploaded by the social media users, which may or may not contain evidence of flood. This metadata contains various fields including relevant description of individual image, user tags, title, date on which the image was uploaded, and the device through which it was

captured. The main objective is to extract and fuse the content of events which are present in satellite imagery and social media (Bischke et al. 2017). A lot of different and diverse techniques are reported including metadata features such as term frequency-inverse document frequency (TF-IDF) (Bischke et al. 2017; Hanif et al. 2017) and word/text embeddings from a large collection of titles, descriptions, and user tags (Tkachenko et al. 2017). Among them, traditional features like TF-IDF are quite useful since it integrates the concept of term frequency that counts the number of occurrences of each semantically similar concepts (“flood,” “river,” “damage”) in the given user tags. Table 2 summarizes the performances of several NLP-based techniques.

Flood Detection from Social Media Visual Big Data Stream: Machine Learning and Deep Learning Techniques

Visual images available on social media can be effectively used for flood management system. Figure 3 shows some sample images from MediaEval 2017 satellite task. Over the years, various computer vision techniques have been investigated to extract local/global visual features from these images (Bischke et al. 2017). These features include AutoColorCorrelogram, EdgeHistogram, Color and Edge Directivity Descriptor (CEDD), Color Layout, Fuzzy Color and Texture Histogram (FCTH), Joint Composite Descriptor (JCD), Gabor, ScalableColor, Tamura, SIFT, Colour SIFT, and local binary patterns (LBP). Machine learning techniques such as support vector machine (SVM), decision tree (DT), and kernel discriminant analysis using spectral

regression (SR-KDA) are then used to distinguish between flood and non-flood images.

Recently, deep learning is quite successful in image classification tasks. Deep learning is an advanced field of machine learning which portrays human brain and produces similar neural network for execution of tasks. It executes input through hierarchy of multiple layers to produce proper information. In contrast to machine learning, features are automatically extracted from the provided input which saves a lot of human effort and computing resources (LeCun et al. 2015). Due to real-time feature extraction and processing according to the required task, more computation is required; that is why graphical processing units (GPUs) are used for efficient results. For improved accuracy, neural networks require large amount of data, so that exact features may be predicted clearly. Deep learning has various applications in different fields including natural language processing (NLP), com-

Flood Detection Using Social Media Big Data Streams, Fig. 3 Some images from MediaEval 2017 satellite task (Bischke et al. 2017)

puter vision, audio processing, and so on. Especially in computer vision, deep learning has produced exceptional improvements to improve various dimensions including image segmentation, compression, localization, transformation, sharpening, completion, colorization, and prediction. Table 3 summarizes the performances of several ML- and DL-based techniques.

Transfer Learning

The effectiveness of deep network is directly related with the availability of training data; greater amount of training data reveals much accurate output. But, the strong training requires a huge quantity of resources. Transfer learning is proposed to resolve the issue of effective training, which does not require training of neural network from scratch. Instead, the mechanism performs little modification in extensively trained network, which is trained on large datasets and strong machines. These pre-trained neural networks can be used in a similar or different domain.

Importance of Deep Learning (DL)

Algorithms in Event Prediction

During disaster and crises, accurate situational awareness and rapid communication are

important to properly manage the situation. Conventional algorithms perform their functionality according to the defined steps, and they are inappropriate to manage crises. On contrary, deep learning algorithms perform their task according to input provided to them, and they are more appropriate to respond contextual awareness, so that accelerated action may be performed. ImageNet dataset: ImageNet is a dataset, which contains 15 million labeled images, categorized into about 22,000 categories (Jiang et al. 2013). Yearly, a contest is organized to produce better results by using ImageNet. The winner of that competition reveals new model, including AlexNet, QuocNet, Inception or GoogLeNet and BN-Inception-v2, and Inception version 3. These pre-trained models are released to be executed on machines having low computational and storage resources. One or more layers of these networks are altered according to domain, and then the network is retrained accordingly. This retrained network produce better efficiency due to the strong training it acquires from ImageNet dataset. The Inception version 3 was introduced in 2016 (Chen and Han 2016), with boosted performance on ILSVRC 2012 classification benchmark. In comparison with the state-of-

Flood Detection Using Social Media Big Data Streams, Table 3 Some state-of-the-art machine learning and deep learning techniques for flood detection using social media visual data stream

Technique	Dataset	Evaluation measure	Performance
Convolutional neural network, AlexNet DL model (Ahmad et al. 2017b)	MediaEval	Average precision (Top 480)	86.0
GoogleNet DL model (Nogueira 2017)	MediaEval	Average precision (Top 480)	74.0
Global/local features, SR-KDA (Hanif et al. 2017)	MediaEval	Average precision (Top 480)	64.0

Discrete cosine transfer (DCT) (Basnyat et al. 2017)	Twitter	Accuracy	67.0%

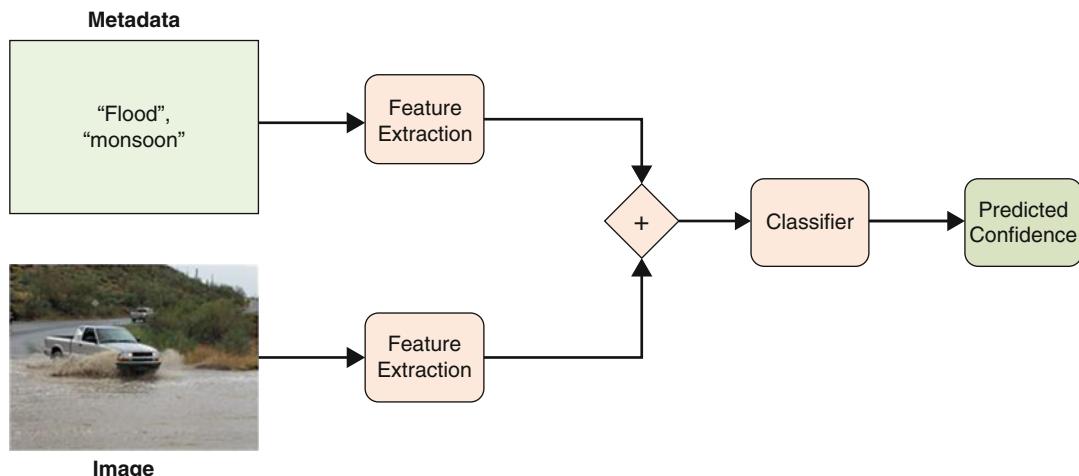

the-art results (Nguyen et al. 2016), it has cut error by 25%, with six times cheaper computing resource with five times less parameters.

Combining Knowledge Using Fusion of Meta- and Visual Data

The performance of flood detection can be improved by using both image uploaded on social media and its metadata. The combination utilizes features of text as well as images; this enhances the effectiveness of the results. Figure 4 shows an example showing fusion of metadata and visual data. Table 4 summarizes the performances of several ensemble techniques. In these techniques, floods are predicted using the combination of meta- and visual data.

Conclusion

The idea of harnessing the social media for emergency management is quite effective. The fundamental rules of social media like instantaneous, cost-effective, transparent, and intentional are very much related to the objectives of emergency management which are collaborative, coordinated, integrated, progressive, and professional. Most emergency agencies around the world now use social media alongside the conventional platforms like newspaper, television, and community channels to establish the process of warning, safety, response, and recovery from the emergency situation. In this paper, we briefly explore the flood detection systems using social media big data streams. Re-

Flood Detection Using Social Media Big Data Streams, Fig. 4 Data flow diagram showing fusion of meta- and visual data

Flood Detection Using Social Media Big Data Streams, Table 4 Some state-of-the-art ensemble techniques for flood detection using fusion of meta- and visual data

Technique	Dataset	Evaluation measure	Performance
Relation networks and CNN (Nogueira 2017)	MediaEval	Average precision (Top 480)	95.0
Logistic regression classifier, multinomial Naïve Bayes, random forest (Tkachenko et al. 2017)	MediaEval	Average precision (Top 480)	66.0
TFIDF, global/ local visual features, SR-KDA (Hanif et al. 2017)	MediaEval	Average precision (Top 480)	64.0

cently, there are several datasets shared across the world from different countries/agencies for flood-related emergency situations. Moreover, there are integrated systems/frameworks for emergency reporting. These systems use several state-of-the-art machine learning approaches to determine the response in the critical situations. The integration of image and social media textual data deals the right mixture, for effective predictions and monitoring. The size of social media data, its integrations, filtration, and categorization to the relevant situation offer many challenges. On the other hand, its effective use in crisis detection, resilience, learning, and capacity building for real and online analysis cannot be denied.

Hadoop-based RDF query processors;
Spark-based RDF query processors

Definitions

RDF, the Resource Description Framework, has been recognized as a de facto standard to describe resources in a semi-structured manner. In particular, RDF is a graph-based format which allows to define named links between resources in the form of triples *subject*, *predicate*, *object*, also called statements. A statement expresses a relationship (defined by a predicate) between resources (*subject* and *object*). The relationship is always from

subject to object (it is directional). The same resource can be used in multiple triples playing the same or different roles, e.g., it can be used as a subject in one triple, as well as a predicate or an object in another one. This ability enables definition of multiple connections between the triples, hence creation of a connected graph of data. Such graph can be represented as nodes that stands for the resources and edges capturing the relationships between the nodes. RDF has been widely adopted in several application domains. For example, a growing number of ontologies and knowledge bases storing millions to billions of facts (e.g., *DBpedia*, *Probbase*, and *Wikidata*) are now publicly available (Poggi et al. 2008). In addition, key search engines like Google and Bing are providing increasing support for RDF. This entry gives an overview of various systems that have been designed to exploit the Hadoop and Spark frameworks for building scale-out RDF processing engines.

Overview

In 2004, Google made a seminal contribution to the big data community by introducing the **MapReduce** model (Dean and Ghemawat 2004). It is a simple and powerful programming model for developing scalable parallel applications that can process large datasets across multiple machines. In particular, MapReduce makes programmers think in a *data-centric* style allowing them to concentrate on dataset transformation, while MapReduce takes care of the distributed execution and fault tolerance details, transparently (Sakr et al. 2013). The Apache Hadoop project has been introduced by Yahoo! as an open-source framework that implemented the concepts of MapReduce. However, one of the main limitations of the Hadoop framework is that it requires that the entire output of each map and reduce task to be materialized into a local file on the Hadoop Distributed File System (HDFS) before it can be consumed by the next stage. This materialization step allows for the implementation of a simple and elegant checkpoint/restart fault-tolerant mechanism;

however, it dramatically harms the system performance. The **Spark** project was developed as a big data processing framework that tackles this challenge (Zaharia et al. 2010). In particular, the fundamental programming abstraction of Spark is called *Resilient Distributed Dataset* (RDD) (Zaharia et al. 2010) which represents a logical collection of data partitioned across machines. In principle, having RDD as an in-memory data structure enables Spark to exploit its functional programming paradigm by allowing user programs to load data into a cluster's memory and query it repeatedly. In addition, users can explicitly cache an RDD in memory across machines and reuse it in multiple MapReduce-like parallel operations. Therefore, Spark takes the concepts of Hadoop to the next level by loading the data in distributed memory and relying on cheaper shuffle during the data processing (Sakr 2016).

Examples of Systems

Hadoop-Based RDF Systems

SHARD (Rohloff and Schantz 2010) is one of the first Hadoop-based approaches that used a clause-iteration technique to evaluate SPARQL queries against RDF datasets. It is designed to exploit the MapReduce-style jobs for high parallelization of SPARQL queries. In particular, SHARD iterates over clauses in queries to incrementally bind query variables to the RDF graph nodes while conforming to all of the query constraints. In addition, an iteration algorithm is used to coordinate the iterated MapReduce jobs with one iteration for each clause in the query. In principle, the *Map* step filters each of the bindings, and the *Reduce* step removes duplicates where the key values for both *Map* and *Reduce* are the bound variables in the *SELECT* clause. The initial map step identifies all feasible bindings of graph data to variables in the first query clause. The output key of the initial map step is the list of variable bindings, and the output values are set to null. The intermediate MapReduce jobs continue to construct query responses by iteratively binding graph data to variables in later clauses as new

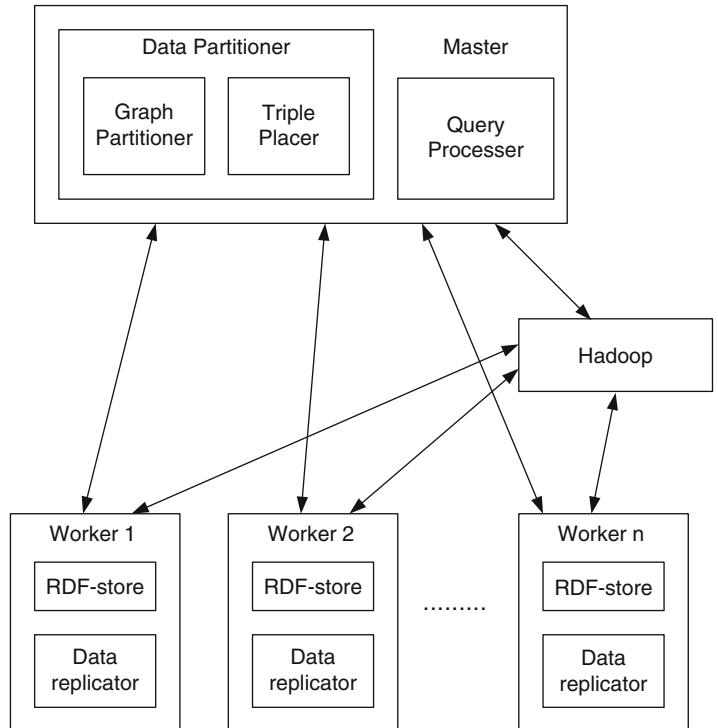

variables are introduced and then joining these new bindings to the previous bound variables such that the joined bound variables align with iteratively increasing subsets of the query clauses. The intermediate steps execute MapReduce operations simultaneously over both the graph data and the previously bound variables which were saved to disk to perform this operation. This iteration of MapReduce join continues until all clauses are processed and variables are assigned which satisfy the query clauses. The initial reduce step removes duplicate bindings without further modifying the output of the initial map step. A final MapReduce step consists of filtering bound variable assignments to obtain just the variable bindings requested in the *SELECT* clause of the original SPARQL query.

Husain et al. (2011) describe an approach to store RDF data in Hadoop Distributed File System (HDFS) via partitioning and organizing the data files and executing dictionary encoding. In particular, this approach applies two partitioning components. The *Predicate Split (PS)* component which splits the RDF data into predicate files. These predicate files are then fed into the *Predicate Object Split (POS)* component which splits the predicate files into smaller files based on the type of objects. Query processing is implemented on top of Hadoop by using a heuristic cost-based algorithm that produces a query plan with the minimal number of Hadoop jobs for joining the data files and evaluating the input query. The cost of the generated query plan is bounded by the log of the total number of variables in the given SPARQL query.

Figure 1 illustrates the architecture of the HadoopRDF system (Huang et al. 2011a) that has been introduced as a scale-out architecture which combines the distributed Hadoop framework with a centralized RDF store, **RDF-3X** (Neumann and Weikum 2010), for querying RDF databases. The data partitioner of HadoopRDF executes a disjoint partitioning of the input RDF graph by a vertex using a graph partitioning algorithm that allows triples which are close to each other in the RDF graph to be allocated on the same node. The main advantage of this partitioning strategy

**Framework-Based
Scale-Out RDF Systems,

is that it effectively reduces the network communication at query time. To further reduce the communication overhead, HadoopRDF replicates some triples on multiple machines. In particular, on each worker, the data replicator decides which triples are on the boundary of its partition and replicates them based on specified n-hop guarantees. HadoopRDF automatically decomposes the input query into chunks which can be evaluated independently with zero communication across partitions and uses the Hadoop framework to combine the resulting distributed chunks. It leverages HadoopDB (Abouzeid et al. 2009) to manage the partitioning of query evaluation across high-performance single-node database systems and the Hadoop framework.

The PigSPARQL system (Schätzle et al. 2013) compiles SPARQL queries into the Pig query language (Olston et al. 2008), a data analysis platform over the Hadoop framework. Pig uses a fully nested data model and provides relational style operators (e.g., filters and joins). In PigSPARQL, a SPARQL query is parsed

to generate an abstract syntax tree which is subsequently compiled into a SPARQL algebra tree. Using this tree, PigSPARQL applies various optimizations on the algebra level such as the early evaluation of filters and uses the selectivity information for reordering the triple patterns. Finally, PigSPARQL traverses the optimized algebra tree bottom-up and generates an equivalent sequence of Pig Latin expressions for every SPARQL algebra operator. For query execution, Pig automatically maps the resulting Pig Latin script onto a sequence of Hadoop jobs. An advantage of taking PigSPARQL as an intermediate layer that uses Pig between SPARQL and Hadoop is being independent of the actual Hadoop version or implementation details. RAPID+ (Ravindra et al. 2011) is another Pig-based system that uses an algebraic approach for optimizing and evaluating SPARQL queries on top of the Hadoop framework. It uses a data model and algebra (the Nested TripleGroup Data Model and Algebra (NTGA) Kim et al. 2013) which includes support for expressing graph pattern matching queries.

The **SHAPE** system (Lee and Liu 2013) uses a semantic hash partitioning approach that combines locality-optimized RDF graph partitioning with cost-aware query partitioning for processing queries over big RDF graphs. In practice, the approach utilizes access locality to partition big RDF graphs across multiple compute nodes by maximizing the intra-partition processing capability and minimizing the inter-partition communication cost. The **SHAPE** system is implemented on top of the Hadoop framework with the master server as the coordinator and the set of slave servers as the workers. In particular, RDF triples are fetched into the data partitioning module hosted on the master server, which partitions the data across the set of slave servers. The **SHAPE** system uses **RDF-3X** (Neumann and Weikum 2010) on each slave server and used Hadoop to join the intermediate results generated by subqueries. For query processing, the master node serves as the interface for SPARQL queries and performs distributed query execution planning for each query received. The **SHAPE** system classifies the query processing into two types: intra-partition processing and inter-partition processing. The intra-partition processing is used for the queries that can be fully executed in parallel on each server by locally searching the subgraphs matching the triple patterns of the query without any inter-partition coordination. The inter-partition processing is used for the queries that cannot be executed on any partition server, of which it needs to be decomposed into a set of subqueries such that each subquery can be evaluated by intra-partition processing. In this scenario, the processing of the query would require multiple rounds of coordination and data transfer across a set of partition servers. Thus, the main goal of the cost-aware query partitioning phase is to generate locality-optimized query execution plans that can effectively minimize the inter-partition communication cost for distributed query processing.

CliqueSquare (Goasdoué et al. 2015; Djahandideh et al. 2015) is another Hadoop-based RDF data management platform for storing and processing big RDF datasets. With the central

goal of minimizing the number of MapReduce jobs and the data transfer between nodes during query evaluation, CliqueSquare exploits the built-in data replication mechanism of the Hadoop Distributed File System (HDFS). Each of its partition has three replicas by default, to partition the RDF dataset in different ways. In particular, for the first replica, CliqueSquare partitions triples based on their subject, property, and object values. For the second replica, CliqueSquare stores all subject, property, and object partitions of the same value within the same node. Finally, for the third replica, CliqueSquare groups all the subject partitions within a node by the value of the property in their triples. Similarly, it groups all object partitions based on their property values. In addition, CliqueSquare implements a special treatment for triples whose property is *rdf:type*, by translating them into an unwieldy large property partition. CliqueSquare then splits the property partition of *rdf:type* into several smaller partitions according to their object value. For SPARQL query processing, CliqueSquare relies on a clique-based algorithm which produces query plans that minimize the number of MapReduce stages. The algorithm is based on the variable graph of a query and its decomposition into clique subgraphs. The algorithm works in an iterative way to identify cliques and to collapse them by evaluating the joins on the common variables of each clique. The process ends when the variable graph consists of only one node. Since triples related to a particular resource are colocated on one node, CliqueSquare can perform all first-level joins in RDF queries (SS, SP, SO, PP, PS, PO, etc.) locally on each node and reduce the data transfer through the network. In particular, it allows queries composed of 1-hop graph patterns to be processed in a single MapReduce job, which enables a significant performance competitive advantage.

Spark-Based RDF Systems

S2RDF (SPARQL on Spark for *RDF*) (Schätzle et al. 2015b) introduced a relational partitioning schema for encoding RDF data called ExtVP (the *Extended Vertical Partitioning*) that extends the vertical partitioning (VP) schema introduced by Abadi et al. (2007) and uses a semi-join-based

preprocessing to efficiently minimize query input size by taking into account the possible join correlations between the underlying encoding tables of the RDF data and join indices (Valduriez 1987). The main idea of the vertical partitioning scheme is to represent the RDF triple table into m tables where m is the number of unique properties in the RDF database. Each of the m table consists of two columns. The first column stores the subjects which are described by that property, while the second column stores the object values. The subjects which are not described by a particular property are simply omitted from the table for that property. ExtVP precomputes the possible join relations between partitions (i.e., tables). The main goal of ExtVP is to reduce the unnecessary I/O operations, comparisons, and memory consumption during executing join operations by avoiding the dangling tuples in the input tables of the join operations, i.e., tuples that do not find a join partner. In particular, S2RDF determines the subsets of a VP table VP_{p1} that are guaranteed to find at least one match when joined with another VP table VP_{p2} where $p1$ and $p2$ are query predicates. S2RDF uses this information to precompute a number of semi-join reductions (Bernstein and Chiu 1981) of VP_{p1} . The relevant semi-joins between tables in VP are determined by the possible joins that can occur when combining the results of triple patterns during query execution. Clearly, ExtVP comes at the cost of some additional storage overhead in comparison to the basic vertical partitioning techniques. Therefore, ExtVP does not use exhaustive precomputations for all the possible join operations. Instead, an optional selectivity threshold for ExtVP can be specified to materialize only the tables where reduction of the original tables is large enough. This mechanism facilitates the ability to control and reduce the size overhead while preserving most of its performance benefit. S2RDF uses the Parquet columnar storage format for storing the RDF data on the Hadoop Distributed File System (HDFS). S2RDF is built on top of Spark. The query evaluation of S2RDF is based on SparkSQL (Armbrust et al. 2015), the relational interface of Spark. It parses a SPARQL query into

the corresponding algebra tree and applies some basic algebraic optimizations (e.g., filter pushing) and traverses the algebraic tree bottom-up to generate the equivalent Spark SQL expressions. For the generated SQL expression, S2RDF can use the precomputed semi-join tables, if they exist, or alternatively uses the base encoding tables.

SparkRDF (Chen et al. 2014, 2015) is another Spark-based RDF engine which partitions the RDF graph into MESGs (Multi-layer Elastic SubGraphs) according to relations (R) and classes (C) by building five kinds of indices (C, R, CR, RC, CRC) with different granularities to support efficient evaluation for the different query triple patterns. SparkRDF creates an index file for every index structure and stores such files directly in the HDFS, which are the only representation of triples used for the query execution. These indices are modeled as RDGSs (Resilient Discreted SubGraphs), a collection of in-memory subgraphs partitioned across nodes. SPARQL queries are evaluated over these indices using a series of basic operators (e.g., filter, join). All intermediate results are represented as RDGSs and maintained in the distributed memory to support faster join operations. SparkRDF uses a selectivity-based greedy algorithm to build a query plan with an optimal execution order of query triple patterns that aims to effectively reduce the size of the intermediate results. In addition, it uses a location-free pre-partitioning strategy that avoids the expensive shuffling cost for the distributed join operations. In particular, it ignores the partitioning information of the indices while repartitioning the data with the same join key to the same node.

The **S2X** (SPARQL on Spark with GraphX) (Schätzle et al. 2015a) RDF engine has been implemented on top of GraphX (Gonzalez et al. 2014), an abstraction for graph-parallel computation that has been augmented to Spark (Zaharia et al. 2010). It combines graph-parallel abstractions of GraphX to implement the graph pattern matching constructs of SPARQL. A similar approach has been followed by Goodman and Grunwald (Goodman and Grunwald 2014) for implementing an RDF engine on top the

GraphLab framework, another graph-parallel computation platform (Low et al. 2012). Naacke et al. (2016) compared five Spark-based SPARQL query processing based on different join execution models. The results showed that hybrid query plans combining partitioned join and broadcast joins improve query performance in almost all cases.

Definitions

High-throughput sequencing platforms generate millions of short reads from a genome sequence, stored in a specific (FASTQ/SAM) format along with other information. Since each position in the genome is redundantly covered by many different reads, genomic data compression algorithms aim to reduce the burden in (high-throughput sequencing) data storage and transmission by reducing this redundancy.

Overview

Current trends in HTS data generation indicate that storage, transmission, and bandwidth costs will soon surpass the costs of sequencing and

become the main bottleneck in genomics as well as in the applications of HTS data to precision medicine. Most HTS data are maintained either as raw sequencing information in a FASTQ file or as reference-aligned (mapped) data in Sequence Alignment/Map (SAM) format. Although they have fundamental differences, the basic FASTQ and SAM schemata are both comprised of distinct data fields with specific properties; e.g., the sequence field consists only of nucleotide reads with length in the order of a few hundred to few thousand base pairs, while the mapping loci (on the reference) are usually represented as a nondecreasing sequence of integers. Much of existing HTS data is compressed by general-purpose compression tools, which treat them as simple plaintext files and thus produce suboptimal compression rates because they are not able to exploit the underlying data schemata.

Specialized FASTQ compressors initially perform a form of data transformation followed by statistical modeling and entropy coding. More advanced approaches achieve significantly higher compression ratios on FASTQ files by replacing each read with a pointer to the underlying reference genome or by reordering the FASTQ records in a manner that brings similar reads together, since the order of the records in FASTQ format is arbitrary. SAM files are mostly stored in their compressed binary equivalent, the BAM format. An alternative to the SAM format is CRAM, a reference-based format that separates different fields in the reads and applies a variety of compression techniques on them. The best

performing SAM compressors encode reads carrying the same sequence variants only once or employ highly optimized statistical models for various SAM fields.

In a recent benchmarking study to evaluate the effectiveness of available compression methods, the MPEG HTS compression working group compiled an HTS data set consisting of both raw (FASTQ) and aligned (SAM or BAM) read data with a wide spectrum of characteristics for ensuring statistically meaningful results (Numanagić et al. 2016). On this data set, compression performance, running times, memory usage, and parallelization capabilities were measured for available compression tools, including both industry-scale tools and research-oriented prototypes. The study declared no overall winner that can perform well on each data type and under every performance measure employed. Therefore, an integrated solution that chooses the specific approach offering the best performance for the specific application and the specific input data type(s) (with respect to the performance measure of importance) would yield the best outcome, both for raw and aligned sequence data.

FASTQ Compression Tools

FASTQ is a standard text format for storing unmapped HTS data provided as a set of reads (Cock et al. 2009). Each record (representing a read) in a FASTQ file consists of read identifier, sequence information, comment, and quality score (Ewing et al. 1998) information, each separated by newline characters. If the sequencer is able to produce *paired-end* reads, FASTQ files usually come in the so-called *library* format consisting of two FASTQ files, each consisting of the reads from the associated strand, such that the k -th read from first file corresponds to the k -th read from the second file.

General FASTQ Compressors

FASTQ files are many times compressed with general-purpose tools, such as Gzip (Deutsch 1996) and bzip2 (Seward 1998), resulting in

suboptimal compression ratios since they treat FASTQ as a simple plaintext file. Another popular format, although only internally used in the large sequencing databanks, is NCBI's SRA (Leinonen et al. 2010), which uses the LZ-77 scheme to encode metadata.

General FASTQ compressors typically decouple distinct streams (read names, sequences, comments, and quality scores) and compress each of them separately. Examples include DSRC and DSRC2 (Deorowicz and Grabowski 2011; Roguski and Deorowicz 2014), FQC (Dutta et al. 2015), LFQC (Nicolae et al. 2015), Fqzcomp (Bonfield and Mahoney 2013; Holland and Lynch 2013), and Slimfastq (Josef 2014). Instead of directly compressing each stream as text symbols, these tools may first perform reformatting on each field, e.g., read identifier *tokenization* to encode the common prefix of read identifiers only once or 2-bit nucleotide encoding. Quality scores are usually compressed by statistical modeling and entropy coding.

Alignment-Based FASTQ Compressors

The order of records within a FASTQ file is arbitrary, and thus an alteration of their order for the purpose of improving compression performance would not result in loss of information. Indeed, some of the newer approaches reorder reads in an input FASTQ file, typically with the goal of approximating their order within the genome sequence. Such reordering is helpful, e.g., when coupled with an encoding scheme that replaces each read with a pointer to a reference genome (together with a list of mismatches, if the alignment is not perfect). The reference can either be user-provided or constructed via *de novo assembly*, which is usually performed by representing the read collection as a de Bruijn graph and traversing it in a way to “cover” all reads.

Provided with a reference, alignment-based compression tools (explicitly or implicitly) sort the reads with respect to their mapping position in the reference. The reads, represented as pointers to the reference, could then be encoded, e.g., via run-length encoding. Naturally the compression performance of this general approach increases

with the read *coverage* (average number of reads that “cover” each position in the genome) and the repeat content of the genome.

Tools that employ this general strategy include LW-FQZip (Zhang et al. 2015) which uses an available reference genome for extracting the pointers, as well as Quip (Jones et al. 2012), Leon (Benoit et al. 2015), k-Path (Kingsford and Patro 2015), and KIC (Zhang et al. 2016) which first perform a de novo assembly of reads into longer contigs.

Reordering-Based FASTQ Compressors

Although the alignment-based methods mentioned above achieve good compression performance, they are typically slow since explicit read mapping and de novo sequence assembly are computation-intensive tasks. Perhaps the best trade-off between the compression rate and running time is achieved by compression methods that perform read mapping or assembly implicitly. Such methods first cluster reads that share long substrings (typically in an online fashion) and then independently compress reads in each cluster after reordering them or assembling them into longer contigs.

The first reordering-based FASTQ compression method, SCALCE (Hach et al. 2012), clusters reads based on their *core substrings*, a small subset of substrings from the input alphabet (in this case, the *four-letter DNA alphabet*) of a given length range, that are guaranteed to be present in all reads. For each read, SCALCE uses the lexicographically smallest core substring in the read for clustering purposes. Follow-up tools, such as Orcom (Grabowski et al. 2014) and Mince (Patro and Kingsford 2015), cluster the input reads into distinct sets according to a variety of *minimizer* (Roberts et al. 2004) schemes (similar to the core substrings, a minimizer is defined as the lexicographically smallest *k*-mer within the read that satisfies certain properties). Another tool, BEETL, uses a generalized version of BWT that operates on sets of strings for reordering (rather than clustering) reads (Cox et al. 2012); somewhat similarly, a more recent tool, HARC, uses a hash-based reordering of reads for improved performance (Chandak et al.

2018). Finally Assembltrie uses a fast, greedy assembly of the reads into trees (Ginart et al. 2018) (rather than strings) to achieve combinatorial optimality with respect to the number of symbols used in the reference constructed. Note that some of the abovementioned compression tools are research-oriented products and do not support compression of read identifiers/quality scores.

G

SAM Compression Tools

The SAM format Sam/bam Format Specification Working Group (2014) is a tab-delimited plaintext representation of sequences mapping to an arbitrary reference genome. It includes all the data from FASTQ files, accompanied by additional mapping information for every read, including (but not limited to) the position within the reference genome and the edit operations (so-called CIGAR strings) necessary to derive the reads from a reference. SAM files are many times stored in their binary compressed equivalent, the BAM format, which is a variation of LZ-77 scheme that allows random access in the compressed file with a negligible overhead. In addition to Samtools (Li et al. 2009), the most widely used software tool for SAM/BAM processing, a few other alternatives also use BAM as their output format, such as Picard Tools – By Broad Institute (2015) and Sambamba (Tarasov et al. 2015).

The CRAM Format and Reference-Based Compressors

As an alternative to SAM/BAM (that does not require any reference during the compression or decompression process), the reference-based CRAM CRAM format specification (version 3.0) format offers improved compression by handling distinct data fields separately. CRAM is implemented in Cramtools (Fritz et al. 2011), Scramble (Bonfield 2014), and more recently also in Samtools and Picard. In particular, Scramble can also compress reads without any reference, at the cost of lower compression rate; many of the

improvements offered by Scramble are now part of the CRAM format.

Variation-Sensitive Compression and Other SAM Compressors

In both SAM and CRAM files, reads harboring the same sequence variation are redundantly encoded due to independent encoding of each read. In order to eliminate this redundancy, a newer tool, DeeZ (Hach et al. 2014) implicitly assembles the underlying genome in order to encode these variations only once. A similar approach is followed by CBC (Ochoa et al. 2014) and TSC (Voges et al. 2016). All of these tools treat distinct SAM fields separately and apply a variety of compression techniques on each field. Finally, some of the best-performing tools in terms of compression rate, such as Quip and sam_comp (Bonfield and Mahoney 2013), employ highly optimized statistical models for various SAM fields at the expense of slower decompression.

Final Remarks

A recent benchmarking study on existing HTS compression methods (Numanagić et al. 2016) provided a comprehensive comparison of FASTQ and SAM compressors, revealing that some of the newly available tools achieve significant gains over universal lossless compression methods such as Gzip and bzip2 (as well as the standard Samtools for SAM compression) both in terms of compression rate and speed. Some of these tools provide significantly better compression rates at the expense of higher running time (both for compression and decompression) or larger memory usage. It is also important to note that the majority of the available tools are optimized for Illumina-style short, fixed-length reads (typically only a few hundred base pairs long) with a low ($\sim 1\%$) sequencing error rate. Compressing long, variable-length and error-prone read collections, such as data obtained with sequencers from

Pacific Biosciences or Oxford Nanopore, has proven to be a more challenging task.

Geo-replication Models

Mahsa Najafzadeh and Suresh Jagannathan
Purdue University, West Lafayette, IN, USA

Synonyms

Data storage replication; Geo-replicated storage; Multi-data center replication

Definitions

Geo-replication copies data in multiple data centers or sites across the globe, in order to bring data closer to the clients. Users can access a nearby data center, and perform operations locally, if possible. This local access improves latency by avoiding the high cost of network latency between data centers and increases availability in the presence of failures (Corbett et al. 2012; DeCandia et al. 2007; Shapiro et al. 2011; Lloyd et al. 2011). For instance, the data for a bank account can be replicated at the bank's branches

in different locations around the world. A bank user can access a local branch and perform transactions.

Overview

Geo-replication models have emerged as an important technique for distributed applications over the Internet, such as cloud computing. Wide area network (WAN) communication becomes a fundamental barrier for developing the large-scale Internet-based applications. User requests incur at least one round-trip across a WAN. While this might be acceptable for some applications, such as web browsing, an important class of applications (e.g., online game applications and e-commerce applications) is actually latency sensitive. For instance, Amazon reported that every 100ms slowdown degrades revenue by one percent. The WAN latency issue becomes more challenging as the market for distributed systems is being fueled by cloud computing, big data, exascale computing, and so on.

Geo-replicated systems decrease WAN-based latency by bringing data closer to users. The replicated system model consists of a set of data centers, each maintaining a copy of the database state. A database contains a set of replicated data items. Each data item has a *value* at any one time and a *type* that determines the set of operations that can be invoked on the data object. Users interact with the database system through running applications. A client accesses a single replica, referred as its *local* replica, and invokes a set of operations on the data objects stored in the database.

Different geo-replicated systems offer different services, ranging from simple *read* and *write* operations into ACID transactions (Gray and Reuter 1993). COPS (Lloyd et al. 2011) and Amazon's Dynamo (DeCandia et al. 2007) are examples of a key-value geo-replicated storage system with read and write operations. COPS (Lloyd et al. 2011) supports read-only operations with a consistent view of multiple keys, but it does not allow multi-key write operations. Eiger (Lloyd et al. 2013), the extended version

of COPS, supports both read-only and write-only transactions across multiple keys. However, Eiger does not support arbitrary transactions with reads and writes across multiple keys.

Some geo-replicated systems, such as Cassandra (Lakshman and Malik 2010) and Yahoo's PNUTS (Cooper et al. 2008), extend read and write semantics by allowing clients to perform high-level update and query operations over data objects. A client's query simply returns the value of an object without changing the database state, but update operations modify the state. Consider PNUTS (Cooper et al. 2008), a geo-replicated data storage that supports a simple relational data model, organizing data into tables of records (or objects). Each record has a version; updating a record creates a new version for the record. PNUTS's API provides several primitive calls for read and update requests with different guarantees. For instance, PNUTS's *read-only* semantics allows a local replica to return a stale version of data, while PNUTS's *read-latest* semantics returns the most current version of data. For update requests, PNUTS allows to atomically create or update records and its update API includes a test-and-set semantics, which allows updating a record only if current version of that record is equals to a given required version.

Recent geo-replicated systems support arbitrary transactions among multiple data objects, which enable the encapsulation of a group of operations into a single unit, guaranteeing certain pleasant properties, i.e., atomicity, consistency, isolation, and durability (ACID). For instance, Google's Spanner (Corbett et al. 2012) proposes a transactional data storage with ACID semantics across multiple data centers.

To maintain state of all replicas of a geo-replicated model consistently, there are two main synchrony protocols that are used: *synchronous replication* and *asynchronous replication*.

Synchronous Replication

Ideally, the geo-replicated system must ensure *strong consistency*, providing the behavior of a single centralized system. Implementing strong consistency semantics, such as linearizability (Herlihy and Wing 1990) and serializability

(Papadimitriou 1979), requires a global total order of updates (*synchronous replication*). Linearizability provides the intuition of a single replica that executes all operations in a real-time order. Serializability (SER) ensures that every execution of operations is equivalent to some serial execution. In a synchronous replication approach, when a user issues a request at a local replica, before proceeding with the request, this replica must synchronize with all other replicas to find out if there are some concurrent conflicts, such as writing to the same data object. For instance, in a bank account application with deposit and debit operations, if one replica wants to perform a debit operation, it must first synchronize with all other replicas to stop other concurrent debits that would make the balance negative.

Such a synchronous protocol ensures that all replicas execute application's requests in the same order, and if some operations conflict, only one of these operations can be accepted; declined operations may be ignored or the application may choose to retry them. This synchronous and strongly consistent approach simplifies reasoning about the behavior of a program in a geo-replicated system, but the synchronization comes at a significant cost in availability (or performance).

Examples

Google's Megastore (Baker et al. 2011) implements a synchronous geo-replication model for a NoSQL data store where data is partitioned into small databases, called *entity groups*. Each entity group is synchronously replicated across data centers via Paxos consensus protocol (Gray and Lamport 2006). A replicated transaction log is assigned to each entity group. Megastore provides transactional ACID semantics within an entity group by enforcing transactions which have access the entity group mutually access the log's group, i.e., only one transaction can update the log at any time. Such synchronous approach serializes transactions running in the same group.

Google's Spanner (Corbett et al. 2012) is another geo-replicated model that supports a synchronous replication model across data centers

using Paxos (Gray and Lamport 2006), ordering transactions with regard to a real-time clock, i.e., transactions commit in an order equivalent to their real-time order. Consider in a bank application, Alice transfers 100 dollar into Bob's account, and sometime later Bob reads his account. A database providing real-time ordering will guarantee that Bob sees 100 dollar in his account. To implement the real-time ordering in a distributed system, Spanner introduces a new API, called *TrueTime*, which bounds the clock uncertainty by specifying an error margin for each local physical time clock. So, a transaction's timestamp is an interval between the earliest time that transaction could possibly be and the latest time. Given the interval, Spanner orders transaction T_1 before transaction T_2 iff $T_1.\text{latest} < T_2.\text{earliest}$. To ensure atomicity and isolation within a data center, Spanner relies on two phase commit and two phase locking.

Asynchronous Replication

Experience with real-world applications shows the synchronous approach often causes more synchronization than the application really needs (Bailis et al. 2013; Wang et al. 2002). To avoid this cost, one alternative approach is to allow a replica to execute a client's request without synchronizing a priori with another replicas. Instead, it returns a response immediately to the client; this request is propagated to all replica in background. Eventually, every replica performs the same request, possibly with a delay. We call this *asynchronous replication*.

For instance, COPS (Lloyd et al. 2011, 2013) is a key-value geo-replicated system that supports asynchronous writes; each client could access a copy of data stored in his local replica and independently perform operations.

Concurrency and Conflict Resolutions

Consistency problems arise when multiple replicas independently (i.e., without synchronizing with other replicas) update the same data object. Concurrent updates to multiple replicas of the same data object may execute in different orders among replicas; this may cause *conflicts*. For instance, consider Alice and Bob both access a

shared file *foo* at different replicas r_1 and r_2 , respectively. Type of file *foo* is registered with operations to read the value or to write a new value. A write to the register rewrites its last successful written value. Alice writes *a* to the file *foo*. Concurrently, Bob writes *b* to the same file. After exchanging the updates, content of file *foo* will be different at replicas r_1 and r_2 . This violates the expectation of convergence to the same state. A replicated system is said to be convergent if all replicas that observed the same set of updates have equivalent state.

There are different approaches used by replicated systems to resolve such conflicts raised by concurrent executions. A common policy is to accept one update of the two conflicting updates and ignore the other, for example, COPS (Lloyd et al. 2011) exploits *last-writer-win* rule(LWW) (also called Thomas's write rule (Johnson and Thomas 1976)) that assigns a unique timestamp to every update, and in case of concurrent conflicts, the update with a higher timestamp is selected and the older one is ignored.

The second approach is that the replicated system may support some application-specific conflict resolutions (DeCandia et al. 2007; Satyanarayanan et al. 1990; Terry et al. 1995). For example, the data store simply keeps the set of all concurrently written values of an object and presents them to the application. It is up to the application how to resolve the conflicts. This approach is prevalent in replicated file systems, such as LOCUS (Popek et al. 1981), Coda (Satyanarayanan et al. 1990), Ficus (Guy et al. 1990), and Roam (Ratner et al. 1999), and in version control systems, such as Git or SVN.

Alternatively, a replicated system may take advantage of replicated data types, such as CRDTs (Shapiro et al. 2011), which automatically resolve conflicting updates, ensuring that database itself has knowledge of resolution semantics in order to integrate the conflict resolution in the replication protocol.

Therefore, an asynchronous geo-replicated system may use one or more conflict resolution strategies to *optimistically* resolve conflicts. For instance, Walter (Sovran et al. 2011) is a geo-replicated transactional key-value data store that

uses two approaches: preferred replicas and counting set (cset). The idea of preferred copy is similar to primary copy in state machine replication model. Each object is assigned a preferred replica where updates into the object can be performed locally. A transaction commits locally within a single replica r if the preferred replica of all objects written by this transaction is r . Otherwise, committing the transaction in a non-preferred replica requires synchronization with all other replicas. Although the preferred replica approach amortizes the cost of distributed transactions, it does not scale well if data objects modified by multiple users in different replicas. Walter provides another technique built upon a commutative data type, called *cset* to avoid conflicts. Like commutative data types (Shapiro et al. 2011), cset supports commutative operations, which address write conflicts on the same data objects.

Application Invariants

An application might have a set of invariants, which are *explicitly* stated. An invariant is a property over the database state that determines the safe behavior of the application in terms of correct values that may be observed by users accessing the data objects. Unfortunately, asynchronous replication trades sequential safety semantics for availability. For instance, the bank application may have an invariant enforcing that the account balance be always non-negative. If the balance is initially \$100, and two users, connecting to different bank branches, try to withdraw \$60, without synchronization, both withdrawals will succeed but the balance will become negative(\$−20).

Key Research Findings

A major challenge in the design of geo-replicated systems is to ensure consistency among data centers. The CAP theorem (Gilbert and Lynch 2002) asserts a replicated system cannot promise both availability and consistency in the presence of failures. Thus, designers of geo-replicated system face a vexing choice between exploiting strong consistency guarantees of synchronous

replication, which promises standard sequential behavior to applications but is slow and fragile, and asynchronous replication, which is highly available and responsive but exposes users to concurrency anomalies.

No single replication model can best suit all purposes: it can provide acceptable consistency requirements for all applications without sacrificing performance and availability (Sovran et al. 2011).

Recent geo-replicated systems, such as Gemini (Li et al. 2012) and Walter Sovran et al. (2011), are evolving toward *hybrid* models, which provide different levels of consistency depending on the given application requirements. In the hybrid approach, the replicated data storage provides the asynchronous replication model by default, and synchronizations are added upon request (Li et al. 2012; Balegas et al. 2015; Terry et al. 2013). For instance, Gemini (Li et al. 2012) is a geo-replicated system implementing a hybrid consistency model, called *RedBlue*. RedBlue consistency model allows both synchronous and asynchronous replication models to coexist by classifying application operations as *red* and *blue*. Blue operations commute with all others; they are fast and always available even when disconnected. Red operations must be totally ordered, requiring system-wide synchronization. RedBlue relies on programmer-specified invariants to determine where synchronization is necessary. Consider a replicated bank application where clients can access different bank branches and perform deposit and debit operations. The application invariant is the account balance to be non-negative. Deposit operations are blue, i.e., clients can add to their account in all circumstances, but debits are red, because the system needs to stop a debit that would make the balance negative. If the client cannot connect with the bank server, all debits are blocked.

Examples of Application

Geo-replicated systems bring tremendous benefits for applications with high availability and

scalability requirements from social networks (Wittie et al. 2010) (e.g., Facebook and Twitter rely on geo-replicated storage) and multi-player online games to e-commerce applications such as Amazon (DeCandia et al. 2007).

Future Directions for Research

Navigating the trade-off between consistency and performance (or availability) is not clear-cut in a geo-replicated system. Although hybrid consistency models significantly improve performance, there are still lots of issues that must be addressed to exploit such techniques effectively; this requires carefully analyzing application semantics and identifying its consistency requirements. Static analysis and verification approaches are promising. They help programmers remove synchronization from critical executions path, adding synchronization only when strictly needed.

A number of verification tools for reasoning about application executions in a geo-replicated setting have been already proposed (Li et al. 2014; Gotsman et al. 2016; Kaki et al. 2018). Li et al. (2014) have presented a static analysis in order to classify operations into synchronous and asynchronous operations in the redblue consistency model. The analysis checks if executing operations preserves a given integrity invariant; if not, the analysis concludes that the operations require synchronization, i.e., it is a red operation. Bailis et al. (2015) have proposed a necessary and sufficient condition, called I-confluent analysis, to check whether operation executions on a replicated database need synchronization or not. The work analyzes various operations of an application and its desired invariants in order to detect necessary synchronization. Recently developed static analysis tools (Gotsman et al. 2016; Kaki et al. 2018) use a form of rely-guarantee (RG) reasoning (Jones 1983), a well-known method for verification of concurrent programs. A successful analysis proves that any execution of operations over replicated data, under a given synchronization protocol, maintains the given invariants.

The later steps of translating synchronization into efficient implementations in a geo-replicated model is also an open question; the challenge is that synchronous operations may hinder the latency advantage of asynchronous operations. There are different ways to implement a synchronous operation, each with own cost and complexity. From a performance perspective, there is no single best concurrency control protocol, since this will depend on dynamic characteristics of the workload, namely, on how often updates are blocked (contention) vs. how often synchronization are acquired (overhead). Combining static and dynamic analysis improves the reliability of the system. A future research direction would be to develop profiling or monitoring tools in order to measure the efficiency of the concurrency control protocol under different workloads and heuristics to improve it.

Another interesting direction is to study how different synchronization protocols perform under different failure models, in particular Byzantine failures. Failures including individual server failures, data center failures, and network failures are common in large-scale systems. A geo-replicated system must handle these failures. Some geo-replicated systems like Walter (Sovran et al. 2011) rely on crash-recovery model to handle failures. In the case of a primary replica's failure, a Paxos-based reconfiguration service can be used to replace the faulty process. After recovery, it must synchronize with the replacement replica to take over its responsibility. Finding solutions that can efficiently capture non-deterministic behavior of a geo-replicated system would be a good direction.

Definitions

Geo-Scale Transaction Processing considers the processing of transactions on nodes that are separated by wide-area links.

Overview

Replication and distribution of data across nodes have been used for various objectives, such as fault tolerance, load balancing, read availability, and others. This practice dates back to the early days of computing (Kemme et al. 2010; Bernstein and Goodman 1981) and continues to develop to accommodate the development and advancement of new computing technologies. The availability of publicly accessible cloud resources that are dispersed around the world has allowed the replication and distribution of data across large distances, potentially covering many continents. This is denoted a geo-scale deployment and allows achieving higher levels of the objectives of replication and distribution. For example, geo-scale deployments can tolerate data center-scale failures and disasters that cover large geographic regions. Also, geo-scale deployments can provide faster access to users across the globe. In addition to the classical objectives of replication and distribution, geo-scale deployment allows a better utilization of cloud resources, as it enables the use of resources from multiple cloud providers and cloud locations. Typically, different cloud providers and locations offer varying services with diverse characteristics. A geo-scale deployment allows leveraging heterogeneous cloud resources to optimize various performances and monetary objectives.

With the increasing distance between nodes, the data management tasks to provide access to data become more challenging. One essential data management task for access is transaction processing. A transaction is an abstraction of data that consists of a collection of operations, typically reads and writes, and that is guaranteed to execute with certain defined properties. These properties include ones about consistency, recoverability, and others, and each property has many flavors, defining the strictness of the provided guarantees. The cost of providing various guarantees increases significantly in geo-scale deployment due to the wide-area link between nodes. This is due to the communication needed between nodes to coordinate access while preserving defined guarantees. This has stimulated interest in developing new transaction processing technologies for geo-scale deployments that ameliorate the cost of wide-area communication. This includes new designs that achieve classical guarantees more efficiently in geo-scale environments and new explorations on transactional access guarantees that are more feasible in geo-scale environments.

Key Research Findings

Geo-Scale Transaction Processing includes work that covers various consistency guarantees. Next is an overview of key research findings for different levels of transactional consistency guarantees. Related research findings on Geo-Scale Transaction Processing follows.

Strongly Consistent Transactions

Serializability (Bernstein et al. 1987) is a strong consistency guarantee that ensures that the outcome of concurrent transaction execution is equivalent to some serial execution of these transactions. It has been extensively studied in the context of database systems and is considered one of the strongest guarantees on consistency that enables abstracting out the complexities of concurrency and replication, thus ridding users from thinking about these complexities. However, serializability is a strong consistency guarantee that requires extensive coordination between nodes executing transactions and nodes hosting data copies. This makes it especially challenging in a geo-scale deployment, where coordination is across wide-area links. To overcome the expensive cost of wide-area coordination, a redesign of well-known transaction processing protocols and approaches has been conducted in addition to the

design of novel transaction processing protocols specifically for geo-scale deployments.

Paxos (Lamport 1998) is a fault-tolerant consensus protocol that has been used widely to implement transaction processing systems that provide strong guarantees. In these implementations, Paxos provides a state machine replication (SMR) component that guarantees the totally ordered execution of requests (e.g., transactions). Due to its wide use in data management systems, there have been many attempts to build Paxos-based protocols for Geo-Scale Transaction Processing, such as megastore (Baker et al. 2011), Paxos-CP (Patterson et al. 2012), Egalitarian Paxos (Moraru et al. 2013), and MDCC (Kraska et al. 2013; Pang et al. 2014).

Megastore (Baker et al. 2011) uses Paxos to execute transactions on multiple nodes in different data centers. Paxos is used to assign transactions to log positions and to make all nodes agree on the assigned order. Then, each node executes the transactions according to the assigned order. This guarantees that all nodes maintain a consistent copy of data, since they all execute transactions in the same order. Assigning the position for a request requires a round of communication, at least, between a Paxos leader and other nodes. Paxos-CP (Patterson et al. 2012) extends megastore by increasing the utilization of Paxos communication. Specifically, in the presence of concurrent transactions, Paxos-CP allows *combining* transactions in the same log position rather than starting a new round of messaging.

MDCC (Kraska et al. 2013; Pang et al. 2014) leverages a follow-up Paxos variant, called Fast Paxos (Lamport 2006) that exhibits better performance characteristics for geo-scale deployments compared to the original Paxos protocol. Fast Paxos, unlike the original Paxos protocol, is a leaderless protocol, meaning that leader election, a major component of Paxos' design, is not needed. Therefore, for users at different locations, it is possible for all of them to process transactions without having to go through a leader. This comes at the cost of larger quorums (i.e., groups of nodes) that are needed to process requests. In Paxos, a simple majority suffices to

process a request (from a leader), whereas Fast Paxos requires a fast quorum that is typically larger than a majority of nodes. Egalitarian Paxos (EPaxos) (Moraru et al. 2013) proposes a new variant of Paxos that combine many attractive features for geo-scale deployments. First, EPaxos is a leaderless protocol; thus, it enjoys the benefits of leaderless protocols in comparison to the original Paxos protocol as we discuss previously for Fast Paxos. Additionally, EPaxos reduces the quorum size to be smaller than what is typically needed by MDCC and achieves the optimal quorum size (i.e., three nodes) of the widely used case of five nodes. EPaxos also utilizes many useful features to increase concurrency, such as allowing nonconflicting operations to execute concurrently. This is done via a multidimensional log, similar to generalized Paxos (Lamport 2005) rather than a simple log of requests that enforce ordering events even if they do not conflict.

Paxos was also shown to be suitable to act as a synchronous communication layer integrated with a transaction commit protocol (Corbett et al. 2012; Glendenning et al. 2011; Mahmoud et al. 2013). For example, Spanner (Corbett et al. 2012) and Replicated Commit (Mahmoud et al. 2013) commit using variants of two-phase commit (2PC) and strict two-phase locking (S2PL) and leverage Paxos to replicate across data centers. Spanner partitions data and assigns a leader for each partition. Each partition is synchronously replicated, for fault tolerance, to a set of replicas using Paxos. Transactions that span more than one partition are executed by coordinating between the corresponding partition leaders. This architecture separates consistency from durability, allowing optimizing each in isolation. Also, transactions that access a single partition are not subject to the multi-partition coordination. Replicated Commit executes transactions by getting votes from a majority of data centers. A data center's positive vote is a promise to not allow the execution of conflicting transactions. Once a majority positive votes are collected, the transaction proceeds to commit. Replicated Commit conflates consistency and durability, which reduces the amount of redundant messages. Additionally,

since there are no leaders, Replicated Commit exhibits better load balancing characteristics. However, a majority vote is always needed for all transactions, even ones that access a single partition.

To ameliorate the cost of wide-area communication, proactive coordination techniques were developed that exchange data continuously to enable early detection of conflicts (Nawab et al. 2013, 2015b). Helios (Nawab et al. 2015b), a work based on proactive coordination, finds the optimal transaction commit latency via a theoretical model of coordination and proposes a protocol design that achieves the optimal latency. Helios shows that for any pair of nodes, the sum of their transaction latency cannot be lower than the round-trip time latency between them (Nawab et al. 2015b).

Timestamp-based and time synchronization techniques have been explored for Geo-Scale Transaction Processing systems (Corbett et al. 2012; Du et al. 2013a,b). Although the distance between data centers may be large, Spanner (Corbett et al. 2012) shows that accurate time synchronization is achievable using specialized infrastructure such as atomic clocks and GPS. Without specialized hardware, accurate time synchronization is challenging. However, other geo-scale systems explored the use of loosely synchronized clock methods (Du et al. 2013a,b; Nawab et al. 2015b).

Weak and Relaxed Transactional Semantics

A major source of performance overhead in Geo-Scale Transaction Processing protocols is due to the coordination between nodes to guarantee consistent outcomes. To overcome the overhead of coordination, many lines of work investigates the trade-off between consistency and performance. In such investigations, consistency is relaxed or weakened to enable higher levels of performance. Central to this study is to understand the implications of relaxing and weakening consistency and what this means to the users and application developers. For example, application developers may have to cope with anomalies that arise due to the weaker consistency levels.

An extreme point in the performance-consistency trade-off spectrum is the weakening of consistency and isolation guarantees in favor of performance (Cooper et al. 2008; DeCandia et al. 2007; Bailis and Ghodsi 2013). Adopting this approach entails weakening the guarantees of how conflicts between requests are handled. For example, eventual consistency delays the arbitration of conflicts and only guarantees that conflicts are resolved eventually – thus creating the possibility of temporary inconsistency. Also, this approach may entail weakening the access abstractions, such as providing single-key access abstractions rather than multi-object transactions. This limits the interface to application developers; however, it is easier to manage and enables higher levels of performance.

In addition to the two extremes in the consistency-performance trade-off spectrum, there are consistency levels in between that exhibit various performance and consistency characteristics. Exploring consistency levels in the context of Geo-Scale Transaction Processing aimed to overcome the high cost of wide-area coordination while providing some consistency guarantees for application developers. To this end, there have been many efforts to study weaker consistency guarantees and then extending them to adapt to geo-scale environments. Causal consistency, that is inspired by the causal ordering principle (Lamport 1978), is one such consistency level. Causal consistency guarantees that events (e.g., transactions) are ordered at all nodes according to their causal relations. Causal relations in this context denote ordering guarantees between events at the same node (total order), ordering of events at a node before any subsequent received events (happens-before relation), and ordering due to transitive total order or happens-before causal relations. There have been many Geo-Scale Transaction Processing systems based on causal consistency (Lloyd et al. 2011, 2013; Bailis et al. 2013; Nawab et al. 2015a; Du et al. 2013a). An example is COPS (Lloyd et al. 2011, 2013) which extends causal consistency with a convergence guarantee and call it Causal+ consistency. COPS provides

a read-only transactional interface that guarantees Causal+ execution via a two-round protocol.

Another relaxed consistency guarantee that was explored for Geo-Scale Transaction Processing is snapshot isolation (SI) (Berenson et al. 1995) which guarantees that a transaction reads a consistent snapshot of data and that write-write conflicts are detected. Geo-Scale Transaction Processing systems have been built by extending the concept of SI (Sovran et al. 2011; Daudjee and Salem 2006; Lin et al. 2005, 2007; Du et al. 2013b). An example is Walter (Sovran et al. 2011) which builds upon SI and proposes Parallel SI (PSI). PSI relaxes the snapshot and write-write conflict definitions to allow replicating data asynchronously between data centers, which is not possible in SI.

Coordination-Free Processing

Another approach to tackle the consistency-performance trade-off is to explore classes of transactions that can be executed without coordination while maintaining consistency. This approach is called coordination-free processing and has been explored in the context of Geo-Scale Transaction Processing (Bailis et al. 2014; Roy et al. 2015; Zhang et al. 2013). An example of this work is transaction chains (Zhang et al. 2013) that analyze an application's transactions and build an execution plan for distributed transactions with the objective of fast response time, equivalent to executing at a single data center with no wide-area communication.

Data Placement

The topology of the geo-scale system plays a significant role in transaction performance. Therefore, placement of data and workers on carefully chosen data centers has the potential of optimizing performance. Placement has been tackled in the context of geo-scale systems (Zakhary et al. 2016, 2018; Wu et al. 2013; Vulimiri et al. 2015; Agarwal et al. 2010; Endo et al. 2011; Pu et al. 2015; Shankaranarayanan et al. 2014; Sharov et al. 2015). Some of these placement frameworks specifically target optimizing placement for Geo-Scale Transaction Processing (Zakhary et al. 2016, 2018; Sharov et al. 2015). For ex-

ample, (Sharov et al. 2015) propose an optimization formulation for placement with an objective of minimizing latency for leader-based transaction processing systems such as Spanner (Corbett et al. 2012). Zakhary et al. (2016, 2018) propose placement formulations for quorum-based transaction processing systems such as Paxos-based systems.

Managing the Consistency-Performance Trade-Off

Rather than a fixed Geo-Scale Transaction Processing protocol, there have been studies on dynamic protocols that adapt their consistency level and protocol characteristics based on the current performance (Wu et al. 2015; Terry et al. 2013; Ardekani and Terry 2014). For example, CosTLO (Wu et al. 2015) introduces redundancy in messaging to lower the variance of latency. Another example is Pileus and Tuba (Terry et al. 2013; Ardekani and Terry 2014) that enables applications to dynamically control the consistency level by declaring consistency and latency priorities. According to these priorities, the system adapts its protocol.

Conclusion

Geo-Scale Transaction Processing provides easy-to-use abstractions of access to data that is globally replicated or distributed. One of the major challenges faced by Geo-Scale Transaction Processing is the large wide-area latency between nodes. To overcome this challenge, redesigns of transaction processing systems are proposed, and studies of the consistency-performance trade-off are conducted. These approaches are shown to optimize the performance of Geo-Scale Transaction Processing by considering the wide-area latency as the main bottleneck.

Examples of Application

Geo-Scale Transaction Processing is used by web and cloud applications.

Future Directions for Research

An avenue of future research is to expand beyond data centers and build Geo-Scale Transaction Processing protocols that utilize edge resources.

GPU-Based Hardware Platforms

Johns Paul¹, Bingsheng He², and Chiew Tong Lau¹

¹Nanyang Technological University, Singapore, Singapore

²National University of Singapore, Singapore, Singapore

Definitions

GPU, SIMD, single-package platforms, multi-package platforms GPU-based hardware platforms are platforms that usually use GPUs in conjunction with CPUs to accelerate specific tasks. GPUs have evolved as a powerful accelerator for processing huge amounts of data in parallel.

Overview

This chapter details the architectural design and internal working of GPU-based hardware platforms. For this, we broadly classify GPU-based hardware platforms into two categories: single-package and multi-package. We then detail the architectural differences as well as the advantages and limitations of each category.

GPU

Graphics processing units (GPUs) were initially designed to accelerate the rendering of images for video editing and gaming. However, more recently, GPUs have evolved as a powerful accelerator for processing huge amounts of data

in parallel. Similar to CPUs, GPUs also contains processing cores, registers, multiple levels of cache, and a global memory unit. However, GPUs differ from CPUs in terms of the design of each one of these components. Instead of a small number of complex cores available on the CPUs, GPUs use large number of relatively simpler cores that work in a single instruction multiple data (SIMD) fashion to process large amounts of data. Modern GPUs contain more than 100x the number of cores in modern CPUs. This allows GPUs to execute the same operation on a large number of data items in parallel. GPUs are able to fit such large number of cores in a single silicon die due to the relative simplicity of each individual core. These cores lack complex components such as branch prediction unit and even have much smaller cache than CPUs.

The GPU cores also have access to a much larger number of registers and a higher bandwidth global memory unit, which is usually smaller (in size) than the main memory available on CPUs. The high bandwidth memory (HBM) units available in modern GPUs can provide close to 10x the bandwidth of main memory accessible to CPUs. This availability of larger number of registers and the much higher global memory bandwidth of GPUs ensures fast data access to the large number of parallel cores, thus making it possible to achieve much better throughput than CPUs. Figure 1 shows an overview of the internal architecture of GPUs.

The high level of parallelism provided by GPUs makes them an attractive platform for many high-performance computing tasks (Owens et al. 2007, 2008; Nickolls and Dally 2010). Over the past few years, GPUs have become popular for applications like 3D rendering (Kruger and Westermann 2003; Cates et al. 2018; Liu et al. 2004), deep-learning (Chetlur et al. 2014; Bergstra et al. 2011), online analytical processing (Paul et al. 2016; Heimel et al. 2013), and weather modeling (Shimokawabe et al. 2010; Mielikainen et al. 2012). Such applications often involve executing the same instruction on large number of data entries in parallel and have minimal amount of incoherent branching. Hence, they benefit from the huge parallelism

provided by GPUs, without encountering any of the penalty associated with divergent execution.

In spite of being able to achieve high performance for parallel tasks, GPUs are not suitable for running generic tasks like an operating system. Hence, any system that takes advantage of GPUs for accelerating tasks needs a CPU component to run generic tasks like schedulers and resource managers. Hence, GPU-based hardware platforms are platforms that usually use GPUs in conjunction with CPUs to accelerate specific tasks. These hardware platforms can broadly be classified into single-package and multi-package platforms, based on the level of integration between the CPU and GPU. Single-package platforms contain a GPU and a CPU on a single semiconductor package (Wikipedia 2011). Multi-package platforms are those that contain a CPU and a GPU in two separate packages, and the communication between the two happens over interconnections like PCIe or NVLink.

G

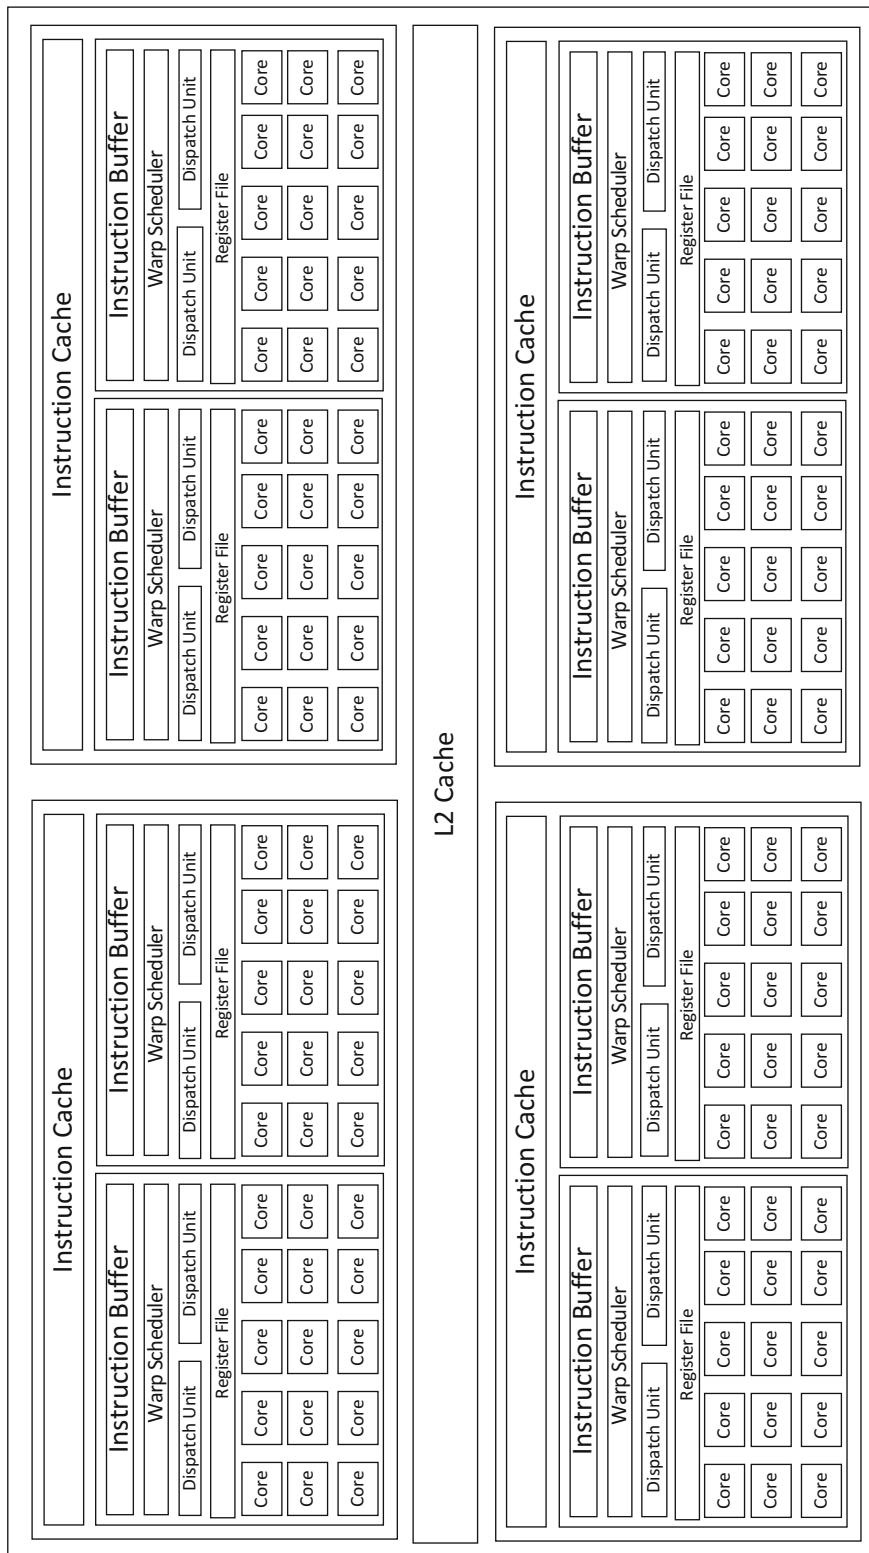

Single Package

In a single-package platform, the CPU and the GPU components are colocated within the same semiconductor package. Such systems can contain a single silicon die or multiple silicon dies interconnected using a silicon bridge. These single-package platforms can further be divided into (1) mobile platforms used in small handheld devices and (2) desktop platforms used in larger systems for more high-performance tasks.

Mobile Platforms

Most SoCs used in mobile devices these days contain GPUs in some form. Some of the most common examples include NVIDIA Tegra (NVIDIA 2015), Qualcomm Snapdragon SoCs (Qualcomm 2017), and Apple's A series SoCs (Wikipedia 2017). The mobile GPU platforms are usually designed to minimize power consumption and are usually cooled passively due to space restrictions.

The latest Tegra X1 SoC from NVIDIA is their successor to the Tegra K1 SoC and contains an ARM CPU combined with an NVIDIA Maxwell

GPU-Based Hardware Platforms, Fig. 1 GPU internal architecture

GPU. The ARM CPU is a 64-bit A57 with four cores and 2MB of L2 cache, while the GPU is 256 core Maxwell generation GPU. The latest Snapdragon 835 SoC from Qualcomm contains the Qualcomm Kryo 280 CPU which is a 64-bit CPU, based on the ARM Cortex Technology. And the A11 SoC from Apple, which is its successor to the A10 SoC, contains 64-bit ARMv8 CPU coupled with a triple-core GPU designed by Apple.

Desktop Platforms

Desktop GPU platforms are generally much more capable than mobile platforms, as these devices can afford to consume much more power and are usually cooled by dedicated hardware. Some of the examples of the commercially available hardware platforms of this kind include AMD Ryzen Accelerated Processing Units (APUs) (AMD 2017a) and Intel's latest efforts to integrate AMD Radeon Graphics with its eighth-generation CPUs (AnandTech 2017) in the same physical package using EMIB technology.

The latest AMD Ryzen 7 2700U APU from AMD, which is their successor to the Fusion series APUs, consists of a quad-core CPU with up to 3.8 GHz boost clock and a Vega 10 GPU with ten CUs operating at up to 1.3 GHz. Finally, the latest announcement comes from Intel regarding their plans to combine an eighth-generation Intel CPU with AMD Radeon graphics. Unlike the other two approaches, Intel plans to interlink two separate silicon die (one containing an Intel CPU and the other containing an AMD GPU) into a single package using the embedded multi-die interconnect bridge (EMIB) technology, where the GPU and the CPU communicate over a high-speed silicon bridge.

Advantages and Limitations

The main advantage of such a single-package design is the high bandwidth and low latency of communication between the CPU and the GPU. Another advantage is that in many cases, due to the close integration between the hardware devices, the GPU is able to directly access data from the CPU like the contents of the L3 cache. Such systems also allow the use of a single unified memory unit (accessible to both CPU and GPU)

instead of having separate memory units for the CPU and GPU. This helps avoid the overhead of explicit movement of data from the main memory to the GPU global memory, as in the case of multi-package systems.

The main limitation of single-package systems comes in the form of higher heat generation and the limitations in terms of package size. Integrating CPUs and GPUs into the same silicon die or semiconductor package will lead to higher energy output, due to more high-performance components cramped into a small space. This can limit the capabilities of the system as a whole. Also mass production of very large semiconductor packages is a difficult endeavor, and hence the size of CPU or GPU that can fit within the unified system will be much more limited than multi-package systems leading to less powerful individual components.

G

Multi-package

Multi-package systems consist of GPUs and CPUs in two separate semiconductor packages on the same physical board or even on two separate physical boards. Examples of such systems include standalone GPU hardware that can be connected to CPUs over interconnects like NVLink and PCIe. Both AMD and NVIDIA release such standalone or discreet GPUs every year. In these systems, the GPUs contain separate physical global memory which stores all the data that can be processed by the GPU. Due to their much larger size and higher-power requirements, multi-package systems are not suitable for mobile devices and are usually restricted to desktop devices.

The latest P100 discreet GPU from NVIDIA (2016) contains more than 3500 individual cores that can operate at frequency of up to 1.4 GHz. The P100 also have two different variants: NVLink based and PCIe based. The PCIe-based model only supports the PCIe bus for communication, while the NVLink version also supports the use of NVLink interconnect which can provide up to 5x speed of the PCIe interconnect. The P100 also supports up to

16 GB of high bandwidth memory. The latest RX Vega 64 GPU AMD (2017b) from AMD on the other hand contains over 4000 cores operating at up to 1.4 GHz. They also contain up to 8 GB of high bandwidth memory.

Advantages and Limitations

The main advantage of the multi-package GPU platforms is that these systems can support much more powerful individual components when compared to single-package designs. This is because separate packages can be cooled more efficiently, and individual components (GPU and CPU) can be much larger in size when compared to single-package systems where both the components need to cramp into a single semiconductor package. Further, the use of interconnects like PCIe means that more GPUs can be added to the platform at a later stage (based on the CPU and available PCIe lanes), making such system more flexible and upgradeable when compared to single-package systems.

However, the multi-package systems suffer from major bottlenecks when it comes to actual performance. Such systems are usually bottlenecked by the speed of the interconnect between the CPU and the GPU. This is because any data that needs to be processed by the GPU needs to be transferred from the system main memory to the GPU global memory via the PCIe bus. Further, these discreet GPUs lack access to CPU cache and in many cases even lack direct access to the CPU main memory leading high communication overhead between the CPU and the GPU.

Grammar-Based Compression

Sebastian Maneth

Department of Mathematics and Informatics,
Universität Bremen, Bremen, Germany

Synonyms

Dictionary-based compression; Graph grammars;
Straight-line context-free tree grammars;
Straight-line programs

Definitions

Grammar-based compression means to represent an object by a grammar that generates the object. For instance, a string can be represented by a context-free grammar that only generates the string, or, a node-labeled tree can be represented by a context-free tree grammar that generates only the tree. Two main questions are how to construct a small grammar for a given object and how to execute algorithms directly over grammars (without decompression).

Overview

This entry presents grammar-based compression of three types of finite objects: strings, trees, and (hyper)graphs, using context-free string, tree,

and hyperedge-replacement grammars. The entry (Bannai 2016) focuses on grammar construction algorithms for strings. Here, only a few grammar construction algorithms are discussed. As a prototypical example of algorithms over grammars, the equivalence problem is considered.

Key Research Findings

String Grammars

A string s consists of a sequence $a_1 \cdots a_n$ of letters a_i of an alphabet Σ . The length n of string $s = a_1 \cdots a_n$ is denoted by $|s|$.

Definition 1 Let Σ be an alphabet. A *straight-line program* (over Σ), for short *SLP*, is a triple $P = (\mathcal{N}, S, \mathcal{R})$ where \mathcal{N} is a finite set of *nonterminals* (disjoint from Σ), $S \in \mathcal{N}$ is the *start nonterminal*, and \mathcal{R} is a mapping from \mathcal{N} to (non-empty) strings over $\mathcal{N} \cup \Sigma$ such that the binary relation $\tau = \{(A, B) \in \mathcal{N}^2 \mid B \text{ occurs in } R(A)\}$ defines a single directed (ordered) acyclic graph (DAG) rooted at S .

The condition concerning τ will be referred to as “the DAG condition.” The DAG condition guarantees that the SLP P represents exactly one string $\text{val}(P)$ and that P does not contain unreachable (useless) nonterminals. The string $\text{val}(P)$ can be obtained from the string S by repeatedly replacing nonterminals X by their *rule* $R(X)$. For instance, let $n \geq 1$ and let P_n be the SLP with the rules

$$\begin{aligned} R(S) &= A_1 A_1, \\ R(A_i) &= A_{i+1} A_{i+1} \text{ for } 1 \leq i \leq n-1 \\ R(A_n) &= ab. \end{aligned}$$

Then $\text{val}(P_n)$ is the string $abab \cdots ab$ with 2^n occurrences of ab . The *size* of an SLP P is $\sum_{X \in \mathcal{N}} |R(X)|$. Note that the size of P_n is $2(n+1)$ and that $|\text{val}(P_n)| = 2^{n+1}$. Thus, an SLP can be exponentially smaller than the string it represents. At the same time, $|\text{val}(P)| \leq 3^{1+m/3}$ for any SLP P with $m = |P|$. This is because for a set of integers $I = \{|R(X)| \mid X \in \mathcal{N}\}$ with

$\sum_{i \in I} i \leq m$, it holds that $\prod_{i \in I} \leq 3^{\lceil m/3 \rceil}$. The origins of grammar-based compression are often attributed to Nevill-Manning and Witten (1997) and Kieffer and Yang (2000) and Kieffer et al. (2000); however as pointed out in Casel et al. (2016), the concept appears already in Storer and Szymanski (1982, 1978) as a particular version of their “external pointer macro.”

Grammar Compressors

A (string) grammar compressor is an algorithm that takes as input a string s and computes a small SLP P with $\text{val}(P) = s$. Several known compression schemes (e.g., LZ78 and with a small blowup also LZ77 (Rytter 2003)) can be seen as grammar compressors. Determining for a given string s and an integer k , whether there exists an SLP P with $|P| \leq k$, is NP-complete (Charikar et al. 2005). In fact, even for “1-level SLPs”, i.e., SLPs where only the start rule contains nonterminals, the problem remains NP-complete (even for an alphabet of size 5) (Casel et al. 2016); the same paper also presents an algorithm which uses dynamic programming to construct a smallest grammar in time $O(3^{|s|})$.

RePair (Larsson and Moffat 1999) is an example of a grammar compressor that runs in linear time and performs well in practice. The idea of RePair is to iteratively replace repeating diagrams (= two consecutive symbols) by new nonterminals (with their corresponding rules), until no repeating diagram exists. The *approximation ratio* of RePair, i.e., the maximum for any string s of length n of the size of an SLP produced by RePair for s divided by the size of a smallest grammar for s , is bounded by $O((n/\log n)^{2/3})$. Another well-known grammar compressor is *Bisection* (Kieffer et al. 2000), with an approximation ratio bounded by $O((n/\log n)^{1/2})$. The idea is to recursively cut the string s into two pieces, starting at position 2^j , where j is the largest integer such that $2^j < |s|$. Afterward, generate a new nonterminal for every distinct string of length greater than one produced in the cutting process. Then $|R(X)| = 2$ for every nonterminal. A space optimal online grammar compressor is presented in Takabatake et al. (2017); see Bannai (2016) for a more

detailed discussion on approximation algorithms of a smallest grammar. It should be noted that the length of the *LZ77 factorization* of a string s is a lower bound to the size of any SLP for s (Rytter 2003; Charikar et al. 2005).

Random Access

Given an SLP P one can construct in linear time (on a RAM) a data structure which supports random access to any given position p of $\text{val}(P)$ in time $\log(N)$, where $N = |\text{val}(P)|$; the substring starting at p of length m can be computed in additional $O(m)$ time (Bille et al. 2015). Moreover, for a string representing the traversal string of a tree (consisting of opening and closing parenthesis, plus (possibly) node labels), they construct in linear time (on a RAM) a data structure that supports a wide range of tree navigation operations (such as child, parent, level ancestor, lowest common ancestor, etc.).

An algorithm that runs in polynomial time with respect to $|P|$ is called *speed-up algorithm*. Many speed-up algorithms are known, for instance, for pattern matching, regular expression matching, edit-distance computation (Hermelin et al. 2009; Takabatake et al. 2016), and equality checking; see (Lohrey 2012) for a survey.

Equality Checking

Equality checking, i.e., deciding if $\text{val}(P_1) = \text{val}(P_2)$ for SLPs P_1, P_2 , can be achieved in time $O((|P_1| + |P_2|)^2)$. This can be shown by *recompression* (Jez 2015). Recompression is the application of two operations in alternation, (1) block compression and (2) pair compression. Block compression means to represent a string s of the form $a_1^{n_1} a_2^{n_2} \dots a_k^{n_k}$ by the string $a_1^{(n_1)} \dots a_k^{(n_k)}$, where the $a_i^{(n_i)}$ are new symbols. Given a partition Σ_l, Σ_r of the alphabet Σ , pair compression means to replace each digram ab with $a \in \Sigma_l$ and $b \in \Sigma_r$ by the new symbol $\langle ab \rangle$. It can be shown that for a string s that does not contain any factor of the form aa for $a \in \Sigma$, a partition Σ_l, Σ_r can be computed so that pair compression generates a string of length $\leq \frac{1}{4} + \frac{3}{4}|s|$. Two strings are equal if and only if their block or pair compressed versions are

equal. Thus, equality of two strings s_1, s_2 can be tested by repeatedly applying the three operations, (i) block compression, (ii) finding a partition, and (iii) pair compression, until one string of length one is obtained. At most $O(\log |s_1|)$ repetitions are needed. It can be shown that the three operations can be efficiently applied to SLPs P_1, P_2 directly. For instance, to carry out block compression over an SLP, one first computes for each nonterminal X the symbols a, b and maximal numbers i, j such that the string generated by X equals $a^i \alpha b^j$ and then uses this information to construct a block compressed SLP. The finally obtained SLPs are isomorphic (which can be checked in linear time) if and only if $\text{val}(P_1) = \text{val}(P_2)$. This yields an algorithm for equality checking of SLPs that runs in time $O((|P_1| + |P_2|)^2)$.

Tree Grammars

Let Σ be an alphabet. A (*node-labeled, ordered*) tree (over Σ) can be represented by a string $t = \sigma(t_1, \dots, t_n)$, where $n \geq 0$, $\sigma \in \Sigma$ and t_i is a tree. The string t_i represents the i -th subtree of the σ -labeled root node of t . The size of a tree t is its number of nodes (i.e., the number of Σ -symbols in t). If Σ is given with a mapping $\text{rk} : \Sigma \rightarrow \{0, 1, \dots\}$, then it is a *ranked alphabet*. A ranked tree (over Σ, rk) is a string $\sigma(t_1, \dots, t_n)$, where $\sigma \in \Sigma$, $n = \text{rk}(\sigma)$, and t_i is a ranked tree. For a ranked tree, parentheses are not needed, i.e., the tree $t = \sigma(t_1, \dots, t_n)$ is uniquely represented by its depth-first left-to-right string $\text{dflr}(t) = \sigma \text{dflr}(t_1) \dots \text{dflr}(t_n)$.

Since trees are strings, they can be compressed using SLPs (as, e.g., in Bille et al. 2015). However, for carrying out common tree operations, such as testing membership in a regular tree language, it is more convenient to use *tree grammars* instead of SLPs. A *straight-line regular tree grammar* (SLRT) is an SLP where each rule $R(X)$ is a tree in which nonterminals only appear at leaves. It is easy to see that SLRTs are just a notation for DAGs; thus the minimal SLRT for a tree t is unique and isomorphic to the minimal DAG of t . The minimal DAG of a tree can be computed in linear time (Downey et al. 1980).

For simplicity, only ranked trees are considered for the rest of this section. While minimal SLRTs can give exponential compression (viz., a full binary tree), they are not able to compress a monadic tree of the form $a(a(\dots a(e) \dots))$. A *straight-line context-free tree grammar* (over Σ) (SLCT) is a triple (\mathcal{N}, S, R) , where \mathcal{N} is a ranked alphabet of nonterminals, $S \in \mathcal{N}$ is the start nonterminal, and a rule $R(X)$ is a ranked tree over $\mathcal{N} \cup \Sigma$ and parameters y_1, \dots, y_m of rank zero. It is required that the DAG condition (see Definition 1 and the sentence below it) holds. A rule $R(X)$ is applied to a subtree $X(t_1, \dots, t_m)$ by replacing the subtree by the tree obtained from $R(X)$ by replacing each y_j by t_j for $1 \leq j \leq m$.

Note that SLCTs can achieve double-exponential compression: let T_n be the SLCT with

$$\begin{aligned} R(S) &= A_1(A_1(e)), \\ R(A_i) &= A_{i+1}(A_{i+1}(y_1)), 1 \leq i \leq n-1, \\ R(A_n) &= f(y_1, y_1). \end{aligned}$$

Then $\text{val}(T_n)$ is a full binary tree of height $2^n + 1$ and size $2^{2^n+1} - 1$.

A *tree straight-line program* (TSLP) is a SLCT such that each y_j occurs exactly once in $R(X)$ for any nonterminal X . TSLPs can achieve only single exponential compression and are better behaved than SLCTs. The rest of this section only deals with TSLPs. In the literature, TSLPs are often called “linear straight-line context-free tree grammars.”

Grammar Compressors

RePair compression can be generalized to construct a small TSLP for a given tree (Lohrey et al. 2013). A digram is now a triple (f, i, g) where f, g are node labels and $1 \leq i \leq \text{rk}(f)$. For instance, the tree $f(f(a, g), g)$ has two occurrences of the digram $(f, 2, g)$. A digram is replaced by a nonterminal A of rank $\text{rk}(f) + \text{rk}(g)$, and an appropriate rule for A is introduced; here $R(A) = f(y_1, g)$. The TreeRePair algorithm is controlled by a maximal rank parameter m to produce TSLPs where the rank of each nonterminal is $\leq m$. This is because many algorithms require time proportional to the

rank of nonterminals; hence it is desirable to keep this number small. TreeRePair works well in practice, but from a theoretical point of view does not approximate well a smallest grammar. For a linear time approximation algorithm that generalizes the recompression idea of SLPs to TSLPs, it has been shown that for a tree t of size n , a TSLP G of size $O(rg + rg \log(n))$ is produced, where r is the maximal rank of a node label in t and g is the size of a smallest grammar (Jez and Lohrey 2016). For another compressor which generalizes Bisection to trees, it was shown that a TSLP of size $O(n \log_\sigma n)$ is produced, where n is the size of the input tree and σ is the number of node labels (Ganardi et al. 2017).

Equality Checking

Similarly as for SLPs, many speed-up algorithms are known for TSLPs, for instance, testing membership in a regular tree language or testing equality. Often the complexity of algorithms of TSLPs depends on the maximal number of parameters of a nonterminal. It has been shown that any given TSLP can be transformed into an equivalent one where each nonterminal uses at most one parameter. For such a TSLP each rule has one of four forms

- (1) $f(A_1, \dots, A_n),$
- (2) $B(C),$
- (3) $f(A_1, \dots, A_i, y_1, A_{i+1}, \dots, A_n),$
- (4) $B(C(y_1)).$

Testing equality of TSLPs T_1, T_2 can easily be reduced to the string case by constructing SLPs P_1, P_2 for the strings $\text{dflr}(\text{val}(T_i))$. The size of P_i is $O(m|T_i|)$, where m is the maximal rank of a nonterminal of P_i . TSLPs can also be used to compress *unordered trees*, by considering the tree $\text{val}(G)$ as unordered. Isomorphism of unordered trees represented by TSLPs T_i can be solved in polynomial time (Lohrey et al. 2015), by computing TSLPs T'_i with $\text{val}(T'_i) = \text{canon}(\text{val}(T_i))$. The canon of a tree t is obtained from t by ordering the subtrees of each node length-lexicographically

with respect to their traversal string (according to some fixed order on Σ). For instance, $\text{canon}(f(d(a), c(a), b)) = f(b, c(a), d(a))$, if c is smaller than d . The result is extended to unrooted unordered trees by constructing TSLPs for rooted version of the trees of the given TSLPs, rooted at the (at most two) center nodes of the trees.

Graph Grammars

There are two well-known notions of context-free graph grammars: node-replacement (NR) grammars and hyperedge-replacement (HR) grammars (Engelfriet 1997). Compression via straight-line HR grammars has been considered recently (Maneth and Peternek 2017).

Let Σ be an alphabet and Γ a ranked alphabet with $\text{rk}(\gamma) \geq 1$ for every $\gamma \in \Gamma$. A (directed hyper) graph over (Σ, Γ) is a tuple $(V, E, \lambda, \text{att}, \text{ext})$ where V and E are finite sets of nodes and (hyper) edges, λ maps each $v \in V$ to Σ and each $e \in E$ to Γ . The attachment mapping att maps each $e \in E$ to a string over V of length $n = \text{rk}(\lambda(e))$. The string $\text{ext} \in V^*$ defines the sequence of *external nodes*. Typically, hypergraphs we compress do not have external nodes (i.e., ext equals the empty string ε); however, in a graph g appearing in the right-hand side of a grammar rule, external nodes indicate how g is merged with the host graph (see below). The graph is of *rank* k if $k = |\text{ext}|$. A conventional (node and edge labeled) graph is a hypergraph where (i) each $\gamma \in \Gamma$ has rank 2, (ii) if $\text{att}(e) = v_1 v_2$ then edge e is directed from v_1 to v_2 , and (iii) $\text{ext} = \varepsilon$.

A *straight-line hyperedge-replacement grammar* (over (Σ, Γ)) (SLHR) is a triple (\mathcal{N}, S, R) , where \mathcal{N} is a ranked alphabet of nonterminals; $S \in \mathcal{N}$ is the start nonterminal, for every $X \in \mathcal{N}$; and the rule $R(X)$ is a hypergraph over $(\Sigma, \mathcal{N} \cup \Gamma)$ of rank $\text{rk}(X)$, and the DAG condition (see Definition 1 and the sentence below it) holds. Let e be an X -labeled edge with $\text{att}(e) = v_1 \dots v_k$. Then a rule $R(X)$ is applied to e by removing e , inserting a disjoint copy of $R(X)$, and then identifying the i -th external node of the copy of $R(X)$ with the node v_i . The external nodes of an

HR grammar have a similar role as the parameters of a context-free tree grammar.

Let $g = (V, E, \lambda, \text{att}, \text{ext})$ be a graph. The *node size* of g is $|V|$. The *edge size* of g is $|\{e \in E \mid \text{rk}(\lambda(e)) \leq 2\}| + \sum\{\text{rk}(\lambda(e)) \mid \text{rk}(\lambda(e)) \geq 3\}|$. The *size* of g is the sum of node and edge sizes. The size of an SLHR grammar is $\sum_{X \in \mathcal{N}} |R(X)|$.

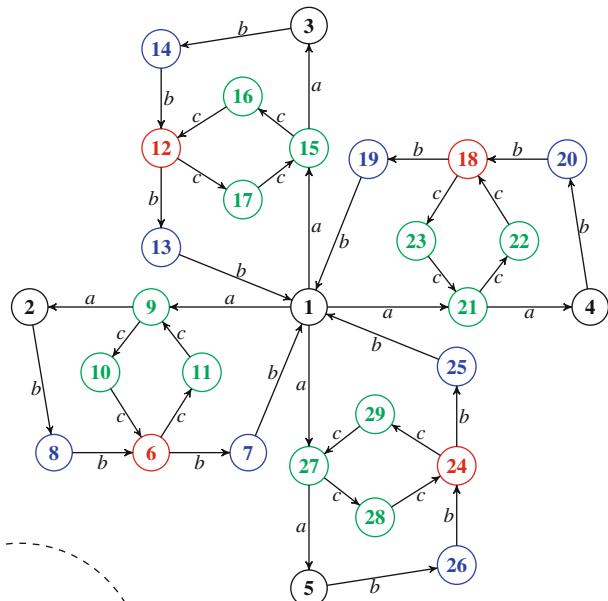

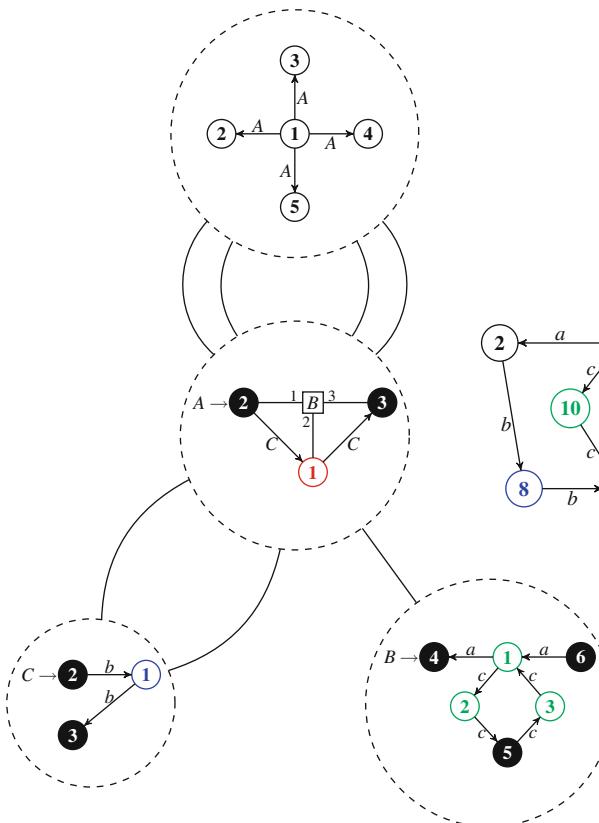

Consider the graph g in right of Fig. 1. This graph is edge-labeled and has no node labels. The nodes are ordered according to the numbers shown in the nodes. The size of the graph is 69. The left of Fig. 1 shows the “derivation DAG” (cf. the DAG condition of Definition 1) of an SLHR grammar G representing g . A rule $R(X) = h$ is written $X \rightarrow h$ and simply h in case of the start nonterminal S . The size of G is 34 (17 nodes, 14 edges, and 1 hyperedge of size 3). Note that there is a smaller grammar, obtained by removing

the nodes 2 to 5 from the start graph (and using A -hyperedges of rank 1). The external nodes are colored black with their order according to the node numbers. Clearly, $\text{val}(G) = g$. The node numbers can be obtained by following a specific order of the nonterminal edges in each rule, namely, lexicographically w.r.t the sequence of incident nodes. The node numbers of nodes 1 to 5 in $R(S)$ stay as they are. The A -edge from node 1 to node 2 is derived first. This generates a new red node labeled 6 (the first free label). Next is the C -edge from 1 to 6 which creates the blue node 8. Next, the green nodes 9, 10, and 11 are generated by application of the B -rule.

G

Grammar Compressors

RePair compression can be generalized to hypergraphs by defining a diagram to be a graph

Grammar-Based Compression, Fig. 1 Derivation DAG of an SLHR grammar G together with the graph $\text{val}(G)$ represented by G

g consisting of two edges plus their incident nodes. Further, the two edges in g must have at least one common incident node, and g must contain $k \geq 1$ distinct external nodes. The RePair idea is to (repeatedly) replace in a graph all occurrences of a most frequent digram by edges labeled by a new nonterminal. However, an issue that is straightforwardly solved in strings and trees turns out to be problematic in the graph case: when counting digram occurrences, only *non-overlapping* occurrences of digrams are of interest. For instance, the string *aaaaaa* contains *four* occurrences of the digram *aa*, but the number of non-overlapping occurrences of *aa* is *two*. In strings (trees) a maximal set of non-overlapping occurrences of a digram can be determined by simply counting greedily in a left-to-right (bottom-up) traversal. Note that in strings (trees), digrams can only overlap if the two letters (node labels) are equal. This is not the case for graphs. The fastest known method for finding a maximal set of non-overlapping digrams in a graph g requires $O(|g|^4)$ time. The RePair algorithm for graphs therefore resorts to a linear time approximation which greedily counts digrams according to a given node order. Interestingly, best results are achieved for a node order where “similar nodes” are visited in order. The order is inspired by the numbering scheme used in the Weisfeiler-Lehman isomorphism test (Weisfeiler and Lehman 1968).

Note that a TSLP P can be seen as a particular SLHR: a node with k children in the right-hand side of P is considered as a hyperedge incident with $k + 1$ nodes (the first node is incident to the edge of the parent node, the rest are incident to the edges of the child nodes). An SLCT (i.e., a TSLP in which parameters may be copied) can also be seen as an SLHR, however, as one that generates a DAG, not a tree. One may wonder if a tree-generating SLHR grammar can achieve better compression than a TSLP. This is not the case (apart from a constant factor): for any tree-generating SLHR G , one can construct an equivalent SLHR G' so that $\text{val}(G') = \text{val}(G)$, $|G'| \leq 2|G|$, and each right-hand side of G' is a tree.

Examples of Application

Grammar-based compression is a mathematical abstraction of known compression schemes, such as LZ78 (Ziv and Lempel 1978) for strings or common subexpression sharing via DAGs for trees (see, e.g., Ershov 1958). While the known schemes are extensively used within applications from industry, there is few mention of “grammar-based compression” within industrial applications. An example of an exception is (Senin et al. 2015) where grammar-based compression is applied to detect anomalies in time series; for this purpose they implemented the tool “GrammarViz” (Senin et al. 2014). Particular variants of grammar-based compression are applied to infer structure from RNA (Zhao et al. 2015; Liu et al. 2008). In Tabei et al. (2016), an algorithm and implementation is presented that performs partial least squares regression (PLS) over data matrices that are grammar-compressed; their results show great improvement in working space and scalability, over uncompressed PLS computations. Grammar-based compression is regularly mentioned in the context of XML compression (see, e.g., Sakr 2009); an implementation of an XPath query evaluator operating directly over TSLPs is presented in Maneth and Sebastian (2010).

Future Directions of Research

In terms of tree grammars, no compressor has yet been constructed for *non-linear* straight-line context-free tree grammars (as mentioned, such grammars allow double-exponential compression). In fact, also with respect to theoretical results, e.g., concerning the availability of speed-up algorithms for such grammars, almost nothing is known yet.

For SLHR grammars G , only a few speed-up algorithms have been investigated so far (Maneth and Peternek 2017). For instance, given two node numbers u, v , it can be determined in time $O(|G|)$ whether or not v is reachable from u .

Given a regular expression α and two node numbers u, v , it can be determined in time $O(|\alpha||G|)$ whether there is a path from u to v that matches α . The existence of such nodes can be determined in the same time bound. Many problems concerning SLHR grammars are still open. For instance, for a given k , it is not known whether isomorphism of two graphs given by SLHRs in which each right-hand side has size $\leq k$ can be solved in polynomial time. The corresponding graphs are of bounded tree width, and for uncompressed such graph isomorphism is decidable in polynomial time (Bodlaender 1990).

Introduction

Graphs have attracted research efforts for about three centuries (Biggs et al. 1986). Earlier, the focus was mainly on mathematical models and algorithms. Graph theory continues to be an active research area that includes many open problems. In the last decade, there has been a considerable amount of research in analyzing and processing large graph structures for real applications. This effort has led to the development of several alternative algorithms, techniques, and big data systems.

Parallel systems are very important and big data challenges are relevant to graph analytics. Although the edge list of some existing graphs are relatively small in size and may fit in one machine, these graphs are often large when considering vertex properties, graph indexes, and intermediate results during query processing. Processing often leads to very large memory requirements, which makes it not practical to fit the entire graph and its data into a single machine.

Big graph data has a special property that makes it harder than typical big data; there is no locality. For example, an employee database could be partitioned based on the employee department. Executing queries and creating reports about each department does not need interaction

between partitions (departments). Therefore, it is possible to keep each department in a machine to parallelize the workload. On the other hand, graph processing is interested in the relationships between entities and queries the relationship structure rather than individual entities. Therefore, when considering the relationship graph of employees, partitions (departments) are expected to be queried together.

The lack of locality in graph data and the need of running an algorithm for multiple iterations before convergence make data shuffling between partitions the major cost. Furthermore, due to the power-law property of many real graphs, each partition/machine needs to make different amount of workload. Most parallel systems try to minimize the data shuffling cost while maintaining balanced workload. They take different approaches to do that. Therefore benchmarking these systems should take into consideration several aspects, such as, memory usage, CPU utilization, graph data, and so on.

This entry briefly introduces the readers to graph data, real graph properties, and synthetic graph generation. Then, it discusses common workloads for graph benchmarking. After that, it summarizes existing benchmarks. The last section discusses experiment design, metrics to be measured, and evaluating the parallel cost.

Graph Data

A graph, G , is defined as $G = (V, E)$, where V is a set of vertices and E is a set of edges, such that $|V| = N, |E| = M$. For an edge $e = (u, v, P_e)$, $e \in E$ if $v, u \in V$ and P_e is a set of properties associated with edge e . A vertex $v \in V$, also, has a set of properties, P_v . P_e and P_v can be empty. If $P_v \neq \emptyset$ or $P_e \neq \emptyset$, it is known as a *property graph*. This definition is flexible to accommodate several graph types, such as directed and undirected, weighted edges, and bipartite graphs among others.

Type of graph used depends on the semantics of the application in hand. The web graph is a directed graph because each edge represents a hyper link from one web page to the other.

Some social networks, such as Facebook, adopt the “friendship” relationship; hence, the friends graph in Facebook is undirected. However, Twitter adopts the “following” relationship; hence, it is represented as a directed graph. A recommendation system graph, between customers and products, is a bipartite graph, where $V = V_1 \cup V_2$ such that V_1 represents customers, V_2 represents products, and edges between the two sets represent preferences.

There are several sources of real graph data in the literature, such as SNAP (Leskovec and Krevl 2014) and LWA (Boldi et al. 2011). Some projects are dedicated for preparing large real graphs, for example, Common Crawl has 64 billion edges. These real datasets are complementary to synthetic datasets. Synthetic datasets are equally important because they allow a benchmark to examine different properties of the same dataset. The main challenge in generating a synthetic dataset is to ensure that it represents the real world. The remaining of this section will discuss the properties of real graphs and synthetic graph generators.

Real Graphs Properties

The problem of studying the patterns and properties of real web and social graphs have been addressed extensively in the literature (Leskovec et al. 2005b; Faloutsos et al. 1999; Chakrabarti et al. 2010). Table 1 shows a few real graph datasets (Boldi et al. 2004, 2011; Boldi and Vigna 2004; Leskovec and Krevl 2014) and their properties. These properties include graph size, average and maximum degrees, diameter, and the percentage of nodes included in the strong connected component.

Social networks and web graphs are very large and have a high growth rate in terms of vertices and edges. They are sparse; the average vertex degree is significantly smaller than the number of vertices; however, the graph density increases as the graph grows. The diameter, which is the longest shortest path between any two vertices in the graph, is typically small and shrinking as the graph grows. Most of these graphs have one very large connected component and a few very small components that are usually ignored. The vertex

Graph Benchmarking, Table 1 Properties of some real graph datasets

Domain	Dataset	$ E $	Avg./Max. degree	Diameter	SCC
Social network	soc-LiveJournal	68 M	14.2/15 K	16	100%
	com-Orkut	117 M	38.1/33 K	9	100%
	com-Friendster	1.8 B	27.5/4223	32	100%
Road network	California	2.7 M	1.4/12	849	99.6%
	Texas	1.9 M	1.4/12	1054	97.9%
Citation graph	US patent	16 M	4.4/779	22	100%
Web graph	uk-2007-05	3.7 B	35.3/975 K	22.78	64.7%
	clueweb12	42.5 B	43.5/75 M	15.7	79%

degree follows the power-law distribution with a very long tail.

Existing graph generators try to represent web and social graph properties. There are typically seven properties:

- Very large
- Sparse
- Small diameter
- One large connected component
- Community structure
- Power law degree distribution
- Dynamic

It is important to acknowledge that these are not the properties of all real graphs. Graphs have different properties based on their source. Indeed, road network graphs have different characteristics than social networks, web, and citation graphs. The average degree is smaller than that of the others; moreover, the maximum degree is very close to the average degree. Apparently, road network graphs do not follow power-law distribution as do many other graphs. Furthermore, the diameter of the graph is significantly larger than all other graphs' diameter; hence, the small diameter phenomenon is not prevalent in this domain.

Synthetic Graph Generation

Erdös-Renyi

ER (Erdös and Rényi 1960) generation model can generate random graphs such that any possible graph with N vertices and M edges have the

same probability. These random graphs could be large, sparse.

Watts-Strogatz

The WS (Watts and Strogatz 1998) model tries to add small world (short diameter) property and high clustering (one large component) to the generated random graphs. Instead of creating edges randomly as in the ER model, it has two parameters β and K , such that:

$$M = \frac{NK}{2}$$

$$N > K > \ln(N) > 1$$

$$0 \leq \beta \leq 1.$$

The model starts by connecting two vertices v_i and v_j if

$$0 < |i - j| \bmod \left(N - 1 - \frac{K}{2} \right) < \frac{K}{2}.$$

Then, for each edge (v_i, v_j) such that $i < j$, the vertex v_j is replaced by v_z with a probability β . v_z is chosen uniformly from all available vertices as long as there is no self-edge and no duplicate edges between vertices. If $\beta = 1$, then the graph is a random graph similar to ER; if $\beta = 0$, then we have a clustered graph without random edges. These random edges help to reduce the diameter.

Barabasi-Albert

The BA (Albert and Barabási 2002) model is based on the preferential attachment mechanism which means that some value is distributed to

agents based on what they already have. This mechanism can generate graphs with power-law distribution; the distributed value in this case is the number of edges.

The algorithm starts with an initial random graph G_0 with N_0 vertices. Every new vertex v added to the graph could be connected to $m < N_0$ vertices. The probability of edge (v, v_i) is $p_i = \frac{d_i}{2 \times M}$, such that d_i is the degree of vertex v_i and M is number of edges in the graph so far.

This approach can create a large sparse dynamic graph with a small diameter and power-law distribution for vertex degree, but it does not create graphs with community structure.

Kronecker Graphs

Kronecker graphs model (Leskovec et al. 2005a) was proposed as an easy to analyze mathematical model for graph generation. The model is based on the Kronecker product of an initial matrix which represents the adjacency matrix of an initial graph. The K th power of the initial matrix represents the generated graph.

The Kronecker product of two matrices A and B is matrix such that each value in position (i, j) is $a_{(i,j)} \times B$. The naive approach of fitting this model to real graphs is expensive and needs exponential time, but the authors proposed an efficient and scalable algorithm called KronFit.

RTG (Random Typing Graphs)

Miller (1957) showed that typing random characters on a keyboard with only one character identified as a separator between words can generate a list of words that follow a power-law distribution. RTG (Akoglu and Faloutsos 2009) builds on this by connecting each pair of consecutive words by an edge. The final result is a graph whose node degrees follow the power-law distribution.

Although Kronecker graph generator is able to create graphs similar to real-world graphs and enables easier analysis of the mathematical model, it has some disadvantages such as generation of multinomial/lognormal degree distributions instead of power-law and being not flexible. Waterloo Graph Benchmark (WGB) generator (Ammar

and Özsu 2014), on the other hand, is built on top of RTG but is very flexible. It is capable of generating directed/undirected, weighted/unweighted, and bipartite/unipartite/multipartite graphs.

RTG enhances the properties of the generated graphs by introducing some dynamic graph properties such as shrinking diameter and densification. Structure preference was also introduced in RTG to match the real-life graph property of having community structures, meaning that nodes form groups and possibly groups of groups. These groups are usually created by connecting similar nodes together to form a community.

G

Workloads

There are three main workload categories in graph applications: online queries, updates, and iterative queries. Online queries are read only and interactive, usually do not have high complexity, and do not require multiple computation iterations; the answer is expected to be computed quickly. Updates are also interactive, but they change the graph's structure by changing its parameters or its topology. Updates also include adding or removing a vertex or an edge. Iterative queries are heavy analytical queries, possibly requiring multiple passes over the data, and usually take a long time to complete. They may include some updates, but the changes to the graph do not need to occur in real time.

Online Queries

Many graph applications include only online queries such as a simple check of the availability of customers' relationship to a retail shop, an update for the news feed in social media, etc. Examples are:

- Find a vertex or edge by its properties
- Report K-hop neighborhood of a query
- Reachability or shortest path query between two vertices
- Pattern matching query

Iterative Queries

Iterative queries are usually analytical workload over graph datasets (graph analytics). There is a large number of analysis algorithms such as subgraph discovery, finding important nodes (PageRank), attack detection, diameter computation, topic detection, and triangle counting. There are several alternatives for each of these problems.

Existing Graph Benchmarks

HPC Scalable Graph Analysis Benchmark

The idea behind HPC Scalable Graph Analysis Benchmark (Bader and Madduri 2005) is to develop an application with multiple kernels that access a weighted directed graph. These kernels represent multiple graph queries. They require irregular access to the graph so it is not expected that a single data structure for the input graph dataset would be optimal for all kernels. There are four kernels designed to address the following operations: bulk insertion, retrieving highest weight edges, k-hops operations, and betweenness calculation. However, the benchmark does not include many other graph operations such as updates or iterative queries.

Graph Traversal Benchmark

The authors of the Graph Traversal Benchmark (Ciglan et al. 2012) classify graph data management systems in two categories: (1) graph databases such as Neo4J and (2) distributed graph processing frameworks such as Pregel (Malewicz et al. 2010) and GraphLab (Low et al. 2012). This benchmark focuses on traversal operations on graph databases. Consequently, the capability of this benchmark is limited, because it does not support graph data queries or graph analysis algorithms. Moreover, it does not consider distributed graph processing frameworks.

Graph500

Graph500 (Murphy et al. 2010) is developed by a group of experts from academia, industry, and research laboratories. The main target is evaluating supercomputing systems for data intensive

applications, focusing on graph analysis, to guide the design of hardware architectures and their software systems.

BigDataBench

BigDataBench (Wang et al. 2014) is a big data benchmark suite. It is generic and includes various types of dataset: text, graph, and table. The graph component uses Kronecker graph model to create synthetic datasets based on real datasets. In this benchmark, the data generator is developed to learn the properties of a real graph and then generate synthetic data with similar characteristics. Two real graph datasets are included: Google web graph and Facebook social graph.

Linked Data Benchmark Council

The Linked Data Benchmark Council (LDBC) has two graph benchmarks: Social Network Benchmark (SNB) (Erling et al. 2015) and GraphAnalytics (Iosup et al. 2016). SNB is a benchmark for graph databases using a large generated social network. The graph is fully connected and simulates social network users' activities during a period of time.

LDBC GraphAnalytics (Iosup et al. 2016) is a new industrial-grade benchmark for graph processing system. Many studies in the literature tried to evaluate the performance of Pregel-like open source graph processing systems (Han et al. 2014; Batarfi et al. 2015; Lu et al. 2014). LDBC GraphAnalytics also include industry-driven systems such as GraphPad (Anderson et al. 2016) from Intel and PGX (Hong et al. 2015) from Oracle. This benchmark uses real and synthetic datasets. The synthetic dataset generator is similar to the SNB benchmark.

Experiment Design

In the process of designing a benchmarking experiment, it is very important to be consistent and accurate. If the experiment includes multiple systems, a special effort should ensure that systems configuration should lead to similar resource allocation; for example, systems should be configured to use the same number of cores.

If the experiment includes multiple dimensions then evaluating the possibilities of each dimension is an independent experiment. It is important to change one dimension at a time to conclude meaningful results. Below is a list of some examples:

- Datasets
- Workloads
- Systems
- Number of cores in each machine (scale-up)
- Number of machines in the cluster (scale-out)

In the rest of this section, we will discuss two important considerations during the design process of the benchmarking experiment.

Metrics Measures

A good benchmarking experiment should measure resources utilization and system performance. High resource usage is better if the system is expected to run in isolation, while low resource usage is better if the system is expected to run in an environment such that systems share resources and run simultaneously. Nonetheless, evaluating system performance should be done in isolation, with no resource sharing across systems or across experiments.

Benchmarks should report the following measures:

- CPU utilization for each process type (user, system, I/O, idle) every second
- Memory usage every second
- Network usages (bytes and packages) before and after execution

They should also report the following components to evaluate system performance:

- Data-loading/partitioning time
- Execution time
- Result-saving time
- Total response time (latency)

Data-loading time includes reading data set from its source (e.g., HDFS) and graph partitioning,

when necessary. Ideally, total response time should equal load + execute + save. However, it should be reported separately, because it represents the end-to-end processing time, and occasionally includes some overhead that might not be explicitly reported by some systems, such as the time of repartitioning, networking, and synchronization.

Parallelization COST

Evaluating the system scalability is very important. However, parallelization usually comes at a cost. Parallel algorithms, either in multi-core or multi-machine environments, are usually more complicated. COST (McSherry et al. 2015) stands for Configuration that Outperforms a Single Thread and is used in the literature to evaluate the overhead of parallel algorithms and systems.

The main idea is that parallel algorithms are often not optimal due to the special design consideration for parallel processing between machines, such as, synchronization and communication overhead. COST factor represents the response time of one thread divided by the response time of a parallel system. The baseline should be an efficient single thread implementation, such as the single thread execution of algorithms in the GAP Suite (Beamer et al. 2015) on a machine with large memory.

Graph Data Integration and Exchange

Angela Bonifati¹ and Ioana Ileana²

Definitions

Data exchange and data integration are two essential tasks of database interoperability. Data exchange (Fagin et al. 2005) is the problem of translating data structured under a source schema into data adhering to a target schema. Virtual data integration (Lenzerini 2002) on the other hand refers to combining data residing in different sources and providing the user with a unified view of these data, typically by means of a global schema.

Both data exchange and data integration essentially exploit a set of assertions relating elements of the source schema(s) with elements of the target (respectively, global) schema, called *schema mappings*. Such assertions typically are expressed in the form of logical implication (or equivalence) and express query containment (or equivalence) for query expressions over the respective schemas.

An important difference between data exchange and (virtual) data integration is that in data exchange we require the target database to be materialized. Data integration in turn requires no materialization of a global database; the integrated data is simply accessed/computed on the fly, by means of queries.

The fundamental difference between data integration and data exchange in a relational setting and a graph setting is the lack of a precise schema definition. Graph instances typically blend schema information and actual instances with no clear distinction between them. To date, no standard schema language for graphs exists that can be used in a similar fashion as in classical data integration and exchange settings. As such, data integration and exchange represent a substantial departure from their counterparts in

the relational setting, where source and target schemas were clearly separated from source and target instances. Another major difference with respect to the relational setting is the increased expressiveness of the query language used to express the mappings.

Both problems of graph data exchange and data integration have started to be explored in our community. In this entry, we review these previous works. We start by introducing the basic formalism of graph data integration and graph data exchange. We then present the state of the art on the topic and conclude by presenting the open challenges and future directions of research.

G

Overview

In the following, we overview the core elements of graph data exchange and integration, from essential concepts such as graph schemas, instances and queries, up to a brief description of the main problems of interest.

Graph Schemas, Instances, and Queries

A schema for a graph database is a finite alphabet Σ . Let \mathbf{V} be a countably infinite set of node ids. A graph database instance over Σ is a directed, edge-labeled graph $G = (V, E)$, where $V \subset \mathbf{V}$ is a finite set of node ids and $E \subseteq V \times \Sigma \times V$ is a finite set of edges labeled with symbols from Σ . Accordingly, a graph database can also be seen as a relational database comprising binary relations E_a , for $a \in \Sigma$.

Generally, queries over graph databases involve traversal of graph edges while testing for existence of paths respecting certain criteria. Such queries typically use recursion and as such significantly depart from usual relational queries. The classes of queries that have been investigated in the context of graph data exchange and data integration mainly comprise (Florescu et al. 1998; Calvanese et al. 2000b; Wood 2012; Barceló et al. 2012):

- Regular Path Queries (RPQs). These “simplest” binary queries of the form (x, exp, y) retrieve all pairs of nodes linked by a path

whose string satisfies a given regular expression.

- Two-way RPQs (2RPQs). Such queries enhance RPQs with the ability to traverse edges backward.
- Nested Regular Expressions (NREs). These extend 2RPQs with an existential (nesting) operator in the manner of XPath (XPathWorkingGroup 2016), allowing for branching/non-linear navigation.
- Conjunctive RPQs (CRPQs), which are n-ary queries consisting in a conjunction of RPQs.
- Conjunctive 2RPQs (C2RPQs), which are n-ary queries consisting in a conjunction of 2RPQs.
- Conjunctive NREs (CNREs), which are n-ary queries consisting in a conjunction of NREs.

CNREs are an extension of both NREs and C2RPQs, and as such they provide the most general class of queries among the above.

Graph Schema Mappings

Schema mappings are essential ingredients of any data exchange and data integration scenario, since they embody the logical rules relating source and target (respectively, global) schemas. Such rules typically express query containment or equivalence, for queries expressed in the appropriate language; accordingly, for graph databases, rules may feature any class of graph queries, including the six categories listed above.

Graph data exchange mappings. A graph data exchange setting is usually represented by a triple $\Omega = (\Sigma_S, \Sigma_T, \mathcal{M}_{st})$, where Σ_S is the source schema, Σ_T is the target schema, and \mathcal{M}_{st} is the source-to-target mapping. All rules in \mathcal{M}_{st} are of the form (Barceló et al. 2013) $\phi_S(\bar{x}) \rightarrow \psi_T(\bar{x})$, with $\phi_S(\bar{x})$ and $\psi_T(\bar{x})$ being graph queries of matching arity over the source schema Σ_S and, respectively, the target schema Σ_T . Such rules are usually called source-to-target dependencies, and are also (borrowing from the relational setting vocabulary) referred to as source-to-target tuple-generating dependencies (s-t tgds).

A pair of source and target graph databases (G_S, G_T) satisfies a source-to-target dependency $\phi_S(\bar{x}) \rightarrow \psi_T(\bar{x})$ iff $\phi_S(G_S) \sqsubseteq \psi_T(G_T)$. A pair of source and target graph databases (G_S, G_T) satisfies a source-to-target mapping \mathcal{M}_{st} , denoted by $(G_S, G_T) \models \mathcal{M}_{st}$, iff (G_S, G_T) satisfy all the source-to-target dependencies in \mathcal{M}_{st} .

Graph data integration mappings. In a graph data integration setting $\Omega = (\{\Sigma_{S_i}\}, \Sigma_G, \mathcal{M})$ with source schemas Σ_{S_i} and global schema Σ_G , rules in the mapping \mathcal{M} may state query containment of a source query into a global query (*sound sources* (Lenzerini 2002)), in which case one obtains mappings similar to data exchange. However, data integration scenarios may also feature rules stating containment of a global query into a source query (i.e., $\psi(\bar{x}) \rightarrow \phi(\bar{x})$ with ψ over Σ_G and ϕ over Σ_{S_i}), or stating equivalence. Rule and mapping satisfiability semantics are similar to data exchange.

LAV and GAV mappings. Two classes of mappings are of special interest in data integration and data exchange:

- Local As View (LAV) mappings are mappings where in all rules the source query ϕ is atomic, i.e., consists in a single symbol of Σ_S (respectively, Σ_{S_i}).
- Global As View (GAV) mappings are mappings where in all rules the target (respectively, global) query ψ is atomic, i.e., consists in a single symbol of Σ_T (respectively, Σ_G).

To distinguish them from these restricted settings, general (i.e., beyond LAV and/or GAV) mappings have also been called *GLAV mappings*.

Data Exchange Solutions and Universal Representatives

Given a graph data exchange setting $\Omega = (\Sigma_S, \Sigma_T, \mathcal{M}_{st})$ and graph databases G_S over Σ_S and G_T over Σ_T , we say that G_T is a *solution* for G_S under Ω whenever $(G_S, G_T) \models \mathcal{M}_{st}$. The set of solutions of G_S under Ω is denoted $Sol_\Omega(G_S)$.

Due to the semantics of mappings, there may be infinitely many solutions for a given source graph database and data exchange setting. Work on data exchange has therefore placed a focus on the computation of a so-called *universal solution*: a database with incomplete information which intuitively “represents all possible solutions.”

In graph data exchange, Barceló et al. (2013) have introduced a similar concept, namely, the *universal representatives*. These have been defined as graph patterns (Barceló et al. 2011) where the set of nodes N comprises both node ids and labeled nulls, and edges are labeled with expressions without variables over a schema Σ . Such graph patterns model incompleteness of universal representatives in two ways: unknown values for nodes (via the labeled nulls) and imprecise relations between the nodes (as witnessed by the expressions on edges).

A homomorphism from a graph pattern π as above to the graph database $G = (V, E)$ is a mapping $h : N \rightarrow V$ such that (i) h is the identity over $N \cap \mathbf{V}$ and (ii) for each edge of π of the form (u, exp, v) , $(h(u), h(v)) \in Q_{exp}(G)$, where $Q_{exp}(x, y) = (x, exp, y)$. We denote by $Rep_{\Sigma}\pi$ the set of all graph databases G over Σ such that there exists a homomorphism from π to G . Given graph data exchange setting $\Omega = (\Sigma_S, \Sigma_T, \mathcal{M}_{st})$ and graph database G_S over Σ_S , Barceló et al. (2013) then formally define universal representatives as follows: the graph pattern π over Σ_T is a universal representative for G_S under Ω iff $Rep_{\Sigma_T}\pi = Sol_{\Omega}(G_S)$.

Problems of Interest

The main problems under scrutiny for graph data exchange and data integration are the following:

1. *Existence and complexity of computation for data exchange solutions and universal representatives.* In the graph data exchange setting, one is typically interested in both the data complexity (i.e., solely the source database is part of the input) and the combined complexity (i.e., including the schemas and the mapping as input) of such problems. The existence of a solution is of particular interest in the presence of target constraints.

2. *Query answering.* This problem is of interest for both data exchange and data integration. In data exchange, we are interested in answering queries over the target schema, whereas in data integration, queries are stated over the global schema. The semantics adopted for both settings are those of *certain answers*, that is, the intersection of the result sets of the query Q for all data exchange solutions, respectively, all possible global instances compliant with the source instances and the mapping. The query answering problem then consists of deciding, given a query Q over the target (respectively, global) schema, whether a given tuple of node ids belongs to the certain answers of Q . As above, complexity analysis can be carried out in terms of both data complexity (the input consists in the source database(s)) and combined complexity (including the schemas, the mapping, and the query). Oftentimes, the query complexity is also considered.

Query answering is closely related to the universal representatives, since it is often the case that the certain answers for a query can be efficiently obtained by evaluating the query over such representatives. Another important related topic is that of query rewriting, which for data exchange and data integration typically involves reformulating a target (or global) query into a query expressed over the source(s).

Key Research Findings

Query Answering and Query Rewriting

A considerable amount of attention has been dedicated to the problem of query answering and the related problem of query rewriting for graph databases, in particular the large body of work by Calvanese, De Giacomo, Lenzerini, and Vardi (e.g., Calvanese et al. 2000a,b, 2001, 2002, 2003, 2007). An important part of their analysis focuses on view-based query answering and query rewriting. A variety of view-based processing settings for graph databases are placed under scrutiny, including sound/complete/exact views, and complexity results are presented for a variety of query and view languages, including

RPQs, 2RPQs, and C2RPQs, regarding both data and combined complexity. Query answering under sound views in particular, corresponding to a typical LAV setting, is shown to be coNP-complete in data complexity and PSPACE-complete in combined complexity for RPQ queries over RPQ views; these bounds extend to 2RPQs, but the problem reaches EXPSPACE-completeness in combined complexity for the broader class of C2RPQs. A subclass of C2RPQs, called *T2RPQs*, is however identified, where the query body is tree-shaped; for such queries over C2RPQs views, query answering is shown to be PSPACE-complete.

With the work of Calvanese et al. (2012), the authors further go beyond view-based query processing and LAV/GAV mappings, to address sound (i.e., source-to-target only) GLAV mappings, though in a setting restricted to RPQ mappings and RPQ queries. Similar to the LAV results, the paper shows that in such setting query answering is coNP-complete in data complexity and PSPACE-complete in combined complexity, whereas deciding whether a non-empty rewriting exists is EXPSPACE-complete. In addition, the authors show that deciding whether a rewriting of a target query is *perfect*, i.e., it always computes the certain answers when evaluated over the source, is NEXPTIME-complete.

Graph Data Exchange

Barceló et al. (2013) lay the foundations of graph data exchange by mainly focusing on the complexity of query answering and universal representative computation. They also investigate the means of obtaining tractable procedures for solving the above problems of interest.

Barceló et al. (2013)'s study considers the general CNRE class for both queries asked over the target (i.e., those for which certain answers are required) and queries involved in the mappings. The paper is the first to define universal representatives for graph data exchange, corresponding to graph patterns with NRE labeled edges. Furthermore, the authors show how the chase-based procedure used to build universal solutions in the relational setting (Fagin et al. 2005) can

be directly adapted to the graph setting, with data complexity in NLOGSPACE and combined complexity in PSPACE.

As argued by the authors, however, focusing on data complexity is insufficient for graph settings, in particular due to the very large instances typically involved (e.g., social networks, scientific databases). Since the hardness results for combined complexity are a consequence of the hardness of CNRE evaluation, the paper further investigates the restriction of source queries in mappings, from CNREs to the simpler class of NREs. Such *NRE-restricted mappings* comprise only rules of the form $(x, exp, y) \rightarrow \psi_T(x, y)$, with ψ_T a binary CNRE over Σ_T . As shown in the paper, in the presence of NRE-restricted mappings, the universal representative computation becomes tractable: its combined complexity is $O(|G_S|^2 \cdot |\Omega|)$. Similar bounds are shown to hold for acyclic source CNREs.

Concerning query answering, the authors start by emphasizing the difficulty of the certain answers problem. Indeed, while the problem has been shown to be PSPACE-complete in combined complexity for RPQ queries and mappings, it is shown to be EXPSPACE-complete for CNRE queries and mappings. On the other hand, going from RPQs to CNREs keeps data complexity in coNP, but the authors refine the lower bound by exhibiting a setting featuring RPQ mappings and a “word” RPQ queries, for which the problem is shown to be coNP-complete. Since word RPQ query can be translated into relational conjunctive queries, such setting shows how query answering in graph data exchange importantly diverges from the relational setting, where computing certain answers to conjunctive queries is known to be tractable in data complexity (Fagin et al. 2005). The hardness results shown also point toward the insufficiency of NRE-restricted mappings for achieving feasible query answering.

The pursuit of tractability then leads the authors to examining further restrictions on the mappings and the queries. A new restriction on the target queries in the mappings leads to the definition of *rigid mappings*, where the right-

hand side does not employ disjunction or recursion. Such mappings in turn are useful for achieving tractability in several cases. For an NRE query exp and mappings that are both NRE-restricted and rigid, the combined complexity of query answering is indeed shown to be $O(|G_S|^2 \cdot |\Omega| \cdot |exp|)$, by relying on the universal representative computation. If one further restricts the setting to mappings that are NRE-restricted and GAV, the combined complexity for NRE query answering becomes linear, i.e., $O(|G_S| \cdot |\Omega| \cdot |exp|)$, this time by employing query rewriting techniques. Moreover, if one only examines data complexity, in the case of CNREs and rigid mappings, query answering can be solved in polynomial time.

Last but not least, the authors initiate the investigation of tractability in data complexity for answering *tame CRPQs*, which are CRPQs that do not employ any Kleene star, over mappings that do not have existential quantifiers on the right-hand side (e.g., NRE mappings), thus leading to universal representatives without labeled nulls. For such queries and mappings, the authors derive two interesting conditions under which query answering becomes tractable and further prove the maximality of the shown classes w.r.t. to tractability.

Target Constraints

A typical relational data exchange setting (Fagin et al. 2005) comprises, in addition to the source and target schemas and the source-to-target mapping, a set of rules applicable to the target database, called *target constraints*. Contrarily to the relational setting, in which target constraints were essential components of a scenario, these constraints have not been included in the foundational definitions of (Barceló et al. 2013), and have been so far poorly adopted in graph data exchange.

Borrowing from the relational setting (Beeri and Vardi 1984, Fagin et al. 2005), one may consider graph data exchange scenarios comprising two classes of target constraints, namely:

- *target tuple-generating dependencies* (or simply *t tgds*), i.e., $\phi_T(\bar{x}) \rightarrow \psi_T(\bar{x})$, with ϕ_T and ψ_T being graph queries of matching arity over the target schema Σ_T
- *target equality-generating dependencies* (or simply *t egds*), i.e., $\phi_T(\bar{x}) \rightarrow (x_1 = x_2)$, with ϕ_T being a query over the target schema Σ_T and x_1, x_2 among the variables of \bar{x} .

Target tgds have the same query containment semantics as s-t tgds, whereas target egds express equalities among node ids, and as such intuitively involve *merging* nodes in the data exchange solution. As is the case in the relational setting, target constraints have an important influence upon the existence of a data exchange solution.

Boneva et al. (2015) have added limited classes of target constraints to the setting of Barceló et al. (2013) by focusing on t egds and limited forms of t tgds. The paper studies the complexity of existence of solutions and query answering with the assumption that the source schema and instance are fixed (query complexity). Another hypothesis made in their work is to be able to export relational tuples from the source rather than graph patterns. The results are quite negative in the sense that both existence of solutions and query answering in the presence of arbitrary t egds and t tgds are shown to be NP-hard and coNP-hard, respectively. Because of this intractability and the difficulty of equating two constants in case of t egds, the authors then focus on a simpler class of constraints. These are called same-as tgds, and they correspond to full GAV t tgds in which the right-hand side contains a unique binary atom *sameAs*. Adding these constraints makes the existence of solutions trivial as it suffices to compute the solutions with s-t tgds as in Barceló et al. (2013) and then add the corresponding tuples to the *sameAs* relation. However, even with this limited fragment of target constraints, query answering stays coNP-hard.

Mapping Management for Data Graphs

The recent work of Francis and Libkin (2017) enriches the landscape of graph mapping management studies by considering *data graphs*. These

are edge-labeled graphs where furthermore vertices are adorned with *data values*. Formally, letting \mathbf{V} be a countably infinite set of node ids, and \mathbf{D} a countably infinite set of values, a node in a data graph is a pair $(v, d) \in \mathbf{V} \times \mathbf{D}$. A data graph is then of the form $G = (V, E)$ with $V \subseteq \mathbf{V} \times \mathbf{D}$ and $E \subseteq V \times \Sigma \times V$.

Data graphs are very suitable for capturing property graphs, which are the models employed by some of the existing graph database management systems, such as Neo4j (NeoTechnology 2017). As shown by the authors, however, adding data to the picture makes query answering sensibly harder than in the standard (i.e., without data adornment) graph database case.

Francis and Libkin (2017) consider mappings based on RPQs and in turn investigate query answering for *data RPQs*, which were defined in Libkin et al. (2015, 2016). These are extensions of RPQs with regular expressions that mix alphabet letters (i.e., edge labels) and data values, in other words queries that mix navigational properties and data. The three main classes of data RPQs under scrutiny are (i) data path queries, (ii) regular expressions with equality (REEs, or equality RPQs), and (iii) regular expressions with memory (REMs, or memory RPQs).

A first strong result of the paper shows that query answering is in general undecidable in data complexity for data RPQs (with a notable exception for the data path queries and REEs without inequalities, for which it is in coNP). The undecidability is moreover shown to hold even in a simple setting comprising a relational/reachability LAV mapping and an equality RPQ.

As identified by the authors, the issue comes precisely from the reachability target queries and thus suggests that in order to recover decidability one needs to focus on mappings where the target queries exclude any form of recursive navigation and only consist in word RPQs. For such mappings, called “relational mappings”, query answering becomes coNP in data complexity and PSPACE in combined complexity. Moreover, the problem becomes NLOGSPACE in data complexity for relational mappings and data path queries comprising at most one subexpression of

the form $c \neq$ retrieving paths whose extremities have different data values.

Pursuing the search for tractability while restricting their focus to relational mappings, the authors investigate two very interesting alternatives for efficient query answering for data RPQs by relying on universal- and canonical-like solutions. For restrictions of REMs and REEs to equalities (no inequalities allowed), the authors show that query answering can be solved by relying on the construction of a so-called *least informative solutions*, which employs labeled nulls for both node ids and data values, in a manner similar to standard relational data exchange canonical universal solutions. Accordingly, data complexity for query answering becomes NLOGSPACE for all the considered queries, whereas combined complexity becomes PSPACE for restricted REMs and PTIME for restricted REEs. A very interesting take further concerns data RPQs in general, without restrictions. It involves providing an *under-approximation* of a query’s result set by relying on universal solutions that employ SQL-like nulls (null value for which all equalities and inequalities evaluate to *false*) for the data on nodes. Query answering over such a null-based universal solution is shown to be NLOGSPACE in data complexity and PSPACE, respectively PTIME in combined complexity for REMs, respectively REEs.

Future Directions for Research

Despite the early work on graph data integration and exchange surveyed in this entry, several open problems can be identified and might deserve the attention of our community in the next future. In particular, for what concerns the coverage of the characteristics of the data exchange setting, one missing component is certainly embodied by target constraints, which have been poorly exploited so far. The definition of universal representatives as in Barceló et al. (2013) cannot be easily adopted in the case of target constraints (Boneva et al. 2015). Indeed, even for full GAV

target tgds, query answering stays intractable (Boneva et al. 2015). Suitable variants of universal representatives, possibly coupled with target constraints, need to be conceived. Proper subclasses of target egds, such as graph keys (Fan et al. 2015), graph functional dependencies, and graph entity dependencies (Fan and Lu 2017), might be relevant for envisioning practical algorithms for data exchange in the presence of these target constraints and in the spirit of Bonifati et al. (2016) for the relational setting. Another important missing component consists of graph schemas, which are presently exemplified as alphabets of graph labels as discussed in this entry. More sophisticated schemas for RDF based on ShEx expressions (ShExCommunityGroup 2017) have been designed, and their adoption in graph data integration and exchange is worth exploring. For what concerns query rewriting, more expressive classes of graph constraints beyond RPQs, 2RPQs, C2RPQs are worth exploring. Due to the high complexity of query answering and rewriting even for basic fragments such as RPQs, alternative Datalog-based rewritings beyond certain answers and computable in polynomial time (Francis et al. 2015) are also desirable for more expressive fragments of graph queries. Finally, the basic fragment of graph queries considered in schema mappings consists of CNRE queries, which correspond to their relational counterparts (CQs). However, in a more comprehensive graph data integration scenario, one can adopt more expressive languages, such as Regular Queries (RQs) (Reutter et al. 2017), which is the largest fragment of graph queries for which containment has been shown to be decidable. The definition of more expressive graph data models, such as the Property Graph data model (Angles et al. 2017), and suitable query languages thereof will also bring fresh valuable insights to graph data integration and exchange along the line of research initiated in Francis and Libkin (2017). Investigating the problems of interest discussed in this entry for queries expressed in modern graph query languages is also an interesting direction for future work.

Classification

The abundance and diversity of massive-scale, graph-structured data and the ever-growing interest of large enterprise companies to analyze them are the key drivers of the recent advances in graph data management research. Further, graph data management has witnessed a steady increase in applications from various industry domains, such as social media, logistics and transportation, gas and oil utility networks, finance, public security, and the pharmaceutical industry.

The widespread adoption of graph technology and the diversity in requirements for the aforementioned application domains are the key drivers for the development of a variety of graph data management systems (GDMSS). These GDMSS are typically tailored to a specific graph workload, which is distinctive to the application domain and drives the design of the core system components, such as the *primary/secondary storage*, the *query execution engine*, and the *user interface(s)*.

From a data model perspective, currently two graph data models (Angles and Gutierrez 2008) receive the widest adoption in GDMSS: the *property graph* data model (PGM) and the RDF data model. While the PGM data model has recently been adopted by various GDMSS, there is also still a growing interest in specialized GDMSS and frameworks supporting the RDF data model and the accompanying SPARQL query language (W3C 2013; Stardog 2017; Erling 2012; Ontotext 2017; Neumann and Weikum 2008; AllegroGraph 2017; MarkLogic 2017; Jena 2017; RDF4J 2017). Few GDMSS offer support

for both, RDF and PGM, by exposing data model-specific query languages and transformations between them (Oracle 2017a; Amazon Neptune 2017).

GDMSS can be broadly classified into *native* and *nonnative* systems. Often GDBMSS provide different degrees of *nativeness* by choosing carefully which core system components should be graph-aware. A GDMS is considered to be *native*, if it (1) provides fast data access—often referred to as *index-free adjacency access*—(2) and a graph-specific query runtime, including graph-specific query optimization and processing strategies, (3) and if it exposes a graph data model, such as the RDF or the property graph data model, and corresponding access methods or query languages directly to the user.

Fully native GDBMSS implement graph-aware components for all three core components (Neo4j 2017; TigerGraph 2017; MemGraph 2017; Sevnenich et al. 2016; Amazon Neptune 2017; Tanase et al. 2014; Cayley 2017; Datastax 2017). In contrast, partially native GDBMSS provide graph-aware implementations for selected components, but typically lack a deep integration of graph-specific components within the core database engine. Most RDBMS are only to some extent *graph-aware*, most commonly by exposing the graph data model by some user interface to the end user (Oracle 2017a; Rudolf et al. 2013; Simmen et al. 2014; Sun et al. 2015; Microsoft 2017; AgensGraph 2017). Moreover, partially native GDBMSS include *multi-model* databases, which combine different data models within a single system (OrientDB 2017; ArangoDB 2017).

Each of the GDBMSS is tailored to specific graph workloads, which are the key drivers for the system design and the level of *graph awareness*. In the following, we discuss two major graph workloads that are predominant in realistic graph use cases.

Operational Graph Processing The ability to handle graph topologies where the structural shape of vertices and edges evolves over time is a fundamental requirement of an operational GDMS. *Structural changes* describe modifications to the structure of a single vertex/edge, i.e., the

addition, manipulation, and removal of attributes on vertices and edges. Especially use cases that target social networks and communication networks demand a flexible and scalable graph persistence that can cope with frequent updates to vertex/edge attributes as well as changes to the graph topology. By *topological changes* we refer to modifications of the graph topology, i.e., the addition and removal of vertices and edges. In addition to the ability to modify the graph, an operational GDBMS also must provide transactional guarantees comprising atomicity, consistency, isolation, and durability. A query workload in such an operational scenario often performs short-running queries accessing only a small portion of the graph. This often includes graph pattern matching queries, which aim at finding query embeddings in the data graph.

Graph Analytics Graph analytics workloads often consist of tasks that are computationally intensive and typically take seconds, minutes, or sometimes hours to complete on large graphs. This is in contrast to operational graph processing where queries are typically short-running and often only consume little time to complete. To target these computationally intensive and mostly read-only analytical workloads, specialized systems have been created that provide efficient data structures for storing relatively static graphs and, typically, process graph algorithms or graph queries in a parallel and/or in a distributed fashion. Because such systems do not always provide strong transactional guarantees, they are typically called “graph analytics toolkits” rather than graph databases.

Storage Representations

Depending on their level of *graph awareness*, GDBMSS implement different storage representations. Broadly speaking, the design space can be divided into *native* and *nonnative* graph representations.

Native, Read-Only/Read-Mostly Immutable, native graph representations tailored for

read-mostly workloads are often implemented using a CSR data structure (Saad 2003; Brameller et al. 1976). A CSR data structure has the advantage that it provides large temporal and space locality when accessing the neighborhood of a vertex. This is often observed for in-memory GDBMSS, such as ORACLE PGX (Sevenich et al. 2016; Hong et al. 2015) and SYSTEM-G (Tanase et al. 2014). If the graph is too large to fit into the main memory of a single machine, suitable alternatives are processing the graph on cheaper yet fast SSDs, applying compression techniques on the graph data or by sharding the graph data across multiple machines in a cluster (Tanase et al. 2014).

Updates to the CSR data structure can be either applied in batch updates (Haubenschmid et al. 2016) or by snapshotting the CSR data structure (Macko et al. 2015).

Native, Transactional NEO4J is the original, prevalent system for native, transactional processing of property graphs. Its graph representation is based on the notion of index-free adjacency, which provides $\mathcal{O}(1)$ cost for traversing a relationship and has been implemented using a proprietary set of record files. It uses direct offset pointers for navigational data access to avoid the additional lookup costs of tree data structures. The record files utilize additional pointers to reduce the overhead of traversing dense nodes as well as generally minimize the amount of records that need to be accessed during the graph traversal. The main storage is complemented by additional indexes for direct by-value lookup and full-text search.

Relational, Read-Only The OPENCYPHER project recently released CYPHER FOR APACHE SPARK (openCypher implementers group 2017a), a new implementation of OPENCYPHER that optimizes and compiles queries for execution by the relational Catalyst engine of APACHE SPARK SQL. Graphs are represented as sets of disjoint scan tables for nodes and relationships with a given label. Using the immutable and lazily materialized tables of APACHE SPARK naturally provides snapshotting, partial caching, and partitioning capabilities. This graph representation relies

on the use of a graph schema since the scan tables themselves are expected to be statically typed by APACHE SPARK.

Relational, Transactional A graph can be seamlessly represented as a set of vertex/edge tables, where each record in a vertex table corresponds to a single vertex and each record in an edge table represents a single edge (Rudolf et al. 2013; Simmen et al. 2014; Oracle 2017a). Each vertex and edge attribute is mapped to a single column in the corresponding vertex and edge tables, respectively. For graphs without or with only few vertex or edge attributes, a database consisting of two universal tables—one for vertices and one for edges—is a commonly used physical representation.

Recently, non-relational extensions of RDBMSS have been applied to encode graph topology information (Microsoft 2017) and vertex/edge properties using JSON document storage functionality (Sun et al. 2015).

Similarly, RDF GDBMSS often rely on relational storage layouts to represent RDF triples through universal tables (Erling 2012) and by using exhaustive, relational indexing techniques (Neumann and Weikum 2008).

Query Languages

Graphs are queried using both declarative and imperative languages. Declarative languages are used by operational DBMSS due to their ease of use and the ability to rely on a vast body of research for query optimization, while imperative languages are used for graph analytics workloads due to their versatility and the provided high level of manual control over query execution.

Declarative QLs

Graph pattern matching, i.e., finding and filtering instances of connected nodes and relationships, is the central functionality of declarative graph query languages. Pattern matching may be expressed using visual “Ascii-Art” graph patterns as pioneered by OPENCYPHER or via explicit recursion. Typically the connections in a pattern are described in terms of a regular expression

over the labels along a matched path. This is called a regular path query (RPQ).

Languages use different pattern matching semantics: Homomorphic matching returns all matches but may lead to infinite results. Isomorphic matching prevents this by disallowing matching nodes or relationships per match but is computationally intractable for certain patterns. Single shortest path matching is tractable and never leads to infinite results, but is non-deterministic.

Languages additionally provide fundamental relational capabilities, such as aggregation, slicing, or sorting of results.

OPENCYpher 9 (Francis et al. 2017; openCypher implementers group 2017b) is the language of the **OPENCYpher** community. Originally developed by NEO4J as a more high-level alternative to **GREMLIN**, it is implemented by multiple vendors (SAP HANA, REDIS, AGENS GRAPH for Postgres, CYPHER FOR APACHE SPARK), as well as research projects. **OPENCYpher** provides graph pattern matching using isomorphism, relational capabilities (including tabular query composition, basic subqueries, query parameters, and calling external algorithms), single and all shortest path matching and all path enumeration using first-class path values, as well as both an update and a schema definition language. The current **OPENCYpher 9** supports no alternation between non-atomic labels. However full RPQs and path patterns have been specified as a separate language extension. The next version of the language, **OPENCYpher 10**, is currently developed with support for a richer type system, more powerful subqueries, and graph query composition for passing graphs between queries and views.

PGQL (Property Graph Query Language) (van Rest et al. 2016; Oracle 2017b) is a pattern matching query language developed at **ORACLE** and is closely aligned to **SQL**. Its latest version (Oracle 2017b) has powerful regular path expressions with arbitrary filter predicates on vertices and edges along paths. Its pattern matching semantic is based on homomorphism, and the language provides basic relational support (ORDER BY, SELECT, etc.).

SQL SERVER provides an extension to **SQL** that allows for creating a graph by turning existing relational tables into vertex or edge tables and provides graph querying support through specification of fixed size graph patterns (Microsoft 2017).

SPARQL (W3C 2013) is the declarative query language used for the **RDF** data model. It provides pattern matching, basic relational capabilities, as well as constructing and returning graphs.

G-CORE (Angles et al. 2017) is a language designed as a community effort between industry and academia, meant to guide the evolution of existing and future graph query languages. **G-CORE** is composable, meaning that graphs are the input and the output of queries, and treats paths as first-class citizens.

Traversals form the foundation of **GREMLIN** (Rodriguez 2015), a language that organizes graph computation as a series of steps for pattern matching, sorting, aggregating, and data flow logic, as well as a step for basic pattern matching and even graph computation. **GREMLIN** was originally closely tied to the Groovy programming language. Recent versions compile to a bytecode that is shared between implementations. However real-world **GREMLIN** often also contains inline logic written in the client programming language.

Imperative QLs

Imperative languages have been the dominant paradigm for analytical graph processing in high-performance computing but also in handwritten applications (e.g., Boost Graph Library for C++). Additionally, many classical graph algorithms were originally developed in an imperative setting, and therefore, many systems have chosen an imperative query language to enable applications to implement such algorithms.

Low Level

Low-level, imperative query languages expose an imperative API to directly access the graph in a fine-granular manner.

Vertex-centric systems such as **PREGEL** (Malewicz et al. 2010) and **SIGNAL/COLLECT** (Stutz et al. 2010) rely on a vertex-centric message-passing abstraction to perform

massively parallel asynchronous or synchronous graph computations. Each vertex executes a user-provided `compute()` function (the query), which receives messages from neighbors, updates internal state, and sends messages to neighbors as well as result collectors to advance the computation until the result converges.

Imperative APIs like BLUEPRINTS (originated at NEO4J) enable programs written in an imperative, general-purpose programming language to directly access the graph. A key development of such APIs is the notion of a traversal: a semi-declarative description of how to search the graph starting from a fixed vertex using different search strategies (BFS, DFS) and user-provided filtering predicates.

High Level

GRAPHSCRIPT (Paradies et al. 2017) is a domain-specific, read-only graph query language tailored to serve advanced graph analysis tasks and to ease the specification of custom, complex graph algorithms. GRAPHSCRIPT is statement-based and provides high-level, graph-specific language constructs to formulate graph algorithms in a user-friendly and intuitive manner while offering competitive execution performance compared to manually tuned graph algorithms in a low-level programming language. It facilitates an imperative programming model with control flow elements and graph querying operations.

GREEN-MARL (Hong et al. 2012, 2013), currently being developed at ORACLE LABS, is among the first domain-specific graph query languages targeting graph analytics. The language has *graph*, *vertex*, and *edge* types as first-class citizens and exposes high-level constructs for graph traversal and iteration, such as breadth-first search (BFS), depth-first search (DFS), and incoming and outgoing neighbor iteration.

Graph Processing

On a high level, current graph processing approaches either fall into the category of “native graph processing,” in which systems are built

from scratch and optimized specifically for graph processing, or “relational graph processing,” in which existing RDBMSs or tools are repurposed and extended for graph processing.

Native Graph Processing

Besides the storage aspect, as discussed before, there are three other important aspects to consider when designing a native GDMS.

Compilation Strategies For processing of graph *queries* (e.g., SPARQL, OPENCYpher, or PGQL queries), the typical approach of GDMSS is that of cost-based query optimization, which is similar to the approach in traditional RDBMSs. Dynamic programming is used to explore the plan space in order to estimate a cost for the various possible plans using a set of heuristics, precomputed data statistics, or through dynamic data sampling. However, graph queries impose additional challenges since they are often recursive in nature and estimation errors increase even faster than for relational queries that typically only have a fixed number of joins. There are systems (e.g., APACHE SPARK) that are adopting mid-query re-optimization to overcome such problems.

For processing of graph *algorithms* (e.g., GRAPHSCRIPT or GREEN-MARL procedures), the typical approach is that of code generation rather than interpretation because the overhead of compiling generated code is typically neglectable as graph analytics algorithms are often computationally intensive and have long-living executions. In ORACLE PGX, GREEN-MARL procedures are translated into optimized and parallel JAVA or C++ programs through code generation. In SAP HANA, GRAPHSCRIPT procedures are directly compiled into parallelized, low-level, LLVM-based executable code and cached for later usage. GRAPHSCRIPT generates code, which directly accesses internal data structures and APIs, thereby eliminating function calls and property-type interpretations. NEO4J provides the OPENCYpher language for querying data as well as a programmatic API for imperative graph processing. OPENCYpher queries are translated into an operator tree that is

a mix of relational and graph-specific operators for graph traversal and that is executed using both interpretation and compilation to Java bytecode.

In-Memory Processing To avoid disk I/O being the bottleneck in graph processing, graphs are often fully or partially loaded into memory. This is especially meaningful for the structural data of the graph, as edge traversal is a crucial operation in graph processing. Nonstructural data, such as labels and properties on vertices or edges, may be partially loaded into memory, depending on available space. In ORACLE PGX, graphs are loaded into memory in their entire, and scaling out is necessary (i.e., partition the graph over multiple machines) when graphs are too large to fit into the memory of a single machine. SAP HANA allows fully or partially loading vertex and edge tables on a column level into memory. Lightweight compression techniques aim at keeping the memory footprint low. For GRAPHSCRIPT, static code analysis is used to determine the accessed vertex/edge properties and only load the corresponding subgraph into memory. In NEO4J, graphs are primarily stored on disk and mapped into memory using a custom page cache, which is optimized for concurrent, low latency, fast random access graph traversal. In practice, the majority of the graph working set of a database cluster machine usually resides in memory.

Parallel Processing Parallel processing of graphs is necessary to make full advantage of available multi-threading capabilities of modern computing architectures. In transactional graph workloads, there are often large amounts of short-living tasks, so multiple tasks are executed concurrently. However, in analytical graph workloads, there are typically fewer but heavier longer-living tasks, so the typical strategy is that of *intra-task* parallelization rather than *inter-task* parallelization. In Neo4j, OLTP graph data is loaded into separate, specialized in-memory data structures for efficient parallel graph analytical processing. Traversals in graph queries or algorithms can naturally be processed in a parallel breadth-first search manner, such that at each step, the available threads are

given an equal number of partial solutions and threads synchronize at the end of each step to produce a new set of partial solutions for the next step (Raman et al. 2014; Hong et al. 2012). Although easily parallelizable, the breadth-first search approach may suffer from a large memory footprint, which can become an issue in graph query processing, as the number of partial solutions can grow exponentially to the size of the graph. Therefore, depth-first search processing, which can be parallelized through work-stealing techniques, may provide a suitable alternative (Roth et al. 2017).

Indexing Techniques Graphs often have labels on vertices and edges for indicating types (e.g., “Person” or “knows”) and also have properties on vertices or edges for providing unique identifiers (e.g., an “email” or “ISBN” property). Because these labels and identifiers are frequently used in filter predicates of graph queries or graph algorithms, they require specialized indexes to speed up processing. For example, in ORACLE PGX and NEO4J, secondary indexes can be created, which retrieve vertices with a particular label in constant time. Furthermore, there is an index for mapping a vertex identifier to the respective vertex, again, in constant time. Both indexes can help avoid scanning over the entire set of vertices. NEO4J always maintains indexes for retrieving vertices with certain labels. Furthermore, NEO4J allows the creation of indexes on properties of nodes with a given label, as well as additional index structures for full-text indexing and globally indexing all properties.

In addition to the primary data location as relational tables, transient secondary index structures, such as adjacency lists or CSR, can be used to accelerate compute-intensive graph analytics tasks by creating them prior to the query execution (Hauck et al. 2015). Since the majority of complex graph algorithms and workflows perform heavyweight, long-running computations on the entire graph, the overhead for the index construction is outweighed by the actual execution time of the task.

Besides indexes that are created ahead of query execution, there are also indexes that

are created during query execution. Some indexing techniques are based on “supernodes” (or “landmarks”), which are vertices with a disproportionate number of incoming or outgoing edges, and are common in real-world graphs. Since the supernodes are well connected, they are traversed many times and computations are cached to avoid expensive recomputations (Valstar et al. 2017).

Relational Graph Processing

Naturally, existing RDBMSS are being extended to process graph data. SAP HANA is the first full-fledged RDBMS that tightly integrates graph processing into the database kernel, allowing to seamlessly combine relational and graph operations within the same database engine (Rudolf et al. 2013; Paradies et al. 2015). OPENCYPHER queries are translated into relational operators, while for processing of GRAPHSCRIPT, there is an additional set of graph-specific operators, such as graph traversal, shortest path computation, and subgraph induction, that are not mapped to relational operators but instead implemented as native graph operators in the RDBMS execution engine (Paradies et al. 2017).

SQLGRAPH (Sun et al. 2015) translates GREMLIN into a combination of pure SQL functions, user-defined functions, common table expressions, and stored procedures. The latter ones are only used for graph updates without side effects and for recursive traversal queries without an explicit recursion depth boundary.

TERADATA ASTER (Simmen et al. 2014), a large-scale analytics platform, provides an iterative vertex-oriented JAVA-based programming abstraction, which can be used to implement bulk-synchronous graph algorithms. Graph analytics functions, both pre-built and user-implemented ones, are modeled as polymorphic table operators that can be invoked directly from SQL.

VIRTUOSO (Erling 2012) is a hybrid columnar relational/graph DBMS with a SPARQL interface. Internally, VIRTUOSO translates SPARQL queries into SQL with graph-specific extensions, such as the computation of the transitive closure using a dedicated operator.

CYPHER FOR APACHE SPARK (openCypher implementers group 2017a) is a new implementation of Cypher atop the relational Catalyst engine of APACHE SPARK. CYPHER FOR APACHE SPARK is noteworthy in providing experimental support for graph query composition and working with multiple graphs via proposed OPENCYPHER 10 language extensions (openCypher implementers group 2017b). Graphs are directly transformed into new graphs by transforming the underlying immutable scan tables.

Discussion

GDMSS are very new, and various advances in storage representation, query interfaces, and processing techniques are to be expected. In particular, we see four trends that will significantly influence the design and implementation choices of upcoming single-node graph processing systems. (1) We observe an increasing interest in the uses of *high-level graph query languages* for graph analysis. (2) We see a convergence toward *hybrid transactional/analytic graph processing*, which combines graph analysis as performed by highly tuned graph processing systems with transactional graph processing as provided by GDMSS or traditional RDBMSS. (3) We observe that existing systems are moving toward becoming *multi-model systems* (relational, RDF, PGM), as evidenced by GDMSS adopting relational features and RDBMSS being extended with graph capabilities. This is supported by convergence on a *common definition of the property graph model* between different languages that is closely related to the ongoing discussions on working with multiple graphs, graph query composition, and schema models for graph data. (4) We observe an interesting line of research on *compressed and skew adaptive storage* of graphs, which is important since efficiency of memory bandwidth usage is an ongoing challenge in large multiprocessor machines.

Graph databases; Linked data models; Network databases; Network data models

Definitions

Following the classic definition of Codd, a data model comprises three basic components: the data structure(s), a transformation and query language, and integrity constraints. Under this conceptualization, a graph data model is characterized as follows:

- The data (and possibly its schema) is represented by graphs or by generalizations of the concept of a graph (e.g., hypergraphs, hypernodes).
- The manipulation of data is done by graph transformations or by operations capturing features such as paths, neighborhoods, graph patterns, etc.
- The integrity constraints enforce the consistency of schemas and graph properties that are relevant to the particular model.

In this entry, we will focus on the data structures part, since query languages for graphs are treated in other entries in this work. Thus we will use the notion “graph data model” for the data structure of a graph data model.

Overview

Graphs have been used for centuries as a modeling tool, usually when there is a need to model the connections or relationships among a number of entities or objects. For example, the objects might be cities with the connections representing roads, or the entities might be people with the relationships being those found in families. More recently, graphs have been used to model various types of big data, such as that comprising social networks or various biological applications.

Although the notion of graph is an old one, the use of graphs in real-life modeling is rather recent. Their first uses were in knowledge representation (e.g., semantic networks Lehmann and Rodin 1992), semantic modeling (e.g., the ER model Chen 1976), and object-oriented languages (e.g., Gyssens et al. 1990 and Levene and Poulovassilis 1991).

It was not until the 1980s that the need arose to design graph data models for databases which gave rise to a “Golden Age” or “Classic Period” of graph databases that produced manifold models. The motivations were also varied, among them: representing the semantics of databases, providing natural database interfaces, generalizing the hierarchical and network models, representing knowledge structures, dealing with object-oriented features, providing transparent representation to the manipulation of graph data, and modeling hypertext (see Angles and Gutierrez 2008 for a detailed survey of this period).

These models did not reach mainstream users. It was not until the early twenty-first century that actual applications of graph databases began in practice, mainly due to huge datasets representing data in the form of graphs (e.g., social networks, complex networks, biological networks, etc.). The need to have data and its relationships directly accessible in its graph representation as well as a query language to systematically retrieve data motivated the design of several commercial systems.

We will concentrate on the three main models that are becoming both the most popular and the most studied:

1. The RDF model. Designed to be a universal representation language for resources, its basic structure consists of triples of resources of the form (s, p, o) representing the subject (s), the predicate (p), and the object (o) of a statement about these resources. Each statement (a, p, b) can be viewed as a two-node labeled graph $a \xrightarrow{p} b$. Thus, a set of RDF triples is a “graph” (even though mathematically such sets of triples are not strictly graphs, e.g., the two statements $a \xrightarrow{p} b$ and $a \xrightarrow{q} p$ are allowed.)
2. The property graph model (e.g., in Neo4j, etc.). This is a more standard model that mathematically is a graph with labels on the nodes and edges and usually multiple properties associated with them. There are several variations on the basic model (identifiers for nodes, multiple labels, etc.).

3. The nested model. This is a revival of the classic OEM (Object Exchange Model) (Papakonstantinou et al. 1995), whose most popular representation today is JSON. Each object is a set of key-value pairs, in which values can again be JSON objects. This gives a graph structure that is enriched in multiple ways (Bourhis et al. 2017).

In this entry, we will study each of these models. Earlier surveys include that by Angles and Gutierrez (2008), while surveys on query languages for graph data models, which also define the graph models under consideration, include those by Wood (2009), Barceló Baeza (2013), and Angles et al. (2017).

G

Key Research Findings

The simplest form of graph data model is that which was proposed centuries ago. A *graph* comprises a finite set of *nodes* and a finite set of *edges*, where each edge connects a pair of nodes. Graphs can be either directed or undirected, depending on whether the relationship between the pairs of nodes is symmetric or not.

More formally, an *undirected graph* G is a pair (N, E) , where N is a finite set of nodes and E is a finite set of edges, where each edge is of the form $\{u, v\}$ for $u, v \in N$. A *directed graph* G is defined similarly, except that each edge is an ordered pair of the form (u, v) for $u, v \in N$. In other words, $E \subseteq N \times N$.

Given that there is only one “type” of edge in directed and undirected graphs, their ability to model relationships is rather limited. As a result, it is common to add *labels* to the edges. These labels can then be used to denote different relationships, such as friend-of, cousin-of, etc. Since directed graphs are more general than undirected ones (an undirected graph can always be modeled by a directed one in which there is a pair of directed edges between any pair of nodes connected by an undirected edge), we will only consider directed graphs from now on.

An *edge-labeled graph* G is a triple (N, E, Lab) , where N is a finite set of nodes, E

is a finite set of edges, and Lab is a set of labels. Each edge is of the form (u, l, v) for $u, v \in N$ and $l \in Lab$; in other words, $E \subseteq N \times Lab \times N$. Edge-labeled graphs can be used to model the data comprising an extensive number of domains, and most current models use them. A good example is the Resource Description Framework (RDF).

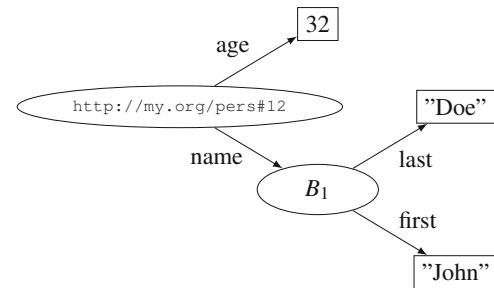

While edge-labeled graphs provide a useful way to model many kinds of data, they still have their limitations: each edge only has one piece of information associated with it, namely, its label, and each node similarly has a single identifier. Sometimes it is important to be able to add more information about an edge, for example, who added it to the graph or for how long it is valid. Nodes too may need to have a number of properties associated with them, especially if they correspond to real-world objects. These requirements have given rise to what have been called property graphs.

The Resource Description Framework

The Resource Description Framework (RDF) is a W3C recommendation (Cyganiak et al. 2014), originally designed to represent metadata on the web but more recently used as a representation layer for the so-called semantic web (Berners-Lee et al. 2001). As mentioned above, an RDF graph can be viewed as an example of an edge-labeled graph, that is, although an RDF graph is a set of triples of the form (u, l, v) , where u , l and v are universal resources, one can view u and v as nodes and l as an edge label of a graph.

An atomic RDF expression is a triple comprising a *subject* u (the resource being described), a *predicate* l (the property of the resource being described), and an *object* v (the value of the property). Known resources are identified by IRIs (Internationalized Resource Identifiers), while unknown resources are denoted by so-called blank nodes. This set can be partitioned into disjoint sets of IRIs, blank nodes, and literals. However, in RDF further constraints are applied to the permitted sets of nodes, labels, and triples.

Example 1 (Simple person example) A basic RDF graph describing John Doe and his age is the following: $G = \{(I_1, \text{name}, B_1), (B_1, \text{first}, \text{"John"}), (B_1, \text{last}, \text{"Doe"}), (B_1, \text{age}, 32)\}$, where $I_1 = \text{http://my.org/pers\#12}$, which graphically looks as follows:

In G , the node with content <http://my.org/pers#12> is a known resource identified by an IRI. The node B_1 is a blank node as mentioned above. The predicates (name, first, last, age) are part of the schema (ontology). Blank nodes and predicates have also IRIs (not shown to save space). The rest are value types (strings and integers in this case). Any resource (IRI) can be further referenced in a triple in another graph, in this way integrating different graphs.

As mentioned, some distinguished resources conform to schemas. A schema in RDF is simply a reserved vocabulary, usually further specified, which can be used to describe other resources. Examples above are “name,” “age,” etc. The RDF specification includes a basic vocabulary (RDF schema) consisting of type, class, property, subClass, subProperty, and the like, plus some basic deductive rules, e.g., transitivity of subClass, etc. (Brickley and Guha 2014).

Although the original idea of RDF was that of a metadata specification for the web, it became a standard to build graph databases with RDF data. In this direction, a standard query language, called SPARQL (Harris and Seaborne 2013), was introduced to query RDF data.

The Property Graph Model

A *property graph* G is a directed multigraph with possibly multiple labels on nodes and edges. Formally, G is a tuple $(N, E, Lab, Prop, Val, \rho, \lambda, \sigma)$, where N and E are finite sets of nodes and edges; $Prop$ is a finite set of properties; Lab and Val are sets of labels and values, respectively;

and ρ , λ , and σ are functions defined as follows (Angles et al. 2017):

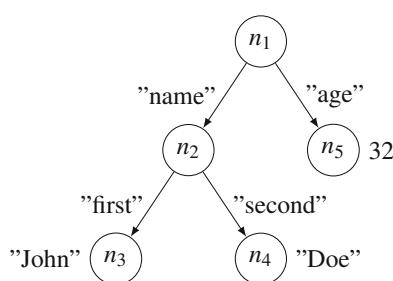

- $\rho : E \rightarrow (N \times N)$ is a total function defining the edges, where, for $e \in E$, $\rho(e) = (u, v)$ means that e is a directed edge from u to v for $u, v \in N$.
- $\lambda : (N \cup E) \rightarrow Lab$ is a total function providing the label for each node and edge. If $v \in N$ and $e \in E$, then $\lambda(v)$ is the label of node v and $\lambda(e)$ is the label of edge e .
- $\sigma : (N \cup E) \times Prop \rightarrow Val$ is a partial function providing values for those properties defined for particular nodes and edges. If $v \in N$, $e \in E$ and $p \in Prop$, then $\sigma(v, p)$ is the value for property p for node v , if defined (and similarly for edge e).

Example 2 Consider again the simple person example used in Example 1. This can be represented as a property graph as follows:

- Nodes $N = \{n_1, n_2, n_3, n_4, n_5\}$.
- Edges $E = \{e_1 = (n_1, n_2), e_2 = (n_1, n_5), e_3 = (n_2, n_3), e_4 = (n_2, n_4)\}$.
- Node labels $\lambda(n_1) = (), \lambda(n_2) = (), \lambda(n_3) = "John", \lambda(n_4) = "Doe", \lambda(n_5) = 32$.
- Edge labels $\lambda(e_1) = "name", \lambda(e_2) = "age", \lambda(e_3) = "first", \lambda(e_4) = "second"$.

Here we have identifiers for all nodes and edges. The rest – strings and numbers – are values, including $()$, which represents the absence of any value. Only nodes can be further referenced. Edges have identifiers only for the purpose of attaching properties to them.

Graphically, the example can be represented as follows:

The schema in current property graph databases plays essentially the role of integrity constraints to ensure safe modeling or improve performance. So a schema includes the possible properties for nodes and edges, the corresponding types, possible checking for existence or cardinality, etc. Some systems include indexes as part of the schema.

Current property graph database systems include storage, a query language (although there is no widely adopted standard), APIs, and application functionalities such as analytics, visualization, and tools to produce code or assemble with other applications. The Neo4J Graph Platform is a native graph database supporting transactional applications and graph analytics. It has developed its own query language called Cypher (<https://neo4j.com>). JanusGraph is designed for storing and querying graphs distributed across a multi-machine cluster. It uses Gremlin as its query language (<http://janusgraph.org/>). DataStax Enterprise Graph is part of the DataStax Enterprise (DSE) data platform. It is built on Apache Cassandra (<http://cassandra.apache.org>) and also uses the Gremlin query language. It supports distribution and benefits from the other functionalities of DSE (<https://www.datastax.com/products/datastax-enterprise-graph>).

The Nested Data Model

The need for a data model that was more flexible than the relational data model originally arose when trying to integrate heterogeneous data into a single representation. This gave rise to the Object Exchange Model (OEM) and subsequently alternative representations for what was to be termed *semi-structured data*. The most recent concrete proposal in this area is JSON (JavaScript Object Notation).

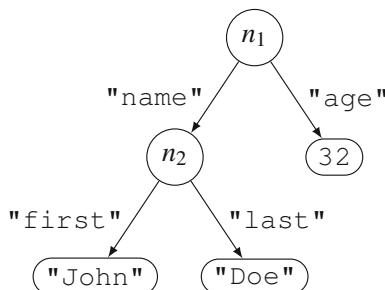

JSON is a lightweight representation based on data types used in JavaScript and is useful when exchanging data between applications. Apart from the primitive values of true, false, and null, and the primitive types of strings and numbers, JSON provides two structuring types, namely, objects and arrays. Objects are represented by key-value pairs (dictionaries), while arrays are simply sequences of values. The values appearing in objects and arrays can be arbitrary

JSON constructs, thereby allowing arbitrary nesting of structures.

Example 3 Consider once again the person example from Example 1. This can be represented in JSON as follows:

```
{
  "name": {
    "first": "John",
    "last": "Doe"
  },
  "age": 32
}
```

The basic structure in JSON is the key-value pair, with key-value pairs being grouped into objects, each delimited by braces. Each key within an object must be a string and must also be unique. Each value can be a basic value (number, string, etc.) or a nested expression. The underlying structure is a graph, in this case:

A schema language for describing what can be expected in a JSON document is JSON Schema (<http://json-schema.org/>), a draft proposal for an IETF standard. It allows the definition of types for JSON values and JSON documents. A type specification usually indicates the basic type, which might be *object*, *array*, or one of the literal types such as *numeral*, *string*, or *null*.

Type definitions in JSON Schema can be assigned an identifier, which can be used to let type definitions recursively refer to each other. This makes it possible to have recursively nested types, but the recursion is restricted to ensure well-defined semantics.

Several DBMSs support JSON as a data format. Those that use it as their main data format are also referred to as *document stores*, *document-oriented databases*, or *JSON databases*. The most well-known of these include *MongoDB* (<https://www.mongodb.com>), *CouchDB* (<http://couchdb.apache.org>), and *Azure Cosmos DB* (<https://azure.microsoft.com/en-gb/services/cosmos-db>). For example, *MongoDB* offers a schema language (its own and JSON Schema) and a proprietary query language to select and query JSON documents. Along with these document stores, there are NoSQL databases, such as *MarkLogic* (<http://www.marklogic.com>) and *OrientDB* (<http://orientdb.com>) that support JSON as one of their data formats. Finally, many popular SQL DBMSs, such as *MySQL* (<https://www.mysql.com>), *PostgreSQL* (<https://www.postgresql.org>), and *Oracle* (<https://www.oracle.com/database/index.html>), support JSON.

A Brief Comparison of Models

Graph data models are designed to represent data and their relationships in an explicit form. Traditionally in mathematics, graphs are defined by a *universe*, the set of nodes, and over it, the edges are defined as an additional structure, either as pairs (directed edges) or two-element sets (undirected edges), allowing one edge or multiple edges between two nodes, etc.

In all three models presented, the two defining sets of elements (nodes and edges) have their own identifiers, that is, are objects themselves. (This marks the difference between the graph model and, say, the relational model: in the latter, only nodes have identifiers, and edges are defined as relations or “tuples” of nodes.) In computer science, this is represented by a two-typed model: vertices and edges. Over this basic level, one can enrich vertices and/or edges. The three models considered do this in different directions.

JSON keeps edges as basic pairs of nodes but enriches the notion of node by allowing recursive structures for them. This allows “edges” between “higher-level” nodes that, once flattened, give a

graph structure. Properties in the form of labels are described inside these structures.

The RDF model keeps the nodes as primitives and enriches the edges with a label that can be a node. This label allows the structure to be enriched. But note that edges do not properly have identifiers (they are pairs of nodes). One can get RDF “graphs” such as $(a, b, c), (b, p, d)$ and (d, q, c) that can be represented as $\{a \xrightarrow{b} c, b \xrightarrow{p} d, d \xrightarrow{q} c\}$. This allows great flexibility, by allowing to “describe” the edge label b recursively. The price for this flexibility is the complexity to implement the model efficiently (because there is a mix between properties of objects and the objects themselves).

The property model keeps identifiers for nodes and edges and enriches the structure by adding additional properties over them. These properties do not have (as in the nested and RDF models) any intersection with the primitive nodes and edges. This model keeps the types (nodes, edges, properties) clearly disjoint, and thus classical graph algorithms can be implemented directly.

Conclusions

In this entry we have concentrated on only three categories of graph data model: edge-labeled graphs as exemplified by RDF, the property graph model, and the nested graph model. We believe these are currently the graphs models that are most widely studied and implemented. Many other graph data models are described in the survey by Angles and Gutierrez (2008).

Graph Exploration and Search

Davide Mottin¹ and Yinghui Wu²

¹Hasso Plattner Institute, Potsdam, Germany

²Washington State University, Pullman, WA, USA

Definitions

Exploratory methods have been proposed as a mean to extract knowledge from relational data without knowing what to search (Idreos et al. 2015). *Graph exploration* has been introduced to perform exploratory analyses on graph-shaped data (Mottin and Müller 2017). Graph exploration aims at mitigating the access to the data to the user, even if such user is a novice.

Algorithms for graph exploration assume the user is not able to completely specify the object of interest with a structured query like a SPARQL (see chapter “► [Graph Query Languages](#)”), but rather expresses the need with a simpler, more ambiguous language.

This asymmetry between the rigidity of structured queries and ambiguity of the user has inspired the study of approximate, flexible, and example-based methods.

Overview

The research on graph exploration has revolved around three main pillars: *keyword graph queries*, *exploratory graph analysis*, and *refinement of query results*.

Keyword graph queries applies user-friendly keyword queries to explore a targeted graph. The query answers are usually defined as subgraphs that contain the nodes and edges with information specified by the query terms. New keywords can be suggested from observed answers and are used to expand the original queries, which triggers a new round of query evaluation. Keyword queries are desirable for end users who do not have prior knowledge of underlying graph data, for which

writing a complex graph query (e.g., SPARQL) is difficult. On the other hand, keywords can be ambiguous. While keyword search has been extensively studied, the major research effort in this category focuses on disambiguation and keyword query refinement.

Exploratory graph analysis entails the process of casting an incomplete or imperfect pattern query to let the system find the closest match. Such exploratory analysis may return a huge number of results, e.g., structures matching the pattern. Thus, the system is required to provide intelligent support. One such strategy is the well-known query-by-example paradigm, in which the user provides the template for the tuples and lets the system infer the others.

Refinement of graph query results is needed to deal with the overwhelming amount of results that is typical in subgraph processing. It includes approaches designed to present comprehensive result sets to the user or intermediate results that can be refined further.

Key Research Findings

Graph Search with Keywords

Keyword search (KWS) has been routinely used to explore graph data (Wang and Aggarwal 2010; Mottin and Müller 2017). (1) A keyword query Q is a set of terms $\{t_1, \dots, t_n\}$. Given graph $G=(V, E)$ and a term t_i , a match function determines a set of *content nodes* $V(t_i) \subseteq V$ that match t_i . (2) An answer G_Q of a keyword query Q is a subgraph of G that contains a node from $V(t_i)$ for each $t_i \in Q$. A function $F(G_Q)$ is used to quantify the cost of connecting all content nodes. Answers with smaller cost have higher quality.

Given a node pair (u, v) in graph G , (1) the distance from u to v , denoted as $\text{dist}(u, v)$, is the sum of edge weight on the shortest path from u to v ; and (2) $\text{len}(u, v)$ denotes the length of the shortest path from u to v . There are three common classes of KWS queries.

Distinct root-based KWS defines G_Q as a minimal rooted tree which (1) contains a distinct root node v_r and at least a content node $v_i \in V(t_i)$ as a leaf for each $t_i \in Q$ and (2) $\text{len}(v_r, v_i) \leq r$ for a predefined hop bound r , for each leaf v_i . Here, G_Q is minimal if no subtree of G_Q is an answer of Q in G . The function $F(G_Q)$ is defined as $F(G_Q) = \sum_{t_i \in Q} \text{dist}(v_r, v_i)$, where v_i ranges over the content nodes. The answers of such queries can be found in $O(|Q|(|V| \log |V| + |E|))$ time (cf. Yu et al. 2010).

Steiner tree-based KWS (Bhalotia et al. 2002) differs from its distinct root-based counterparts in that it uses a different cost function $F(G_Q)$, which is defined as $\sum_{e \in G_Q} w(e)$, i.e., the total weight of the edges in the Steiner tree G_Q . It is NP-hard (Yu et al. 2010) to evaluate a Steiner tree-based query by computing a minimum weighted Steiner tree, a known NP-hard problem (Ding et al. 2007). Both exact (Ding et al. 2007) and approximation algorithms (Byrka et al. 2013) have been developed to evaluate such queries.

Steiner graph-based KWS (Li et al. 2008; Kargar and An 2011) finds G_Q as graphs rather than trees. For Steiner graph-based queries with a number r , G_Q is a Steiner graph that contains content and Steiner nodes (i.e., nodes on shortest paths between two content nodes), with either radius bounded by r (i.e., r -radius Steiner graph (Li et al. 2008)) or distance between any two content nodes bounded by r (i.e., r -clique (Kargar and An 2011)). For an answer G_Q with nodes $\{v_1, \dots, v_n\}$, its cost $F(G_Q)$ is computed as $\sum_{i \in [1, n]} \sum_{j \in [i+1, n]} \text{dist}(v_i, v_j)$, i.e., the total pairwise distances of the content nodes in G_Q . It is in general NP-hard to evaluate Steiner graph-based queries (Yu et al. 2010). Approximate algorithms are developed for such queries to find r -radius graphs (Li et al. 2008) and r -cliques (Kargar and An 2011).

Keyword query suggestion. Keyword query suggestion and its variants (e.g., query refinement and reformulation) have been studied to suggest new queries that better describe search intent

for graph exploration. Most prior work adopts information retrieval techniques that make use of query logs and user feedback (Carpinetto and Romano 2012). Keyword query suggestion for graphs has been studied in Tran et al. (2009) by suggesting structured queries computed from the keywords over RDF data. In order to summarize the results of KWS over structured data, tag clouds (Koutrika et al. 2009) discover the most significant words retrieved as a part of the initial results. Provable quality guarantees of the answers are not addressed in these works.

Query suggestion has been studied for XML data (Zeng et al. 2014), with a focus on coping with missed matches. An approximate answer of original query Q is computed by expanding its answer with content nodes of the same type, and new keywords are suggested to replace those without match in Q .

Exploratory Graph Analysis

One of the earliest attempts employing examples as search conditions is query-by-example (Zloof 1975). The main idea was to help the user in the query formulation, allowing her to specify the shape of the results in terms of templates for tuples, i.e., examples. Query by example has been lately revisited, and the use of examples has found application in graph data. The definition of example has transformed from a mere template to the representative of the intended results the user would like to retrieve. *Examples* for a graph $G = (V, E)$ can be either *set of nodes* $Q \subseteq V$, *tuple* of nodes $(v_1, \dots, v_n) \in V^n$, or *subgraphs* $Q \subseteq G$, where with an abuse of notation \subseteq indicates both set and structural inclusion.

Set of nodes as examples. Several analyses can be performed when a set of example nodes $Q \subseteq V$ is provided; this includes the discovery of dense graph regions (Gionis et al. 2015; Ruchansky et al. 2015), central nodes (Tong and Faloutsos 2006), and communities (Staudt et al. 2014; Perozzi et al. 2014). Discrepancy maximization in graphs (Gionis et al. 2015) aims at finding a connected subgraph $G' = (V', E')$, $G' \subseteq G$ that maximizes the discrepancy $\delta(G') = \alpha|Q| - |V \setminus Q|$, $\alpha > 1$; in other words,

G' is a subgraph containing more nodes from Q than other nodes. Discrepancy maximization is NP-hard. On a similar line, the centerpiece subgraph problem (CEPS) (Tong and Faloutsos 2006) finds the maximum weight subgraph that contains at least k query nodes and at most b other nodes. A generalization of the CEPS problem, the minimum Wiener connector problem (MWC) (Ruchansky et al. 2015) computes dense regions of a graph potentially representing community structures, given a set of nodes as input. MWC aims at finding a subgraph of G induced by Q , denoted as $G[Q]$, that minimizes the sum of the pairwise distances among the nodes in Q , i.e., $\arg \min_{G[Q]} \sum_{\{u,v\} \in Q} d_{G[Q]}(u, v)$.

Examples have also been used as a mean to detect communities, where a community is a set of nodes, in which every node is connected to many more nodes inside the community than outside. One approach is to consider each node $v \in Q$ as a representative of a different community (Staudt et al. 2014). In graphs with attributes on nodes, FocusCO (Perozzi et al. 2014) introduced a clustering algorithm that learns a similarity function among nodes, based on the attributes in the examples. Formally, FocusCO takes an attributed graph $G = (V, E, F)$, where F is a feature matrix $F \in \mathbb{R}^n \times f$ and F_i represents the attribute vector for node v_i , and returns clusters that better represent the seed nodes Q . FocusCO returns outliers that do not belong to any community identified so far. (For community detection, see chapter “Community Analytics in Graphs.”)

Node tuples as examples. In graph query by example (GQBE) (Jayaram et al. 2015b) a tuple of nodes $(v_1, \dots, v_n), v_i \in V^n$ is a representative of the result tuples. For instance, if the pair (*Yahoo, Jerry Yang*) is provided, the result is expectedly other *IT company, founder* pairs. The solution first computes the *minimal answer graph* connecting the query nodes and then finds other subgraphs isomorphic to such graph.

Subgraphs as examples. Subgraphs are more expressive than nodes and tuples; hence they can

be exploited to obtain more accurate results. In the case of graphs, the example can constitute an exemplar query (Mottin et al. 2016) $Q \subseteq G$, and a result is a subset of G congruent to Q . Exemplar queries is a flexible paradigm that allows the definition of multiple congruence relations among the input example and the intended results, such as isomorphism or strong simulation (Ma et al. 2014). Moreover, it supports efficient retrieval of top- k results.

A generalization of exemplar queries, PANDA (Xie et al. 2017), studies partial topology-based network search, that is, finding the connections (paths) between structures node-label isomorphic to different user inputs. PANDA first materializes all isomorphic graphs, then groups them into connected components, and finally finds undirected shortest paths among them. More techniques on graph pattern queries are introduced in chapters “► Graph Pattern Matching” and “► Graph Query Processing.”

Reformulation of Graph Queries

Users with exploratory intent typically provide indefinite queries that are likely to return either too few or too many results. For this reason, query reformulation techniques aim at modifying the query to lead the user to the intended result (Motin et al. 2015; Hurtado et al. 2008; Islam et al. 2015). A *reformulation* for a query $Q \subseteq G$ on a labeled graph $G = (V, E, \ell)$ with labeling function on nodes and edges ℓ is another query Q' that is either a supergraph $Q' \supseteq Q$ or a subgraph $Q' \subseteq Q$ of Q . Therefore, Q' can be more specific (supergraph) or more generic (subgraph) than Q . Queries considered in graph query reformulation are usually subgraph isomorphism queries (Lee et al. 2012). Query reformulation has been proposed for collections of graphs, or *graph databases*, as well as *large graphs*.

Query reformulation in graph databases. Query reformulation in graphs can apply to collection of graphs or *graph databases* $\mathcal{D} = \{G_1, \dots, G_n\}$, where each G_i is a graph $G_i = (V_i, E_i, \ell_i)$. In such graph databases, the query Q returns a subset of the collection $\mathcal{R}(Q) \subseteq \mathcal{D}$ containing the structure Q .

Graph query reformulation (GQRef) (Mottin et al. 2015) discovers query reformulations having small overlap and high coverage; thus ideally no result is missing from the reformulated queries, yet the reformulations have little redundancy. The objective is to find a set R of k reformulations with high coverage and diversity (i.e., small overlap) maximizing $f(R) = |\bigcup_{Q \in R} \mathcal{R}(Q)| + \lambda \sum_{Q_1, Q_2 \in R} |\mathcal{R}(Q_1) \cup \mathcal{R}(Q_2)|$, with λ trading-off coverage and diversity. Maximizing f is NP-hard, but an approximate greedy solution can guarantee a $(1/2)$ -approximation.

Alternatively, AutoG (Yi et al. 2017) proposes a top- k reformulation approach for visual autocomplete of queries. AutoG returns the k best relaxations according to a ranking function that favors a large number of results for each reformulation and large diversity. Such ranking function (excluding normalization) is $u(R) = \alpha \sum_{Q \in R} |\mathcal{R}(Q)| / |\mathcal{D}| + (1 - \alpha) \sum_{Q_1, Q_2 \in R} \text{dist}(Q_1, Q_2)$, where $\alpha \in [0, 1]$ strikes a balance between coverage and a user-defined distance dist among queries. For visual query analysis, see chapter “► [Visual Graph Querying](#).”

Query reformulation in large graphs. Few works explicitly explore query reformulation in large graphs. Early attempts in this direction propose to enrich the SPARQL semantics with a RELAX clause that returns a set of reformulations following some predefined rules (such as expanding edges with a specific label) (Hurtado et al. 2008). In Arenas et al. (2014) the SPARQL reformulations are extended to OWL logic, where the semantics of each reformulation is captured by the RDF taxonomy. The user can interactively accept or reject the possible expansions of a query such that the navigation is consistent with the rules.

Query reformulation is also employed in query debugging to understand why the query returned too-many or too-few answers (Vasilyeva et al. 2016). In order to explain the dependency between the number of results and the query (Vasilyeva et al. 2016), first compute the *maximum common subgraph* (MCS) among the graph G

and the query Q and then use a *differential graph* to profile the query by adding edges from the differential graph to the MCS. The maximum common subgraph is the largest connected graph G' that is subgraph of both Q and G .

VIIQ (Jayaram et al. 2015a) employs query logs to rank the possible reformulations of the query Q . VIIQ’s ranking function generates *correlation paths* among the sequence of reformulations in the current query Q and the sequences in the query log. Among the candidate *single* edges that can be added to Q , the ranking function proposes those that have a larger support in the query log.

Why-not queries in graphs. Why-not queries additionally require the user to provide a set of missing answers from the results of Q , and the system proposes a new query Q' returning those results and the least number of irrelevant results. The only work in this direction is Islam et al. (2015). In order to compute why-not queries, the maximum common subgraph (MCS) among the query Q and the missing answers \mathcal{D}^- is computed. The best query is found minimizing the maximum distance among Q' and the missing answers \mathcal{D}^- as $\arg \min_{Q' \in \mathcal{D}} \max\{\Delta(Q', G) | G \in D^-\}$, where given $G_1 = (E_1, V_1, \ell_1)$, $G_2 = (E_2, V_2, \ell_2)$, $\Delta(G_1, G_2) = |E_1| + |E_2| - 2|\text{MCS}(G_1, G_2)|$.

G

Key Applications

The need of graph exploratory is evident in user-friendly knowledge exploration (Achiezra et al. 2010), “why-not” query processing (Tran and Chan 2010), and database security, where highly correlated queries are identified to reverse engineering the sensitive entity information (Tran et al. 2014). Another application is interactive sensemaking of complex graph data (Pienta et al. 2015), with broader applications in literature search and collaboration recommendation in academic networks, attack and anomaly detection in cyber networks, and event detection in social media.

Future Directions

The challenges remain open for interactive graph exploration. Real-time interactivity is crucial to exploration over large graphs. This requires scalable graph analytics and query suggestion; both are nontrivial for graph data. One direction can be to integrate emerging scalable graph mining and learning methods to graph exploration tasks, beyond query-based exploration. Uncertainty and trustworthiness of graph data sources is another challenge for exploration tasks, especially for knowledge bases. This requires truth-aware exploration that guarantees the correctness of retrieved information. A third direction is to combine usable user interfaces and scalable graph visualization techniques to facilitate sensemaking and knowledge discovery by graph exploration.

Graph Generation and Benchmarks

Angela Bonifati¹ and Arnau Prat-Pérez²

¹Lyon 1 University, Villeurbanne, France

²Universitat Politècnica de Catalunya, Barcelona, Spain

Definitions

Benchmarking has been crucial for the uptake and evolution of database technologies. Benchmarks allow systems to compete on a fair, non-biased setup, giving users an understanding of how two or more systems would compare in the same real setting. Additionally, the competition for obtaining the best benchmark scores has

guided the research and development of database systems during years, speeding up their progression and their impact in society. Among many benchmarking initiatives, the Transaction Processing Council (TPC 2017) family of benchmarks is the best example of influential database benchmarks.

Industry and academia are aware of the benefits benchmarking can provide to the evolution and adoption of graph database technologies, and as such, many graph benchmarking initiatives have emerged such as Erling et al. (2015), Iosup et al. (2016), Armstrong et al. (2013), or Bagan et al. (2017) just to cite a few of them. However, designing a benchmark is not a trivial task. A benchmark has several components that need to be carefully designed/selected. For instance, which is the target audience of the benchmark? Which are the datasets the benchmark works with? How do we quantitatively measure the performance of a system running the benchmark? These are just a few questions that must be answered when designing a benchmark.

In this chapter, we review the elements a graph benchmark consists of and how the different existing graph database benchmarks address them. Finally, we discuss the different open challenges in graph benchmarking.

Overview

Given the diversity of systems and use cases, graph database benchmarks are typically designed to target specific types of systems working on a reference use case. These highly influence the three main components that form a database benchmark: the *workload*, the *scoring metric*, and the *auditing rules*.

The Workload

The main component of a benchmark is the workload, which consists of the definition of the queries the *systems under test (SUTs)* will execute, the query mix (i.e., how many instances of each query and when these will be executed), and the data that will be used.

Queries and Query mixes. There are different strategies usually followed when designing the queries of a benchmark workload. One commonly adopted strategy is the one based on analyzing a reference use case (e.g., the operation of a social network web site) in depth. From this analysis, representatives of the most relevant queries (e.g., a friend recommendation query, a group recommendation query, etc.) are synthesized, which exhibit either a read or a write mode. Additionally, the query mix is carefully designed to reproduce the query frequencies typically observed. This strategy pursues to accurately model the reference use case with the goal of providing the user with insight about how different SUTs will perform in a similar but real setting. Benchmarks following this approach are typically known as *macro-benchmarks*.

However, the purpose of a benchmark is not only to assess of the current status of an industry but also to drive its evolution and path to maturity. Thus, some benchmarks do not only focus on accurately modeling the reference use case queries but also on making the queries hard to challenge the different industry and academia actors. This is usually achieved by understanding how queries are typically executed on the target systems and by identifying which low-level operations or operators dominate the execution time of typical queries issued against the SUTs and become their bottlenecks. Then, queries are crafted (in combination with the input data) to deliberately stress such low-level operations and to push the SUTs to their limits. When following this strategy, the benchmark designer must find a trade-off between the realism of the queries and their hardness. This also applies to the definition of the query mix, which may consist of frequencies that do not necessarily strictly reproduce those observed in a reference use case. For instance, one might decide to increase the frequency of particular operations (e.g., write operations) to stress the systems in this aspect. This approach has the advantage of testing the SUTs more comprehensively (bringing them out of their comfort zone), which in turn stimulates their evolution toward usages not considered by the reference use case, and making the whole industry to advance.

By pushing this strategy to an extreme, one typically ends up with a *micro-benchmark*, which are benchmarks whose queries are directly the low-level operations/operators used to build more complex queries (e.g., getting the k-hop neighborhood of a node, computing the path between two nodes, performing a join, etc.).

The Data. The performance of most of the queries in database applications is data driven, that is, it is highly influenced by the characteristics of the data used. This is especially true for graph database applications, which usually perform expensive operations. For instance, one might think about the computation of the k-hop neighborhood of a given node. Depending on the query node, its degree, and the diameter of the graph, a hypothetically small two- or three-hop neighborhood could lead to visit almost all nodes of the graph (Backstrom et al. 2012). Thus, when designing the workload, designers must carefully choose the data to be used, not only to meet functional requirements (e.g., the presence of attributes that are involved in the queries) but also other characteristics that may affect the performance of the SUTs (number of joins, number of recursive steps, number of disjuncts, and so on).

In general, benchmarks use two types of datasets: real datasets gathered from the real reference use case and synthetically generated datasets. The former has the advantage of containing the desired characteristics, but they are typically scarce since their owners are reluctant to share them, and they do not always obey the desired scale. For this reason, many benchmark designers opt for using synthetic graph generators, paying attention to accurately model the characteristics observed in their realistic counterparts. This strategy has the advantage that graphs at different scales can be modeled, allowing the definition of *scale factors* to test the SUTs at different scales. The importance of synthetic graph generation has significantly grown during the last years, and thus there is a considerable amount of research on the topic.

Real networks like social networks, biological networks, scientific collaboration networks, or the World Wide Web share particular characteristics including a skewed degree distribution that can be approximated with a power law with a long tail, a community structure, a small diameter, or a large largest connected component (Girvan and Newman 2002; Newman 2003; Boccaletti et al. 2006). As such, many synthetic graph generation techniques focus on reproducing such observed characteristics, including the method proposed by Newman et al. (2001), the RMAT method proposed by Chakrabarti et al. (2004), the Kronecker graphs proposed by Leskovec et al. (2005), the LFR graph generator introduced by Lancichinetti et al. (2008), or the BTER graph generator described by Kolda et al. (2014), just to cite a few of them. Typically, graph benchmarks adopt these techniques to build their own graph generators, since the former are mostly focused on the structure of the graph but do not consider the generation of properties, usually required by benchmarks.

The Scoring Metric

The main goal of a benchmark is to provide a non-biased, fair measure of how a system performs for a given task. In order to provide such a measure, one or more scoring functions are defined. These scoring functions typically measure things such as throughput or latency, to give a sense of the performance of the SUTs. However, some benchmarks define scoring functions that measure a trade-off between performance and cost, where cost is defined as the cost of operating the SUT, including the cost of purchasing the system and sometimes also its maintenance during a period of time. As a consequence, the user can know which is the best system given his budget or how much he needs to spend given the desired throughput and/or latency. Also, some use cases that allow systems to return partial or incomplete results. Thus, some benchmarks define scoring functions to measure how complete the results of a query are.

Finally, in those cases where a benchmark defines several scoring functions, it is also a common practice to define a combined metric

that unifies all such scores into a single score value in order to ease the comparison of systems.

The Auditing Rules

The third main component of a benchmark is the auditing rules. The auditing rules are a set of rules that define the conditions under which the benchmark execution must be performed in order to consider the score as valid and to ensure that it has not been gamed. The rules define various aspects such as the process to follow in order to execute the benchmark and publish its results, whether this must be executed by an independent auditor or not, what information of the SUT must be disclosed to the audience, or how to compute the cost of the SUT.

G

Key Research Findings

LUBM

The LUBM (Lehigh University Benchmark) (Guo et al. 2005) is a macro-benchmark designed for Semantic Web that has also been used to benchmark graph database systems due to the more expressive property graph data model.

The benchmark contains 14 queries crafted to be both realistic and diverse. In order to assess this diversity, the authors define a set of features for each query (e.g., *input size*, the *selectivity*, the *complexity*, etc.) and guide the definition of the queries trying to maximize the space of features covered.

The query mix consists of ten executions of each query. The benchmark uses several scoring functions, including the loading time, the repository size (i.e., the size used to store the loaded data), and the query response time per query, which are computed as the average execution time of the ten executions of each query. Additionally, the benchmark uses the notion of *completeness* and *soundness* for each query, which captures how precise and complete are the returned results (partial results are allowed). Finally, the benchmark proposes a *combined metric* that unifies all the aforementioned scoring functions into a single number.

LUBM uses a synthetic data generator, namely, the Univ-Bench Artificial (UBA) data generator, that generates datasets representing universities, their departments, the staff, the students, and the courses. The minimum unit of data generation (used to scale up the dataset) is the university, and the amount of different departments, professors, students, and courses per university is based on the authors’ “reasonable assumptions” but not backed on real data. Finally, the LUBM benchmark does not define a set of auditing rules nor any cost-based scoring function.

BSBM

The Berlin SPARQL Benchmark (Bizer and Schultz 2009) is a macro-benchmark settled in an e-commerce use case, where there are products offered by different vendors and reviews posted by consumers on various review sites. The benchmark initially targeted RDF stores, both those that execute SPARQL directly and those that rely on SPARQL-to-SQL rewritings, but it has also been used to test graph databases.

The benchmark uses a synthetic data generator to generate the different classes like product, vendor, persons, or review, just to cite a few of them. The generator scales based on the number of generated products, and for each of them, a description and reviews are generated. Then, the number of persons depends on the number of reviews generated until each review is assigned to one and only one person. The data distributions are tuned to follow the author’s “realistic assumptions,” including normal distributions for the number of reviews per product and the number of reviews per person.

The workload consists of the 12 queries that represent the interactions of users with the e-commerce site. The authors define a query mix as the succession of queries that emulates the search and navigation pattern of a consumer looking for a product, which consists of 25 query executions. The final workload is composed of different query mixes representing different users using the e-commerce site concurrently.

The BSBM benchmark uses three scoring functions: query mixes per hour (QMph) (i.e.,

the number of users served per hour), queries per second (QpS), and load time (LT), but neither a combined metric nor a cost-based metric is provided. Finally, the benchmark defines the set of steps to be properly executed, including the process of loading, system warm-up, and execution, but a formal auditing process is not specified.

LinkBench

The LinkBench (Armstrong et al. 2013) is a macro-benchmark created by Facebook to test the performance of alternative database systems when dealing with Facebook’s social graph. The benchmark replicates Facebook’s data model and the transactional query mix used on their production MySQL store.

The benchmark provides a data generator that generates a social graph similar to that of Facebook, based on statistics obtained from the original Facebook data, and that can be scaled based on the desired number of users of the social network. Similarly, the authors profiled the operations received in the MySQL back end and identified ten different types of basic operations (including read and write operations) that operate on different nodes and edges of the social graph, as well as their corresponding frequencies that conform the query mix. The workload also tries to reproduce the observed proportions of hot data (data accessed frequently) and cold data (data barely accessed).

The benchmark defines several performance metrics that need to be reported. These include the latency at 50th, 75th, 95th, and 99th percentiles and the throughput. They define the throughput per dollar as a cost/performance metric. Additionally, they suggest the gathering of resource utilization statistics (e.g., CPU usage, I/O operations, etc.) at regular intervals for understanding the performance and efficiency, but they do not provide a combined nor a cost-based scoring function. Finally, they do not define auditing rules.

LDBC SNB Interactive

The Social Network Benchmark: Interactive workload (SNB-I) (Erling et al. 2015) is a

macro-benchmark created by the Linked Data Benchmark Council, an industry and academia initiative to build benchmarks for graph-based technologies.

SNB-I models the operation of a social network site, similar to that of Facebook in terms of its data model. The SNB-I provides a synthetic data generator that simulates a social network consisting of persons, posts, comments, images, likes, groups, etc. The data generator models the characteristics typically observed in real networks, including a Facebook-like degree distribution (Ugander et al. 2011), spiky post/comment distribution based on real events (Leskovec et al. 2009), correlated attributes of entities and among connected entities (McPherson et al. 2001), etc. The benchmark defines several scale factors (SF1, SF3, …SF1000) named after the number of GB on disk that takes the generated dataset files.

The workload is a transactional workload targeting graph databases, RDBMS with graph extensions support, and RDF systems. The workload consists of 14 complex reads, which are complex yet interactive queries that explore the neighborhood of a given node; 7 short reads, which represent those short queries used to retrieve the user information like its friendships, messages, likes, etc.; and 8 update queries, which modify the state of the social network.

Complex reads are designed using a novel “choke-point”-based approach, which consists of identifying scenarios that are challenging for SUTs and designs the queries to stress such scenarios deliberately yet being use case based.

The query mix is generated at the beginning of the execution by the provided driver, such that for each query instance, a scheduled issue time is given. The query mix is designed not to make any complex read to dominate the execution, given that queries have different complexities whose runtime depends on the expected amount of data touched. Additionally, updates and their scheduled issue times are read from data provided by the data generator, while short reads are interleaved between complex reads and updates in such a way that a final read-write proportion of 80/20 is obtained.

Regarding the scoring function, the benchmark uses throughput and throughput per cost as the scoring function. Additionally, the benchmark defines a “valid run” condition, which consists of 95% of the queries to start no later than 2 s after the scheduled issue time.

Finally, the benchmark defines a comprehensive set of auditing rules that define both the process to follow to execute the benchmark (done by an official benchmark auditor) and the information that must be disclosed from the SUTs.

G

LDBC Graphalytics

The LDBC Graphalytics benchmark (Iosup et al. 2016) is an industry-backed macro-benchmark that targets graph processing systems specialized on analytics on large graphs, including distributed systems and heterogeneous systems based on GPUs.

The workload consists of six traditional structure-based (no properties are used) graph analytic algorithms: breadth-first search, PageRank, weakly connected components, community detection with label propagation, local clustering coefficient, and single-source shortest paths.

The Graphalytics benchmark uses both real graphs and synthetic graphs of different scales named after the traditional T-shirt size labeling (S, M, L, XL, XXL, etc.) that includes a renewal process that is revisited every 2 years. For generating synthetic graphs, the benchmark uses both the SNB-I data generator and the RMAT data generator.

The benchmark uses several performance metrics, including the loading time; the make-span, which is the time of executing the algorithm including the system-specific overheads; and the processing time, which is the actual time of executing the algorithm. Additionally, they collect the edges processed per second (EPS) and the edge-vertex processed per second (EVPS). The benchmark also specifies a EVPS/cost metric.

Graphalytics comprehensively defines the steps to follow to execute the full benchmark, including the experiments to run and measurements to take, as well as all the information that needs to be disclosed. So far no auditing rules

have been proposed, but their definition is on the benchmark’s development road map.

gMark

gMark (Bagan et al. 2017; gMark 2016) is a synthetic graph instance and query workload generator, which is both domain- and query language-independent. It allows the creation of domain-specific use cases by means of a highly configurable number of input parameters. Contrarily to other synthetic benchmarks, the benchmark is neither a macro-benchmark nor a micro-benchmark since it allows to simulate both cases and all the variants in between. The gMark benchmark is also workload centric as it leverages the presence of multiple queries in the workload as opposed to single-query executions. It is system- and language-independent in that it allows to generate queries for a broad variety of systems and query languages (among which SPARQL, openCypher, LogicQL, and SQL are included in the default package). It is extensible to upcoming systems and graph query languages.

The graph configuration consists of the *size* of the graph (number of nodes), the *edge predicates*, the *node types*, and the occurrence constraints (expressed as percentages of occurrence in the generated graph instance), along with the in-degree and out-degree distributions associated with each extreme of an edge. Such distributions vary among uniform, Gaussian, and Zipfian and allow to represent many realistic graph datasets. The query workload configuration allows to specify the *workload size* (in terms of number of queries), the minimum and maximum *arity* of the generated queries, the *shape* classes that are desired in the generation (out of chain, star, cycle, and star-chain queries), the *selectivity* of the queries (representing the number of results returned by the queries, which depends on the graph size and topology and can be chosen among constant, linear, and quadratic), the *probability of multiplicity* (in terms of proportion of recursive queries in the generated query workload), and the *query size* (the maximum and minimum number of conjuncts, disjuncts, etc.).

The parameters in the query workload indirectly suggest the scoring metrics to adopt in order to compare the systems under test. For instance, one can decide to measure the coverage of recursive queries of the SUTs or their robustness with respect to quadratic selectivities or to the number of queries in the workload. Nevertheless, gMark does not impose a fixed set of scoring metrics to be adopted for all cross-comparisons among the SUTs.

Finally, the gMark benchmark does not define a set of auditing rules to measure the cost of the systems under test. However, since it has been proved effective to reproduce existing benchmarks and provide expanded query workloads, such as WatDiv (Aluç et al. 2014) and LDBC SNB (Erling et al. 2015), one might adopt their respective auditing rules on the expanded query workloads.

Usage-Driven Query Analysis and Benchmarking

The rise of SPARQL endpoints has allowed to collect query logs containing manually written queries as formulated by end users and machine-generated queries through specific APIs. DBpedia 2010 logs have been examined in Morsey et al. (2011) in order to come up with a set of 25 most frequently used queries that can be considered as prototypical queries in performance studies of triple stores of the so-called DBpedia SPARQL benchmark. The identification of representative user queries has recently been carried out for Wikidata datasets and has led to define a collection of 309 Wikidata user example queries derived from real Wikidata queries (Wikidata 2018). These queries are intended to showcase systems behavior and/or highlight characteristics of the Wikidata dataset and are thus meant to produce a nice output. Recent large SPARQL query logs have been lately analyzed in Bonifati et al. (2017), encompassing DBpedia, BioPortal, SWDF, British Museum, LinkedGeoData, and OpenBioMed queries. These logs are inspected in order to understand the structural characteristics of the queries, their syntactic features, their disparate shapes, and their graph and hypergraph classification in order to understand their com-

plexity. Moreover, such true query logs contain the “development process” of queries: users start by formulating a query and gradually refining it until they are satisfied with it. Query logs can thus reveal streaks of the same evolving query, which correspond to gradual modifications of a seed query.

The above works show that much work is left to be done in order to harvest the characteristics of real user queries and feed future benchmarking initiatives devoted to target queries that users are coveting. They also highlight the importance of benchmarks that are self-adaptive to evolving users’ needs.

Future Directions of Research

Despite the fact that there has been a considerable effort from both industry and academia to create comprehensive and equitable graph benchmarks, their adoption is still far from being achieved. The graph processing industry is not yet mature for this adoption, and the number of involved industrial actors in the definition of these benchmarks is still narrow. Even though this number is increasing lately, a paradigm shift is needed in order for the involved companies to fiercely compete for the best benchmark scores. The opposite occurs in the academia, where graph processing is a hot topic and many benchmarks have been proposed as discussed in this chapter. Implementing an industry-graded benchmark is usually a time-consuming task that requires a considerable effort, not only in implementing the necessary queries but also in setting up the execution environment properly. Thus, the evolution of graph benchmarking must put a special emphasis in lowering the entry bar as much as possible, either by providing the required tools and software to ease their adoption (like workload drivers, reference query implementations, dataset repositories, etc.). A non-negligible issue is, for instance, tied to the comparison of results and their reproducibility in a benchmarking environment. Another matter concerns the definition of a standard graph query language that would

certainly help the design of valid and widely recognized benchmarks.

Another aspect is the generation of data for benchmarking purposes. The performance of graph queries is heavily affected by the characteristics of the underlying data, both structurally and in terms of attributes, which influence the size of the search space and the memory access patterns, among others. Properly understanding the relationship between different data characteristics and the performance of graph queries is one of the goals of benchmarking, and data generators that help tuning the characteristics of such data are of high importance. Moreover, the creation of tools to assist in the exploration and identification of the performance bottlenecks of graph databases and their relationship with the input data is a research direction worth to be investigated in the near future.

Definitions

In this section, we cover some of the basic general definitions related to graphs, with a special emphasis on the most elementary properties of interest for link analysis; for more details and further definitions and results, see, for example, (Bollobás 1998; Diestel 2012).

Overview

Graphs are one of the basic representation tools in many fields of pure and applied science, useful to model a variety of different situations and phenomena. Besides the ubiquity of graphs as a representation tool, the emergence of social networking and social media has given a new strong impetus to the field of “social network analysis” and, more generally, to what is called “link analysis.” In a nutshell, link analysis aims at studying the graph structure in order to unveil properties, discover relations, and highlight pattern and trends. This process can be seen as a special type of data mining (Chakrabarti et al. 2006), sometimes referred to as graph mining.

A (*directed*) graph (or digraph, or network) G consists of a finite set of nodes N_G and a set

of *arcs* $A_G \subseteq N_G \times N_G$ (the subscript, here and in the following, is omitted whenever it can be deduced from the context). According to this definition, a graph is given by a certain ensemble of objects (its “nodes,” whose nature depends on the actual context) and a binary relation between them, represented by its arcs. An arc of the form $\langle x, x \rangle$ is called a *(self-)loop*; unless otherwise specified, loops are allowed to exist.

The adjective “directed” emphasizes that arcs have a direction (they go *from* one node *to* another); in some applications, though, the direction does not make sense, and one talks of “undirected graphs,” i.e., graphs whose arcs do not possess an orientation. In the context of undirected graphs, nodes are often called *vertices*, and arcs are called *edges*. An *undirected graph* can be alternatively defined as a loopless graph such that if $\langle x, y \rangle$ is an arc then also $\langle y, x \rangle$ is one (the pair of opposite arcs represents a single edge).

A few examples of directed and undirected networks that arise in different scientific contexts include the following: hypertextual document collections (the most famous instance being the World Wide Web), computer communication networks (among them, the network of Internet autonomous systems), telephone call networks, email-exchange networks, social interaction networks (of different kinds and over a variety of social networking applications and websites), biological networks (e.g., protein-protein interaction networks, metabolic networks, etc.), road-connection networks...

We let $n = |N|$ and $m = |A|$ be the number of nodes and arcs of the graph, respectively; for undirected graphs, we write $e = |A|/2$ for the number of edges. We also let \mathcal{G} denote the family of all graphs.

Note that $0 \leq m \leq n^2$ for directed graphs (and $0 \leq e \leq \binom{n}{2}$ for undirected graphs): if $m = 0$, we say that the graph is an *independent set*; if $m = n^2$ (or $e = \binom{n}{2}$, in the undirected case), we say it is a *clique* (or complete graph).

An *out-neighbor* (*in-neighbor*, respectively) of the node x is any node y such that $\langle x, y \rangle$ ($\langle y, x \rangle$, respectively) is an arc. The set of out-neighbors (in-neighbors, respectively) of x is

denoted by $N^+(x)$ ($N^-(x)$, respectively). For undirected graphs, we just talk of *neighbors* of x and write $N(x)$.

The number of out-neighbors (in-neighbors, neighbors) of x is called its *out-degree* (*in-degree*, *degree*), and it is denoted by $d^+(x)$ ($d^-(x)$, $d(x)$).

Given a set of nodes $X \subseteq N$, the *subgraph induced by X* is the graph $G[X]$ with node set X and with arcs given by $A \cap (X \times X)$.

A *k -partite graph* is a graph whose nodes can be partitioned into k disjoint subsets N_1, \dots, N_k such that, for all $i = 1, \dots, k$, $G[N_i]$ is an independent set.

G

Invariants and Centrality Indices

In some cases, the actual nature of the nodes of a graph is important and relevant, for example, when drawing an undirected graph, its vertices are (identified with) points in the Euclidean plain, and its edges are segments (or curves) connecting them; moving one vertex to another location would change the drawing of the graph.

Nonetheless, in many cases one is not interested in the concrete attributes of the graph nodes, but rather in the graph “structural” (or “topological”) properties, the ones that can be deduced solely from the organization of its arcs. Formally, those properties are called invariants; to define them, we first need to say what a graph morphism is.

Given two graphs $G = (N_G, A_G)$ and $H = (N_H, A_H)$, a *graph morphism* is a function $f : N_G \rightarrow N_H$ such that $\langle x, y \rangle \in A_G$ iff $\langle f(x), f(y) \rangle \in A_H$. If f is a bijection, we say that f is a graph *isomorphism*; if such an isomorphism exists, we say that G and H are isomorphic and write $G \cong H$.

A *V -valued graph invariant* (Lovász 2012) is any function $\pi : \mathcal{G} \rightarrow V$ such that $G \cong H$ implies $\pi(G) = \pi(H)$: a graph invariant is a property of a graph that does not depend on its actual representation (i.e., on the names of its nodes) but only on the graph structure. Binary invariants are those for which $V = \{\text{true}, \text{false}\}$: for

instance, properties like “the graph is connected,” “the graph is planar,” and so on are all examples of binary graph invariants. Scalar invariants have values on a field (e.g., $V = \mathbb{R}$), for instance, “the number of connected components,” “the average length of a shortest path,” and “the maximum size of a connected component,” are all examples of scalar graph invariants. Distribution invariants take as value a *distribution*, for instance, “the degree distribution” or the “shortest-path-length distribution” are all examples of distribution invariants.

It is convenient to extend the definition of graph invariants to the case where the output is in fact a function assigning a value to each node. Formally, a V -valued *node-level graph invariant* is a function π that maps every $G \in \mathcal{G}$ to an element of V^{N_G} (i.e., to a function from N_G to V), such that for every isomorphism $f : G \rightarrow H$ one has $\pi(G)(x) = \pi(H)(f(x))$.

For example, suppose that π assigns to every graph G the function that maps each node $x \in N_G$ to the number of triangles (closed cycles of length three) involving x ; if $G \cong H$ and $x' \in N_H$ is the node of H that corresponds to $x \in N_G$, the number of triangles of H involving x' is the same as the number of triangles of G involving x , that is, $\pi(G)(x) = \pi(H)(x')$.

Introducing node-level graph invariants is crucial in order to be able to talk about graph centralities (Newman 2010). A node-level real-valued graph invariant that aims at estimating node importance is called a *centrality (index or measure)*; given a centrality index $c : N_G \rightarrow \mathbb{R}$, we interpret $c(x) > c(y)$ as a sign of the fact that x is “more important” (more central) than y . Since the notion of being “important” can be declined to have different meanings, in different contexts, many indices were proposed in the literature (Boldi and Vigna 2014); some of the most important ones will be mentioned in this section.

A notable, simple example of centrality in an undirected graph is simply node degree; in a friendship network, degree centrality amounts at measuring the importance of a node (person) by the number of friends (s)he has. As simple as it may seem, degree contains a lot of information,

and in some contexts it is actually almost as good as other more sophisticated alternatives (Craswell et al. 2003). We take this opportunity to notice that most centrality measures proposed in the literature were actually described originally only for undirected graphs; adapting those measures to the directed case often implies to choose between looking at incoming or outgoing paths: in the case of degree, for example, we should choose whether to consider in-degrees or out-degrees. In most cases, the so-called “negative” version (the one that considers incoming paths) is more meaningful than the “positive” alternative (Boldi and Vigna 2014). In-degree, for instance, is probably the oldest measure of importance ever used, as it is equivalent to majority voting in elections (where the presence of an arc $\langle x, y \rangle$ means that x voted for y).

Local Properties

The *average degree* of a graph m/n and its *density* m/n^2 ($e/\binom{n}{2}$) in the case of undirected graphs) determine how close the graph is to being a clique. A family of graphs is said to be *sparse* if their average degree is $o(n)$, *dense* if it is $\Theta(n)$.

A more fine-grained invariant measuring the density of a graph is given by its full *(in/out-)degree distribution*, a discrete distribution whose probability mass function evaluated at k is the fraction of nodes with (in/out-)degree k .

The degree distribution is quite distinctive and contains by itself much information about the structure of the graph. The degrees of a random graph (in the sense of Erdős and Rényi 1959) follow a binomial distribution. It was noted, however, that many networks corresponding to empirical phenomena have a peculiarly different behavior and were called scale-free: a graph is *scale-free* (Barabási and Albert 1999) if its degree distribution follows a power law, that is, if the cumulative function $F(\cdot)$ of its degree distribution has the property that

$$1 - F(x) \propto x^{-\gamma}$$

for some constant $\gamma > 1$.

The degree of a node tells us how many direct connections a node has but does not give any information about how much those neighbors are connected with one another. An informative index in this direction (a node-level graph invariant itself) is the *clustering coefficient* (Watts and Strogatz 1998) of node x , defined for undirected graphs by

$$\frac{\sum_{y \in N(x)} |N(y) \cap N(x)|}{d(x)(d(x) - 1)}.$$

This is the probability that two neighbors of x chosen at random turn out to be connected by an edge: its extreme values are 0 if $G[N(x)]$ is an independent set and 1 if $G[N(x)]$ is a clique. It is possible to extend this definition to the directed case, but we shall not discuss this extension here.

Of course the *distribution of clustering coefficients* can be used as a graph invariant; in particular, its average is a quite distinctive network feature, called *global clustering coefficient* (Newman 2003). An alternative (albeit not quite equal) definition used by some authors is the ratio between the number of closed triplets (i.e., induced complete subgraphs with three nodes) and the number of connected triplets (i.e., induced subgraphs with three nodes none of which has degree zero in the subgraph).

Paths and Connectivity

A *path* of length $k \geq 0$ from node x to node y is a sequence of nodes v_0, v_1, \dots, v_k such that $x = v_0$, $y = v_k$ and $\langle v_{i-1}, v_i \rangle \in A$ for all $i = 1, \dots, k$. A path is called a *cycle* if $k > 0$ and $x = y$ (in the undirected case it is also required that $v_{i-1} \neq v_{i+1}$ for all $i = 1, \dots, k - 1$). A graph with no cycles is called *acyclic*; in particular, if it is directed, it is called a *DAG* (directed acyclic graph); if it is undirected, it is called a *forest*.

A graph is *connected* if there is a path between every ordered pair of nodes; note that, in the case of directed graphs, this requirement implies that for any two nodes x and y , there is both a path from x to y and a path from y to x . Maximal sets of nodes that induce a connected subgraph

are pairwise disjoint, so they define a partition of the node set whose parts are called *connected components*.

In the case of undirected graphs, there can exist no edge between vertices belonging to different components; this is not true for directed graphs, but a similar property is true of cycles (there can be no cycles involving nodes in different components). An undirected connected acyclic graph (i.e., a connected forest) is called a *tree*.

The number of paths ending at a node x can be used to estimate its importance in the network; for example, *Katz's index* (Katz 1953) of node x is defined as

$$\sum_{t=0}^k \beta^t |G^t(-, x)|$$

where $G^t(-, x)$ is the set of paths of length t ending in x and β is a parameter that must be chosen so that $\beta < 1/\rho$ where ρ is the spectral radius of the adjacency matrix G (Gross and Tucker 1987).

Shortest Paths

A *shortest (or geodesic) path* is a path of shortest length connecting two given nodes; the *distance* $d(x, y)$ from node x to node y is the length of (any) shortest path from x to y or $+\infty$ if there is no such path. Note that $d(x, y) = d(y, x)$ if the graph is undirected, whereas this is not true in general for directed graphs.

For every node x , the maximum distance from x to any other node $\max_y d(x, y)$ is called the *out-eccentricity* of x ; in-eccentricity is defined analogously; in the undirected case they of course coincide and are simply called "eccentricity." The maximum eccentricity (i.e., the maximum distance between any two nodes) is called the *diameter* of the graph; the diameter is finite only if the graph is strongly connected. Eccentricity (i.e., maximum distance to/from a node), or more precisely its reciprocal, is a natural centrality index, but it is very sensitive to outliers;

a smoother alternative is closeness centrality that corresponds, up to constants, to (the reciprocal of the) average distance. More precisely, the *closeness centrality* (Bavelas 1948) of x is defined as

$$\frac{1}{\sum_y d(y, x)}.$$

The summation ranges over the nodes y for which $d(y, x)$ is finite (otherwise, in non-strongly connected graphs, almost all nodes would have null centrality). An alternative definition, which works better in the non-strongly connected case, is *harmonic centrality* (Harris 1954; Boldi and Vigna 2014), defined for a node x as

$$\sum_y \frac{1}{d(y, x)}$$

where this time the summation is over all $y \neq x$, with the proviso that $1/\infty = 0$.

Eccentricity, closeness, and harmonic may all be seen as variants of the same idea of measuring centrality the centrality of a node x through the set of distances $d(-, x)$: such centralities are called *geometric* (Boldi and Vigna 2014). A quite popular centrality index, which is also related to shortest paths, but not to distances in the strict sense, is *betweenness* (Anthonisse 1971; Freeman 1977); the betweenness centrality of a node x is defined as

$$\sum_{u,v} \frac{\sigma_{u,v}(x)}{\sigma_{u,v}}$$

where $\sigma_{u,v}$ is the number of shortest paths from u to v and $\sigma_{u,v}(x)$ is the number of such paths that pass through x ; the summation is extended over all pairs u, v (both distinct from x) such that $u \neq v$ and there is a path from u to v .

Special Invariants

Spectral graph theory (Cvetkovic and Rowlinson 2004) studies invariants that are related to the

eigenvalues and eigenvectors of the adjacency matrix of the graph or of some matrices derived from it. There is by now an immense body of literature showing the deep and unexpected connections between spectral properties and topological structure, in some cases leading to interesting node-level invariants.

The first and most obvious spectral centrality (called the *Wei-Berge index*) is the left dominant eigenvector of the adjacency matrix G itself (Berge 1958). But other centrality measures are of spectral nature; for instance, it turns out that Katz's index is the left dominant eigenvector of a perturbed version of the adjacency matrix:

$$\beta\lambda G + (1 - \beta\lambda)\mathbf{e}^T \mathbf{1}, \quad (1)$$

where λ is the dominant eigenvalue of G and \mathbf{e} is a right dominant eigenvector of G such that $\mathbf{1}\mathbf{e}^T = \lambda$ (Vigna 2016).

As another example, define \bar{G} as the matrix obtained by dividing each nonnull row of G by its L^1 -norm and substituting null rows with $\mathbf{1}/n$. The left dominant eigenvector of the matrix

$$\alpha\bar{G} + (1 - \alpha)(\mathbf{1}/n)^T \mathbf{1}, \quad (2)$$

is the well-known *PageRank* centrality index (Brin and Page 1998). Since \bar{G} has dominant eigenvalue 1, the analogy with (1) should be clear. The popularity of PageRank is related to the fact that it was supposedly used by Google to rank websites in their search engine results.

Alternative Definitions

The graph definitions considered in this section (directed and undirected graphs) are only the two most important representatives of a wide spectrum of objects that are subtly different and may be called themselves “graphs” or “networks” without further specification, largely depending on the research area and context.

A *weighted graph* is a graph endowed with a weighting function that assigns a weight (a

positive real number, usually) to each node or arc (edge, in the case of undirected graphs). Weighted graphs appear in a variety of situations, and typically one wants to take weights into account when dealing with a weighted graph. All the definitions and properties discussed above can be adapted to the weighted case. For example, the length of a path in an arc-weighted graph is usually defined as the sum of the weights of the arcs along the path; obviously, under this definition, shortest paths have no longer the minimum number of arcs, and the distance between two nodes is not an integer anymore, in general. In some cases, the modification needed to deal with the weighted case is straightforward; in other cases, some domain knowledge (of the meaning behind weights) is required to decide how the definitions should be modified.

An *uncertain graph* (Jin et al. 2011) is special type of weighted graph whose weights are interpreted as probabilities (and, therefore, are constrained to be values between 0 and 1). An uncertain graph U with n nodes may be interpreted as a compact way to define a distribution over the graphs of n nodes, in which only arcs of U may appear and every arc is drawn independently with a probability equal to its weight. They are a natural generalization of Erdős-Rényi random graphs (Erdős and Rényi 1959) (that are equivalent to uncertain cliques with constant weights).

A *multigraph* (Gross and Tucker 1987) is a graph whose arcs are a multiset and not a set; in other words, there may be more than one arc connecting two nodes. Again, many of the definitions carry over to this case without almost any effort.

A k -*hypergraph* (Berge 1984) is an undirected graph whose edges (called “hyperedges”) are not pairs, but rather sets of nodes of cardinality k .

Graph aggregation; Graph analytics; Graph Summarization

Definitions

Online analytical processing (OLAP) comprises tools and algorithms that allow querying multidimensional databases, where data can be seen as a cube and each cell contains one or more measures that can be aggregated along dimensions. A graph database management system (GDMS) allows creating, reading, updating, and deleting a graph data model. Graph databases provide better support for graph data management than relational databases, mainly due to the fact that relational databases deal just implicitly with connected data, while graph databases store actual graphs. Applying OLAP techniques to graph databases is denoted Graph OLAP.

Overview

Two graph database models are used in practice:

- (a) Models based on RDF (Hayes and Patel-Schneider 2014), oriented to the Semantic

Web. A practical example of this model is AllegroGraph.

- (b) The models based on Property Graphs. An example of this model is Neo4J.

Models of type (a) represent data as sets of triples, where each triple consists of three elements that are referred to as the subject, the predicate, and the object of the triple. These triples allow describing arbitrary objects in terms of their attributes and their relationships to other objects. An important feature of RDF-based graph models is that they follow a standard, which is not the case for the other graph databases at the moment of writing this entry. In the *Property Graph* data model, nodes and edges are labeled with a collection of (attribute-value) pairs. Hartig (2014) presented a formal way of reconciling both models through a collection of well-defined transformations between Property Graphs and RDF. In that work, the author proves that Property Graphs could, in the end, be queried using SPARQL (Harris and Seaborne 2012), the standard query language for the Semantic Web.

Graph data management systems can also be classified in many other ways. For example, *graph databases* are in general adequate for medium-sized graphs, since they do not partition the graph for parallel processing. When there is the need to handle very large graphs, the so-called graph processing frameworks are used. Further, graphs whose nodes are of the same kind are denoted *homogeneous*. Opposite to this, graphs that can have nodes of different kinds are called *heterogeneous*. Finally, graphs can be classified according to their temporal support: graphs that do not change across time are called *static*, and they basically represent a snapshot of a network at a certain moment in time. However, in real-world applications, graphs change over time. A typical example is social networks, where people add and delete connections and/or change communication patterns. This extends to almost every application field. Graphs accounting for the time dimension are called *dynamic*, and they are aimed at representing the history of the network. Sometimes they are also called

temporal graphs. A particular and novel variation of dynamic graphs are *stream graphs*, where edge (and possibly node) streams arrive in real time.

Graph analytics has been steadily gaining momentum in the data management community, since many real-world applications are naturally modeled as graphs, in particular in the domain of social network analysis. Given the extensive use of graphs to represent practical problems, multidimensional analysis of graph data and graph data warehouses are promising fields for research and application development. There is a need to perform graph analysis from different perspectives and at multiple granularities. This poses new challenges to the traditional OLAP technology. This is generically called Graph OLAP. The remainder of this entry will address research on this topic.

Key Research Findings

This section starts with a review on graph summarization. Graph OLAP is then discussed. Finally, relevant contributions on analytics over dynamic graphs are presented.

Graph Summarization

Graph summarization is a critical operation for multilevel analysis of graph data and must be accounted for when addressing OLAP on graphs. However, early work on graph summarization was aimed at different goals, mainly trying to find a smaller representation of the input graph, which can reveal patterns in the original data preserving specific structural properties. This is why graph summarization is also called graph coarsening. Thus, graph summarization aims at (a) reducing the data volume producing a graph summary of the original graph, (b) speeding up algorithms, (c) noise elimination, and (d) effective visualization. Graph summarization will be discussed below, although its goal is in some sense broader than the one of Graph OLAP, which mainly refers to exploratory and interactive data analysis on graphs.

The work by Tian et al. (2008) introduces the SNAP operation (standing for summarization by grouping nodes on attributes and pairwise relationships) to produce a summary graph by grouping nodes based on node attributes and relationships selected by the user. The k-SNAP operation is proposed, allowing drilling down and rolling up at different aggregation levels. The work also presents an algorithm to evaluate the SNAP operation, shows that the k-SNAP computation is NP complete, and proposes two heuristic methods to approximate the k-SNAP results. Nodes are aggregated based on the strength of the relationships between them.

OLAP on Graph Data

A first approach to performing OLAP on graphs is called *Graph OLAP* (Chen et al. 2009) and presents a multidimensional and multilevel view of graphs. To illustrate the idea, consider a set of authors working in a given field, say data warehouses. If two persons coauthored x papers in the DaWaK 2009 conference, a link is added between them, which has a collaboration frequency attribute x . For every conference in every year, there is a coauthor graph describing the collaboration patterns between researchers. Thus, each graph can be viewed as a snapshot of the overall collaboration network. These graphs can be aggregated in an OLAP style. For instance, graphs can be aggregated to obtain the collaborations by conference type and year for all pairs of authors. For this, nodes and edges in each snapshot graph must be aggregated according to the conference type (e.g., database conferences) and by year. For example, if there is a link between two authors in the SIGMOD and VLDB conferences, the nodes and the edges will be in the aggregated graph corresponding to the conference type "Databases." More complex patterns can be obtained, for example, by merging the authors belonging to the same institution, enabling to obtain patterns of collaboration between researchers of the same institutions. In *Graph OLAP*, dimensions are classified as *informational* and *topological*. The former are close to traditional OLAP dimension hierarchies using information of the snapshot levels, for example,

Conference → Field → All. They can be used to aggregate and organize snapshots as explained above. Topological dimensions can be used for operating on nodes and edges within individual networks. For example, a hierarchy for authors like **AuthorId → Institution** will belong to a topological dimension since author institutions do not define snapshots. These definitions yield two different kinds of *Graph OLAP* operations. A roll-up over an informational dimension overlays and joins snapshots (but does not change the objects), while a roll-up over a topological dimension merges nodes in a snapshot, modifying its structure.

Graph Cube (Zhao et al. 2011) is a model for graph data warehouses that supports OLAP queries on large multidimensional networks, accounting for both, attribute aggregation and structure summarization of the networks. A multidimensional network consists of a collection of vertices each one of which contains a set of multidimensional attributes describing the node properties. For example, in a social network, nodes can represent persons, and multidimensional attributes may include **UserID**, **Gender**, **City**, etc. Thus, multidimensional attributes in the graph vertices define the dimensions of the graph cube. Measures are aggregated graphs summarized according to some criteria. Opposite to *Graph OLAP*, where the model consists in several snapshots, in *Graph Cube* there is only one large network, leading to a graph summarization problem. For example, consider a small social network with three nodes, two of them corresponding to male individuals in the network, while the other one corresponds to a female. A graph that summarizes the connections between genders will have two nodes, one labeled **male** and the other labeled **female**. The edges between them will be annotated with the number of connections of some kind. For instance, if in the original graph there were two connections between two male persons (in both directions), the summarized graph will contain a cycle over the **male** node, annotated with a “2.” If there was just one connection between a woman and a man, there will be an edge between nodes **male** and **female** annotated with a “1.”

Based on the idea of defining graphs at different levels of aggregation, denoted graph cuboids, *Distributed Graph Cube* (Denis et al. 2013) presents a distributed framework for graph cube computation and aggregation, implemented using Spark and Hadoop. This proposal addresses homogeneous graphs. Along the same lines, *Pagrol* (Wang et al. 2014) introduces a MapReduce framework for distributed OLAP analysis of homogeneous attributed graphs. *Pagrol* extends the model of *Graph Cube* by considering the attributes of the edges as dimensions. The idea behind these two proposals is similar: to efficiently compute all possible aggregations of a homogeneous graph.

To handle heterogeneous graphs, and also starting from the topological and informational dimensions introduced in Chen et al. (2009), Yin et al. (2012) proposed a data warehousing model based on the notion of entity dimensions. In this work, two basic operations are defined, namely, rotate and stretch, which allow defining different views of the same graph, defining entities as relationships and vice versa.

Gómez et al. (2017) propose a formal multidimensional data model for graph analysis, where graphs are node- and edge-labeled directed multi-hypergraphs, called *graphoids*, defined at several different levels of granularity, according to dimension hierarchies associated with them. Over this model, the authors define Graph OLAP operations. This model addresses heterogeneous graphs.

Dynamic Graph Analytics

The methods discussed above apply, basically, to static graphs. The work on dynamic graph analytics has mainly focused in graph mining rather than in graph summarization and temporal Graph OLAP. However, some works on graph summarization and temporal OLAP are briefly commented below.

An early approach to dynamic graph summarization consisted in creating an aggregate graph that summarizes the input dynamic one, based on how recent and frequent were the interactions. This is called an *approximation graph* (Hill et al. 2006; Sharan and Neville 2008). The approxi-

mation graph is built aggregating the node interactions across time, giving a weight to them, and this weight is higher when the interactions are more recent and frequent. These solutions are used for mining and visualization. Another approach is based on compression techniques. This is the case of *TimeCrunch* (Shah et al. 2015), which aims at extracting meaningful patterns from temporal data, in order to describe a dynamic graph. The method first generates static subgraph instances in each defined time stamp, labels each instance using a dictionary of static templates (e.g., star, clique, chain), and puts them together to form temporal instances. Then, it labels each structure using a dictionary of temporal signatures (e.g., one-shot, ranged, periodic). Finally, it selects for the summary the temporal structures that produces the shortest lossless decomposition (MDL) for describing the time-evolving graph.

A temporal graph model has been presented in Cattuto et al. (2013), where temporal data are organized in so-called frames, namely, the finest unit of temporal aggregation. A frame is associated with a time interval and allows to retrieve the status of the social network during such interval. A limitation of the model is that it does not allow registering changes in attributes of the nodes and that frame nodes become too cluttered with edges.

A proposal for temporal OLAP on graphs was introduced by Campos et al. (2016). Here, a temporal model for graphs is presented, based on Property Graphs, along with a query language, which extends Cypher with temporal capabilities.

Examples of Applications

Graph summarization can be applied in several different settings. On the technical side, for improving graph query efficiency, for example, some queries can be answered using a summary graph instead of the whole one. This happens in social network analysis when issuing a typical query to compute whether an edge exists between two nodes, which can be evaluated more

efficiently over a summary rather than on the whole network. Summarization is also relevant for graph visualization since, normally, graphs are too large to visualize in an effective way. Pattern discovery is also a field of application of graph summarization and Graph OLAP. Patterns or outliers that are not immediately noticeable over the whole graph can become evident on certain summarizations along some dimensions.

G

Future Directions of Research

There is a consensus in the database community in that novel models and techniques are required for enabling multidimensional analysis of big data (Cuzzocrea et al. 2013). From the discussion in this entry, it follows that several challenges arise: on the one hand, traditional data warehousing and OLAP operations on cubes are clearly not sufficient to address the current data analysis requirements; on the other hand, OLAP operations and models can expand the possibilities of graph analysis beyond the traditional graph-based computation, like shortest-path, centrality analysis and so on. Nevertheless, from the discussion in the present entry, it is clear that there is still no consensus on what Graph OLAP means. Each proposal commented above presents a different model, with different operators. Therefore, the main challenge for the OLAP and databases communities is to agree in the model and operators for Graph OLAP.

Many challenges in Graph OLAP occur in the field of dynamic graphs. As expressed above, summarization techniques for these kinds of graphs have not been studied as in the case of static graphs. The addition of the time dimension introduces many problems, not only theoretical but also practical. Analogously to the case of temporal relational databases, recording the history of graph data involves enormous amounts of data, which is also highly dependent on the time granularity that is chosen. Temporal query languages for graphs and query processing techniques must be developed. Temporal graph summarization also opens many

research opportunities in the graph visualization field. Finally, stream processing for (dynamic) graphs is still in its infancy, and there is a fertile field of research there.

Graph Partitioning: Formulations and Applications to Big Data

Christian Schulz¹ and Darren Strash²

¹University of Vienna, Vienna, Austria

²Department of Computer Science, Colgate University, Hamilton, NY, USA

Definitions

Given an input graph $G = (V, E)$ and an integer $k \geq 2$, the *graph partitioning problem* is to divide V into k disjoint blocks of vertices V_1, V_2, \dots, V_k , such that $\cup_{1 \leq i \leq k} V_i = V$, while

simultaneously optimizing an objective function and maintaining balance: $|V_i| \leq (1 + \epsilon) \lceil |V|/k \rceil$ for some $\epsilon \geq 0$.

Overview

Subdividing a problem into manageable pieces is a critical task in effectively parallelizing computation and even accelerating sequential computation. A key method that has received a lot of attention for doing so is *graph partitioning*. The simplest and most common form of graph partitioning asks for the vertex set to be partitioned into k roughly equal-sized blocks while minimizing the number of edges between the blocks (called *cut edges*). Even this most basic variant is NP-hard (Hyafil and Rivest 1973). Graph partitioning has many application areas, including VLSI (Karypis et al. 1999), scientific computing (Langguth et al. 2015), designing scalable distributed systems (Shalita et al. 2016), and genome sequencing (Jammula et al. 2017). Given its usage in many varied areas, it is critical to understand how a high-quality graph partition can be computed and used in practice.

Here, we give a structured overview of different graph partitioning formulations and applications in the *big data* context. More specifically, we give in-depth prototypical applications in this context and outline points where application-specific tailor-made graph partitioning algorithms may exist or would be highly useful. For a more detailed picture on how the field has evolved, we refer the interested reader to a number of surveys (Bichot and Siarry 2011; Schloegel et al. 2003; Buluç et al. 2016; Kim et al. 2011).

Preliminaries

In the remainder of the entry, we use the following notation. A graph $G = (V, E, c, \omega)$ consists of a vertex set $V = \{0, 1, \dots, n - 1\}$ of n vertices and a set $E \subseteq \{\{u, v\} : u, v \in V\}$ of m undirected edges formed between pairs of vertices. Nodes and edges may have a real-

valued weight, given by $c : V \rightarrow \mathbb{R}_{\geq 0}$, $\omega : E \rightarrow \mathbb{R}_{> 0}$. For brevity, c and ω are defined on sets as $c(V' \subseteq V) := \sum_{v \in V'} c(v)$ and $\omega(E' \subseteq E) := \sum_{e \in E'} \omega(e)$. For unweighted graphs, node and edge weights are one. We further let $d(v)$ be the *degree* of the vertex v , which is the size of v 's neighborhood $N(v) = \{u \in V : \{u, v\} \in E\}$.

G

Key Research Findings

The goal of graph partitioning is to partition the graph into roughly equal-sized subgraphs, called *blocks*, while optimizing an objective function. Many flavors of graph partitioning exist and can be categorized by the objectives and the graph primitives (vertices or edges) that make up the blocks.

Vertex-Based Partitioning

Vertex-based partitioning is the most common formulation of graph partitioning. Given an input graph $G = (V, E)$ and an integer $k \geq 2$, V must be divided into k disjoint blocks of vertices V_1, V_2, \dots, V_k , such that $\cup_{1 \leq i \leq k} V_i = V$ and $V_i \cap V_j = \emptyset, \forall i \neq j$, which is called a k -way partition. The goal is to minimize (or maximize) an objective function, subject to the constraint that blocks are balanced according to the *balancing constraint*: for all $i \in \{1, \dots, k\}$: $|V_i| \leq L_{\max} = (1 + \epsilon) \lceil |V|/k \rceil$ for some imbalance parameter $\epsilon \geq 0$. The most common objective is to minimize the total *cut*, $\sum_{i < j} \omega(E_{ij})$, where $E_{ij} = \{\{u, v\} \in E : u \in V_i, v \in V_j\}$.

This variant of graph partitioning is NP-hard by a reduction from 3SAT (Hyafil and Rivest 1973) and is even hard to approximate within a constant factor (Andreev and Räcke 2006). Therefore, no efficient algorithm is currently known for solving the problem exactly, and perhaps no efficient algorithm exists. Therefore, heuristic methods are used in practice to attempt to minimize the objective function while maintaining the balancing constraint. Many methods exist for this purpose and are very successful in practice.

Although the vast majority of techniques for graph partitioning are for graphs that fit into memory on a single machine, these techniques are sufficient for many big data problems. For example, to process large datasets in parallel, a graph representing the communication required for these computations, or for the dependencies between computations, can be formed. While the data may not fit into memory, the graph may. For graphs that fit into memory on a single machine, the fastest techniques in practice include variants of the KL/FM local search algorithm (Fiduccia and Mattheyses 1982), which efficiently swap nodes between partitions and keep the assignment with lowest cut size. For balancing quality and speed, the *multilevel* approach (Hendrickson and Leland 1995; Sanders and Schulz 2011) contracts subgraphs of the graph in a coarsening phase, solves the smaller instance with a high-quality (but slow) partitioner, and uncontracts while applying local search. For high-quality partitions, methods using max-flow/min-cut are used (Sanders and Schulz 2011, 2013). Other techniques include evolutionary methods (Kim et al. 2011), diffusion (Meyerhenke and Sauerwald 2012), and spectral methods (Alpert et al. 1999). For an overview of in-memory techniques, see the survey by Buluç et al. (2016).

Though these techniques have an important place in graph partitioning, they are sparingly used to process massive datasets – those that do not fit into the working memory of a single machine.

Techniques for Massive Graphs

Recent research focuses on solving much larger instances, either by using external memory (i.e., using the disk) or in a distributed setting. These methods use variants of the *label propagation* algorithm initially proposed by Raghavan et al. (2007) for graph clustering. Label propagation is used as a parallel local search algorithm (Ugander and Backstrom 2013; Aydin et al. 2016; Slota et al. 2017), and in some approaches it is additionally used to find clusterings that are contracted in a multilevel scheme (Meyerhenke et al. 2017; Akhremtsev et al. 2015). Using these

techniques complex networks with up to a trillion edges can be partitioned.

Objective Functions

Cut Size. As discussed above, the most common objective function is to minimize the total cut size $\sum_{i < j} \omega(E_{ij})$. A related objective is to minimize the *maximum cut size* $\max_{i < j} \omega(E_{ij})$. Minimizing the cut size is useful in reducing the amount of computation required by combinatorial optimization problems, where the strategy is to subdivide the graph into blocks that are solved independently (possibly in parallel) and combine these solutions optimally (using branch and bound along the boundary vertices) or approximately by stitching together solutions across the cut edges (Lamm et al. 2017).

Communication Volume. In parallel computing, the *communication volume* is often more representative than the cut (Hendrickson and Kolda 2000). Let V_ℓ be the block containing vertex v . Then we let $D(v)$ denote the number of blocks in which vertex v has a neighbor, excluding the block containing v . That is, $D(v) = |\{j : \exists u \in V_j \neq V_\ell \text{ s.t. } \{u, v\} \in E\}|$. For a block V_i , the *total communication volume* is $\text{comm}(V_i) := \sum_{v \in V_i} c(v)D(v)$. Similar to cut size, one can minimize the *maximum communication volume* $\max_{1 \leq i \leq k} \text{comm}(V_i)$ or the *total communication volume* $\sum_{1 \leq i \leq k} \text{comm}(V_i)$. Suppose that c maps a vertex to its data size, and whole blocks of vertices are stored on a single machine, then the total communication volume represents the total amount of bandwidth needed to communicate data between adjacent blocks simultaneously, and the maximum communication volume would represent the maximum bandwidth required for communicating from a single block. Choosing the total or maximum variant of the objective function here is typically dictated by the topology of the interconnection network (Hendrickson and Kolda 2000).

Other Objectives are less common; these include the maximum degree in the *quotient graph* (the graph formed by blocks and their connections), expansion and conductance (Lang and Rao 2004), and optimizing the “shape” of partitions (Meyerhenke and Sauerwald 2012).

Edge-Based Partitioning

Edge-based partitioning is a relatively new formulation that partitions the *edges* of the input graph into k blocks of roughly the same number of edges. The objective now is to minimize the number of partitions in which each vertex is a member (Gonzalez et al. 2012). This formulation was introduced for PowerGraph (Gonzalez et al. 2012), an extension of the think-like-a-vertex (TLAV) model of computation (McCune et al. 2015) that focuses on dividing *edges* among machines, which requires vertex-centric computations to be duplicated across machines to avoid communication overhead introduced by high-degree nodes in power-law graphs. In this model, a balanced edge-based partition ensures that little communication occurs between machines containing the same vertex.

More formally, the objective is to divide the edges into k blocks $E_1, \dots, E_k \subseteq E$ such that for all $i \neq j$, $E_i \cap E_j = \emptyset$ and $\cup_{1 \leq i \leq k} E_i = E$. For each vertex v_i , denote by $A_i = \{j : \exists u \in V \text{ s.t. } \{u, v_i\} \in E_j\}$ the set of *replicas* of v_i . Then the goal is to minimize the average number of replicas $\frac{1}{|V|} \sum_{v_i \in V} |A_i|$ while satisfying the balance constraint $\max_{1 \leq i \leq k} |E_i| < (1 + \epsilon) \frac{|E|}{k}$ for some $\epsilon \geq 0$. This models the total communication between machines performing computations for that vertex.

Like other graph partitioning formulations, edge-based partitioning is NP-hard (Bourse et al. 2014), and constant factor approximations cannot be computed in polynomial time unless $P = NP$. However, Bourse et al. (2014) gave a polynomial time $O(\sqrt{\log k \log n})$ -approximation algorithm.

If the graph fits into memory, edge-based partitioning can be solved by forming a hypergraph with a node for each edge in E , and a hyperedge for each node, consisting of the edges to which it is incident. Thus, general hypergraph partitioners can be applied to this problem; however, they are more powerful than necessary, as this conversion has mostly small hyperedges.

This problem can also be solved with vertex-based graph partitioning, by creating a new graph

G' with the *split-and-connect transformation* (SPAC) of Li et al. (2017), which splits vertices and links them together, assigning weights to prevent certain edges from being cut. Then a vertex-based partition of G' gives an edge-based partition of the input graph. Combining SPAC with the kMetis partitioner gives partitions of quality comparable to hypergraph partitioning, but up to hundreds of times faster. It also gives much higher-quality partitions than streaming partitioners (discussed next); however, streaming algorithms are designed to handle massive graphs in a distributed setting.

G

Techniques for Massive Graphs

Gonzalez et al. (2012) investigate the streaming case, where edges are assigned to partitions in a single pass over the graph. They investigated randomly assigning edges to partitions, as well as a greedy strategy that prioritizes partitions that already cover a vertex incident to the edge (to avoid replicating the vertex). Their greedy method gives an average of *five* replicas per vertex for power-law graphs, and it is possible to maintain the partition information in a distributed table, giving a significant speed up over TLAV implementations. Bourse et al. (2014) later improved the replication factor by weighting each vertex by its degree. Rahimian et al. (2014) present a parallel and distributed algorithm for large graphs which is essentially a local search algorithm that iteratively improves an initial random assignment of edges to partitions.

Examples of Application

We now discuss applications of graph partitioning in the big data context.

High-Performance Computing. Scientific computing is one of the main applications and motivators for graph partitioning techniques. Typical applications in this area include lattice Boltzmann methods (Langguth et al. 2015) and simulations using the finite element method (Zhou et al. 2010) or finite volume method (Fietz et al. 2012), all of which need to partition a model of computation

and communication in order to run on a parallel computer. In this model vertices denote computation and edges represent communication. In large-scale simulations, models can contain billions of elements and simulations involve more than 100 k processors (Zhou et al. 2010). Graph partitioning is used to partition the model and then distribute the computation over a given number of processing elements while minimizing the communication overhead. For large-scale simulations, it can be helpful to choose groups of mesh nodes (Fietz et al. 2012). We very briefly outline the finite element method (leaving out technical details) and then relate it to graph partitioning.

In scientific simulations one often wants to compute an approximation to some partial differential equation that models a physical process. We use the heat equation to illustrate that. Let Ω be a region. The system that one wants to solve here is $-\Delta u = f$ in Ω with $u = 0$ on $\partial\Omega$ where $\Delta = \sum \partial_{ii}$ – the sum of the second-order derivatives. The problem asks for a function u in some function space \mathcal{V} that solves the system. However, the solution space does usually not have finite dimension. Hence, one seeks an approximation to the system. One possibility to do so is to use weak formulations of the system: Find $u \in \mathcal{V}$ such that $a(u, v) = (f, v) := \int_{\Omega} fv dx \forall v \in \mathcal{V}$ where $a(u, v) := \int_{\Omega} \nabla u \cdot \nabla v dx$ is a continuous bilinear map. In a second step, the solution space is approximated by a vector space of finite dimension, e.g., choosing $\mathcal{V}_h := \text{span}\{\phi_1, \dots, \phi_n\} \subset \mathcal{V}$ for some ϕ_i . The weak formulation now becomes: Find $u_h \in \mathcal{V}_h$ such that $a(u_h, \phi) = (f, \phi) \forall \phi \in \mathcal{V}_h$. First, since \mathcal{V}_h has finite dimension, there are $\alpha_i \in \mathbb{R}$ such that $u_h = \sum_{i=1}^n \alpha_i \phi_i$. Hence, one wants to find α_i such that $a(\sum_{i=1}^n \alpha_i \phi_i, \phi) = (f, \phi) \forall \phi \in \mathcal{V}_h$ which is easily rewritten to $\sum_{i=1}^n \alpha_i a(\phi_i, \phi_j) = (f, \phi_j) \forall j \in \{1, \dots, n\}$. This however means that one can solve a linear equation system $Ax = b$ with $a_{ij} = a(\phi_i, \phi_j)$ and $b_i = (f, \phi_i)$. Also note that due to the approximation that is done here, the output solution may differ from the real solution, e.g., there are errors involved. Roughly speaking, in practice one increases n to reduce

the error which is why the linear equation systems become very large. However, typically the arising equation systems are sparse and solved using an iterative method such as the Jacobi method which requires sparse matrix-vector multiplication as a core component. In essence, at each time step, one has an approximate solution x_k to the linear equation system and computes a new approximation x^{k+1} using the equation $x^{k+1} = D^{-1}(b - Rx^k)$ where $D = \text{diag}(A)$, $R = A - D$. The process is repeated until the residual error is small. One approach to parallelize the computation is to distribute columns of A and x over equally processors such that communication is minimized. To build our model of computation and communication, one rewrites the iterative formula as $x_i^{k+1} = \frac{1}{a_{ii}}(b_i - \sum_{j \neq i} a_{ij} x_j^k)$.

It is now easy to define a graph/model $G = (\{1, \dots, n\}, E)$ which has one node per column of the matrix and edges such that $e = \{i, j\} \in E \Leftrightarrow a_{i,j} \neq 0$. Since the amount of computation for a node is proportional to its degree, one uses vertex degrees as vertex weight. Additionally, one associates $x_i^k, x_i^{k+1}, A_{i,*}$ with node $i \in V$. After partitioning the model, PE l obtains columns associated with block V_l , stores $x_i^k, x_i^{k+1}, A_{i,*}$, and computes x_i^{k+1} for $i \in V_l$.

Decades ago, minimizing edge cut was the way to go since in meshes it is highly correlated with communication volume. For networks with complex structure, it is more important to optimize the total/maximum communication volume (Buluç and Madduri 2012).

Scalable Distributed Systems. Large companies that offer web services to users like Amazon, Facebook, Google, or Twitter face the problem of distributed system design. Assigning components in a distributed system has a significant impact on performance, as well as resource usage. A problem that often arises is to assign users to servers or data records to storage units (Tran et al. 2012). This is a prototypical big data application as the underlying networks that need partitioning often contain billions of vertices and trillions of edges (Shalita et al. 2016). Shalita et al. (2016) disclose two concrete applications used at Facebook: HTTP request

routing optimization and storage sharding optimization.

For example, in HTTP request routing, HTTP requests have to be assigned to compute clusters. If a HTTP request arrives, any required data to serve the request has to be fetched from external storage servers and will be cached in a local main memory-based cache. Intuitively, it is clear that HTTP requests that request similar data should be assigned to the same compute cluster to use the main memory-based caches efficiently. As friends and socially similar users tend to consume the same data, the static assignment is done by partitioning a graph where vertices represent users and edges represent friendships between them. Here, the edge cut is used as the optimization objective.

Large-Scale Biology Applications. There are numerous big data applications in biology that use graph partitioning techniques, for example, 3D cell nuclei segmentation and sequencing datasets for parallel genomics analyses.

Recent advances enabled researches to do in vivo investigation of biological structures. The instances can contain images with total size of about 10 TB per embryo (Tomer et al. 2012). This yields demand for automated methods to process these images. Arz et al. (2017) use graph partitioning to split the connected components of a binarized image recursively. The graph model of a connected component is built by setting foreground voxels to be vertices and inserting edges between neighboring cells. Edge weights depend on the likelihood that vertices belong together.

Nowadays, high-throughput sequencing machines allow researchers to generate massive numbers of short genomic fragments (reads) per run. Sequencing has become an important technology for a wide range of applications. In many of these applications, mapping sequenced reads to their potential genomic origin is the first fundamental step for subsequent analyses. The large amounts of data generated from such machines present significant computational challenges for analysis. Jammula et al. (2017) present a parallel algorithm for partitioning

large-scale read datasets in order to facilitate distributed-memory parallel analyses. Roughly speaking, a de Bruijn graph represents overlaps between the reads that have been computed by the sequencing machine. The algorithm works as follows: build a de Bruijn graph from the given set of input reads, compact it to reduce its size, partition the resulting graph using a standard parallel graph partitioning algorithm, and then generate a partition of the read dataset from the partition of the de Bruijn graph. This enables further analyses that run on the distributed memory machine to run efficiently.

Synonyms

Navigational queries; Path queries; Regular path queries

Definitions

Navigational query languages for graph databases allow to recursively traverse the edges of a graph while checking for the existence of a path that satisfies certain regular conditions. The basic building block of such languages is the class of *regular path queries* (RPQs), which are expressions that compute the pairs of nodes that are linked by a path whose label satisfies a regular expression. RPQs are often extended with features that turn them more flexible for practical applications, e.g., with the ability to traverse edges in the backward direction (RPQs with *inverses*) or to express arbitrary patterns over the data (*conjunctive* RPQs).

Overview

Graph Databases

Graph databases provide a natural encoding of many types of data where one needs to deal with objects and relationships between them. An object is represented as a node, and a relationship between two objects is represented as an edge, where labels are assigned to these edges to indicate what types of relationships they represent. This interpretation of data often arises in situations where one needs to *navigate* in the graph

and reason about the *paths* in it. To talk about such navigation, we can abstract graph databases as edge-labeled graphs. Formally, assuming that \mathbf{L} is a fixed infinite set of edge labels, we have the following formal definition of a graph database.

Definition 1 A graph database G is a pair (N, E) , where:

1. N is a finite set of *nodes*; and
2. E is a finite set of *labeled edges*, that is, a finite subset of $V \times \mathbf{L} \times V$. \square

Example 1 Figure 1 shows a simple graph database $G = (N, E)$ storing information about people and their relationships. Here N has four nodes:

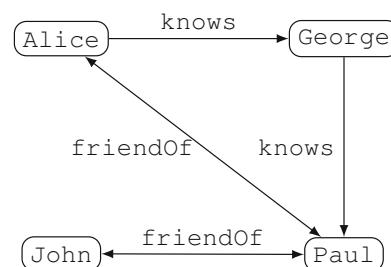

{Alice, George, John, Paul}

and E contains six labeled edges:

$\{(Alice, \text{knows}, George),$
 $(George, \text{knows}, Paul),$
 $(Alice, \text{friendOf}, Paul),$
 $(Paul, \text{friendOf}, Alice),$
 $(John, \text{friendOf}, Paul),$
 $(Paul, \text{friendOf}, John)\}$. \square

Path Queries

The simplest type of query on a graph database extracts nodes according to the relationship between them. We assume that \mathbf{V} is an infinite set

Graph Path Navigation, Fig. 1 A graph database

of variables that is disjoint with \mathbf{L} . Then given $x, y \in \mathbf{V}$ and $\ell \in \mathbf{L}$, the following is a basic query

$$x \xrightarrow{\ell} y$$

that asks for the pairs of nodes in a graph database connected by an edge-labeled ℓ . The semantics of a such a query Q on a graph database $G = (N, E)$, denoted by $\llbracket Q \rrbracket_G$, is the set of *matchings* $h : \{x, y\} \rightarrow N$ such that $(h(x), \ell, h(y)) \in E$.

Example 2 Evaluating the basic query $Q_1 = x \xrightarrow{\text{knows}} y$ over the graph database G in Fig. 1 produces as a result:

	x	y
h_1	Alice	George
h_2	George	Paul

As depicted in the table, we have that $\llbracket Q_1 \rrbracket_G = \{h_1, h_2\}$, where $h_1(x) = \text{Alice}$, $h_1(y) = \text{George}$, $h_2(x) = \text{George}$, and $h_2(y) = \text{Paul}$.

□

While basic queries like the one above allow for extracting valuable information from a graph database, it is often useful to provide more flexible querying mechanisms that allow to *navigate* the topology of the data. One example of such a query is to find all friends-of-a-friend of some person in a social network. We are not only interested in immediate acquaintances of a person but also in people he/she might know through other people, namely, his/her friends-of-a-friend, their friends, and so on. For instance, in the graph in Fig. 1, we may want to discover that Alice is connected with John through a common friend.

Queries such as the one above are called *path queries*, since they require navigation in a graph using paths of arbitrary lengths. Path queries have found applications in areas such as the Semantic Web (Alkhateeb et al. 2009; Pérez et al. 2010; Paths 2009), provenance (Holland et al. 2008), and route-finding systems (Barrett et al. 2000), among others. In this entry, we provide a brief

overview of path queries and some of their extensions; for detailed surveys, the reader is referred to Barceló (2013) and Angles et al. (2017).

Regular Path Queries

A *path* p in a graph database G is a sequence e_1, e_2, \dots, e_n of edges of the form $e_i = (a_i, \ell_i, b_i)$ such that $n \geq 0$ and $b_j = a_{j+1}$ for every $j \in \{1, \dots, n-1\}$. That is, each edge in a path starts in the node where the previous edge ends. If $n = 0$ we refer to p as the empty path. We write *labels*(p) for the string of labels formed by the sequence of edges in p , that is, *labels*(p) = ε if $n = 0$ and *labels*(p) = $\ell_1 \ell_2 \dots \ell_n$ otherwise. Finally, we say that a_1 is the starting node of p and b_n is the ending node of p .

Example 3 $p = (\text{Alice}, \text{knows}, \text{George}), (\text{George}, \text{knows}, \text{Paul})$ is a path in the graph database in Fig. 1. This path p is a path of length 2, its starting node is Alice, its ending node is Paul, and *labels*(p) = knows knows. □

Definition 2 A *regular path query* (RPQ) Q is an expression of the form

$$x \xrightarrow{r} y,$$

where $x, y \in \mathbf{V}$ and r is a regular expression over \mathbf{L} . The evaluation of Q over a graph database $G = (N, E)$, denoted by $\llbracket Q \rrbracket_G$, is the set of matchings $h : \{x, y\} \rightarrow N$ for which there exists a path p in G whose starting node is $h(x)$, ending node is $h(y)$, and *labels*(p) is a string in the regular language defined by r . □

Thus, an RPQ $x \xrightarrow{r} y$ asks for the pair of nodes in a graph database that are the endpoints of a path whose labels conform to the regular expression r .

Example 4 Assume that Q_2 is the RPQ $x \xrightarrow{\text{knows}^+} y$, where knows^+ is a regular expression that defines the language of nonempty strings of the form $\text{knows } \text{knows } \dots \text{knows}$. The following is the result of evaluating Q_2 over the graph database G shown in Fig. 1:

	x	y
h_1	Alice	George
h_2	George	Paul
h_3	Alice	Paul

In this case, $h_3 \in \llbracket Q_2 \rrbracket_G$ since for the path $p = (\text{Alice}, \text{knows}, \text{George}), (\text{George}, \text{knows}, \text{Paul})$ in G , we have that the starting node of p is Alice, the ending node of p is Paul, $\text{labels}(p) = \text{knows} \text{ knows}$, and $\text{knows} \text{ knows}$ is a string in the regular language defined by knows^+ . \square

Notice that Definition 2 does not impose the restriction that x and y be distinct variables, so an RPQ of the form $x \xrightarrow{r} x$ is valid, and its semantics is well defined. Such an RPQ asks for cycles whose labels conform to the regular expression r .

Constant values are usually allowed in RPQs. For the sake of readability, we do not consider them separately, as the syntax and semantics of an RPQ with constants are defined exactly in the same way as in Definition 2. We only give an example of such a query to illustrate how constants are used in RPQs.

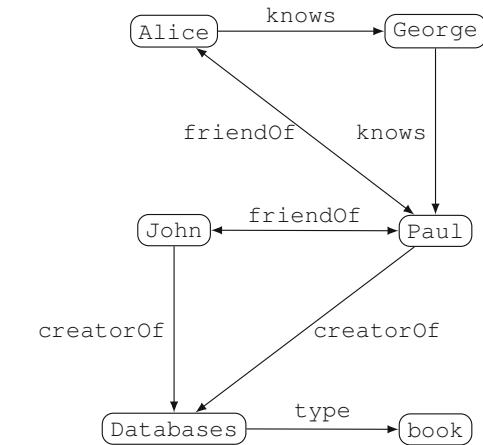

Example 5 Assume that Q_3 is the RPQ $\text{Alice} \xrightarrow{\text{knows}^+} z$, where z is a variable and Alice is a constant representing a node in a graph. The following is the result of evaluating Q_3 over the graph database shown in Fig. 1:

	z
h_4	George
h_5	Paul

\square

Regular Path Queries with Inverse

Let G be the graph database shown in Fig. 2, which is an extension of our running example with information about creations. Assume that we want to retrieve pairs of people that are co-creators of the same artifact. We can think of this query as a path in G : starting from a person, we traverse an edge with label `creatorOf` to reach an artifact, and then from there we traverse again an edge with label `creatorOf` to reach a person,

Graph Path Navigation, Fig. 2 A graph database including information about creations

who is then another creator of the artifact. But there is an issue with such a path as the second edge with label `creatorOf` has to be traversed in the opposite direction.

To overcome this problem, RPQs are often extended with the ability to traverse edges in both directions, which gives rise to the notion of RPQ with *inverses* (Calvanese et al. 2000). To define this, let \mathbf{L}^\pm be the extension of \mathbf{L} with the symbol ℓ^- , for each $\ell \in \mathbf{L}$. Moreover, for a graph database $G = (N, E)$, let G^\pm be the extension of G by adding the edges (b, ℓ^-, a) , for each $(a, \ell, b) \in E$.

Definition 3 A *regular path query with inverses* (2RPQ) Q is an expression of the form

$$x \xrightarrow{r} y,$$

where $x, y \in \mathbf{V}$ and r is a regular expression over \mathbf{L}^\pm . The evaluation of Q over a graph database G , denoted by $\llbracket Q \rrbracket_G$, is defined as $\llbracket Q \rrbracket_{G^\pm}$. \square

In this definition, $\llbracket Q \rrbracket_{G^\pm}$ is well defined as Q is an RPQ over G^\pm .

Example 6 The following 2RPQ Q_4 can be used to retrieve pairs of people that are co-creators of the same artifact in the graph database shown in Fig. 2:

$$x \xrightarrow{\text{creatorOf creatorOf}^-} y$$

In particular, if h_6 is a matching such that $h_6(x) = \text{John}$ and $h_6(y) = \text{Paul}$, then we have that $h_6 \in \llbracket Q \rrbracket_G$ as $p = (\text{John}, \text{creatorOf}, \text{Databases})$, $(\text{Databases}, \text{creatorOf}^-, \text{Paul})$ is a path in G^\pm such that $\text{labels}(p)$ is a string that conforms to the regular expression `creatorOf creatorOf^-`.

Notice that we can retrieve pairs of people who are connected by a co-creation path of arbitrary length by using the following 2RPQ:

$$x \xrightarrow{(\text{creatorOf creatorOf}^-)^+} y$$

□

Conjunctive Regular Path Queries

A more expressive form of graph database queries is obtained by viewing RPQs as basic building blocks and then defining conjunctive queries over them. Recall that conjunctive queries, over relational databases, are obtained by closing relational atoms under conjunction and existential quantification (or, equivalently, under selection, projection, and join operations of relational algebra). When the same operations are applied to RPQs, they give rise to the notion of conjunctive RPQs.

Definition 4 A *conjunctive regular path query* (CRPQ) is an expression of the form

$$\text{ans}(u_1, \dots, u_k) :- \bigwedge_{i=1}^n v_i \xrightarrow{r_i} w_i \quad (1)$$

where each $v_i \xrightarrow{r_i} w_i$, for $i \in \{1, \dots, n\}$, is an RPQ that may include constants and u_1, \dots, u_k is a sequence of pairwise distinct variables among those that occur as v_i s and w_i s. □

The left-hand side of (1) is called the head of the query, and its right-hand side is called the body. Variables in the body of (1) need not be pairwise distinct; in fact, sharing variables allows joining results of the RPQs in the body

of the query, which is a fundamental feature of CRPQs. As in the case of relational conjunctive queries, variables mentioned in the body of (1) but not in the head (i.e., those that are not in the answer) are assumed to be existentially quantified (in other words, projected away). Finally, if $k = 0$, then (1) is called a Boolean CRPQ, as its evaluation results in either a set containing a matching with empty domain or an empty set of matchings, which represent the values true and false, respectively.

The semantics of (1) is defined as follows. Assume that $G = (N, E)$ is a graph database, and let x_1, \dots, x_m be the variables occurring in the body of (1). Then a matching $h : \{x_1, \dots, x_m\} \rightarrow N$ is said to satisfy the body of (1) if for every $i \in \{1, \dots, n\}$:

$$h|_{\{v_i, w_i\} \cap V} \in \llbracket v_i \xrightarrow{r_i} w_i \rrbracket_G,$$

where $h|_{\{v_i, w_i\} \cap V}$ is the restriction of matching h to the domain $\{v_i, w_i\} \cap V$. A matching $g : \{u_1, \dots, u_k\} \rightarrow N$ is an *answer* to (1) over G if there is an extension $h : \{x_1, \dots, x_m\} \rightarrow N$ of g that satisfies the body of (1). The evaluation of a CRPQ Q over G , written $\llbracket Q \rrbracket_G$, is the set of answers to Q over G .

Example 7 Let $G = (N, E)$ be the graph database in Fig. 2. Then the following CRPQ Q_5 can be used to retrieve the pairs of people that are co-authors of the same book:

$$\begin{aligned} \text{ans}(x, y) :- & x \xrightarrow{\text{creatorOf}} z \wedge \\ & y \xrightarrow{\text{creatorOf}} z \wedge \\ & z \xrightarrow{\text{type}} \text{book} \end{aligned}$$

Let $g : \{x, y\} \rightarrow N$ and $h : \{x, y, z\} \rightarrow N$ be matchings such that $g(x) = \text{John}$, $g(y) = \text{Paul}$, $h(x) = \text{John}$, $h(y) = \text{Paul}$, and $h(z) = \text{Databases}$. We have that $g \in \llbracket Q_5 \rrbracket_G$ since $g = h|_{\{x, y\}}$, $h|_{\{x, z\}} \in \llbracket x \xrightarrow{\text{creatorOf}} z \rrbracket_G$, $h|_{\{y, z\}} \in \llbracket y \xrightarrow{\text{creatorOf}} z \rrbracket_G$, and $h|_{\{z\}} \in \llbracket z \xrightarrow{\text{type}} \text{book} \rrbracket_G$. □

Key Research Findings

The Complexity of Evaluating Path Queries

We now consider the cost of evaluating a query in a graph query language \mathcal{L} . More precisely, the complexity of the problem \mathcal{L} -EVAL is defined as follows: Given a graph database G , a query $Q \in \mathcal{L}$, and a matching h , does h belong to the evaluation of Q over G ? (in symbols, is $h \in \llbracket Q \rrbracket_G$?). Notice that the input to \mathcal{L} -EVAL consists of a graph database G , a query Q and a matching h , and, thus, it measures the *combined complexity* of the evaluation problem. Since the size of h is bounded by the size of Q and the size of G , it suffices to measure the combined complexity in terms of $|Q|$ and $|G|$, the sizes of Q and G .

In practice, queries are usually much smaller than graph databases, so one is also interested in the *data complexity* of the evaluation problem, which is measured only in terms of the size of the graph database (i.e., the query is assumed to be fixed).

The combined and data complexities of RPQ-EVAL, 2RPQ-EVAL, and CRPQ-EVAL are shown in Fig. 3.

When we state that data complexity is NLOGSPACE-complete, we mean that for each fixed query Q in those language, the evaluation problem can be solved in NLOGSPACE, and there are some queries – in fact, RPQs – for which it is NLOGSPACE-hard.

We now outline the key ideas behind the $O(|G| \cdot |Q|)$ algorithm as well as NLOGSPACE-completeness and NP-completeness.

Given a database graph $G = (N, E)$, a 2RPQ $Q = x \xrightarrow{r} y$, and a matching $h : \{x, y\} \rightarrow N$, we show that 2RPQ-EVAL can be solved in time $O(|G| \cdot |Q|)$. The idea is from Mendelzon and Wood (1995). Assume that $h(x) = a$ and $h(y) = b$. First, we compute G^\pm from G in time $O(|G|)$, and then we compute in time $O(|Q|)$, a nonde-

terministic finite automaton with ε -transitions (ε -NFA) A_r , that defines the same regular language as r . Let $G^\pm(a, b)$ be the NFA obtained from G^\pm by setting its initial and final states to be a and b , respectively. We know that $h \in \llbracket Q \rrbracket_G$ if and only if $h \in \llbracket Q \rrbracket_{G^\pm}$, and the latter is equivalent to checking whether there exists a word accepted by both $G^\pm(a, b)$ and A_r . In turn, this is equivalent to checking the product of $G^\pm(a, b)$ and A_r for nonemptiness, which can be done in linear time in the size of the product automaton, i.e., in time $O(|G^\pm| \cdot |A_r|)$. The whole process takes time $O(|G| + |Q| + |G^\pm| \cdot |A_r|)$, that is, $O(|G| \cdot |Q|)$.

If the query Q is fixed, the same algorithm can be performed in NLOGSPACE. Indeed, we just need to compute reachability in the product automaton, and reachability in graphs is computable in NLOGSPACE. Of course the whole product requires more than logarithmic space, but it need not be built, as reachability can be checked by using standard on the fly techniques. Moreover, reachability in graphs is known to be NLOGSPACE-complete, so even RPQ query evaluation can be NLOGSPACE-complete in data complexity.

Finally, to see that CRPQs can be evaluated in NP in combined complexity, it just suffices to guess the values of all the v_i s and w_j s and then check in polynomial time that all the RPQs from (1) hold. And since the evaluation problem for relational conjunctive queries over graphs is NP-hard in data complexity, so is the evaluation problem for the more expressive CRPQs.

Simple Path Semantics

The evaluation of RPQs as defined here is based on a semantics of arbitrary paths. It has been argued, on the other hand, that for some applications it is more reasonable to apply a semantics based on *simple paths* only, i.e., those without repeating nodes. Under such a semantics, an RPQ $x \xrightarrow{r} y$ computes the pairs of nodes that are

Graph Path Navigation,

Fig. 3 The complexity of the evaluation problem for path queries

	Combined complexity	Data complexity
RPQ-EVAL	$O(G \cdot Q)$	NLOGSPACE-complete
2RPQ-EVAL	$O(G \cdot Q)$	NLOGSPACE-complete
CRPQ-EVAL	NP-complete	NLOGSPACE-complete

linked by a *simple path* whose label satisfies r . However, evaluation of RPQs under the simple path semantics becomes NP-complete even in data complexity (Mendelzon and Wood 1995).

While this casts doubt on its practical applicability, a closely related semantics was implemented in a practical graph DBMS, namely, Neo4j (Robinson et al. 2013). There, paths in graph patterns can only be matched by paths that do not have repeated *edges*. While still NP-complete in data complexity in the worst case, in practice this semantics could behave well, as worst-case scenarios do not frequently occur in real life.

Extensions

(C)RPQs have been extended with several features. One extension is a *nesting* operator that allows one to perform existential tests over the nodes of a path, similarly to what is done in the XML navigational language XPath (Pérez et al. 2010). Another extension is the ability to compare paths (Barceló et al. 2012). The idea is that paths are named in an RPQ, like $x \xrightarrow{\pi:r} y$, and then the name π can be used in the query. Without defining them formally, we give an example:

$$\text{ans}(x, y) :- x \xrightarrow{p_1:a^*} z \wedge z \xrightarrow{p_2:b^*} y \wedge \text{equal_length}(p_1, p_2)$$

says that there is a path p_1 from x to z labeled with as and a path p_2 from z to y labeled with bs and these paths have equal lengths (expressed by the predicate $\text{equal_length}(p_1, p_2)$). The equal length predicate belongs to the well-known class of regular relations, but the above query says that there is a path from x to y whose label is of the form $a^n b^n$ for some n . This of course is not a regular property, even though we only used regular languages and relations in the query. Such extended CRPQs still behave well: their data complexity remains in NLOGSPACE, and their combined complexity goes up to PSPACE, which is exactly the combined complexity of relational algebra. However such additions must be handled with care: if we add common predicates

on paths such as subsequence or subword, query evaluation becomes completely infeasible or even undecidable. We refer to Barceló et al. (2012) and Barceló (2013) for further discussions.

The last extension is constituted by adding mechanisms for checking regular properties over an extended data model in which each node carries data values from an infinite domain. This models graph databases as they occur in real life, namely, *property graphs*, where nodes and edges can carry tuples of key-value pairs. Extending RPQs and CRPQs requires choosing a proper analog of regular expressions. There are many proposals, but with few exceptions they lead to very high complexity of query evaluation. The one that maintains good complexity is given by *register automata*. Such extensions still have NLOGSPACE data complexity and PSPACE combined complexity and come with different syntactic ways of describing navigation that mixes data and topology of the graph. We refer the reader to Libkin et al. (2016) for details and the surveys by Barceló (2013) and Angles et al. (2017) for a thorough review of the literature on extensions of CRPQs.

Graph Pattern Matching

Yinghui Wu¹ and Arijit Khan²

Singapore

Definitions

The graph pattern matching problem is to find the answers $Q(G)$ of a pattern query Q in a given graph G . The answers are induced by specific query language and ranked by a quality measure. The problem can be categorized into three classes (Khan and Ranu 2017): (1) Subgraph/supergraph containment query, (2) graph similarity queries, and (3) graph pattern matching.

In the context of searching a graph database D that consists of many (small) graph transactions, the graph pattern matching finds the answers $Q(G)$ as a set of graphs from D . For subgraph (resp. supergraph containment) query, it is to find $Q(G)$ that are subgraphs (resp. supergraphs) of Q . The graph similarity queries are to find $Q(G)$

as all graph transactions that are similar to Q for a particular similarity measure.

In the context of searching a single graph G , graph pattern matching is to find all the occurrences of a query graph Q in a given data graph G , specified by a matching function. The remainder of this entry discusses various aspects of graph pattern matching in a single graph.

Overview

G

This entry discusses foundations of graph pattern matching problem: formal definitions, query languages, and complexity bounds.

Data graph. A data graph $G = (V, E, L)$ is a directed graph with a finite set of nodes V , a set of edges $E \subseteq V \times V$, and a function L that assigns node and edge content. Given a query $Q = (V_Q, E_Q, L_Q)$, a node $v \in V$ in G with content $L(v)$ (resp. edge $e \in E$ with content $L(e)$) that satisfies the constraint $L(u)$ of a node $u \in V_Q$ (resp. $L(e_u)$ of an edge $e_u \in E_Q$) is a candidate match of v (resp. e). Common data graph models include RDF and property graphs (see chapter “► Graph Data Models”).

Graph pattern query. A graph pattern query Q is a directed graph (V_Q, E_Q, L_Q) that consists of a set of nodes V_Q and edges E_Q , as defined for data graphs. For each node $v \in V_Q$ (resp. $e \in E_Q$), a function L_Q assigns a predicate $L(v)$ (resp. $L(e)$) for each v (resp. e). The predicate $L(\cdot)$ can be expressed as conjunction of atomic formulas of attributes from node and edge schema in a data graph or information retrieval metrics.

Graph pattern matching. A match $Q(G)$ of a pattern query Q in a data graph G is a substructure of G induced by a matching function $F \subseteq V_Q \times V$. The node $F(u)$ (respectively, $F(e)$) is called a match of a node $u \in V_Q$ (respectively, $e \in E_Q$). Given a query $Q = (V_Q, E_Q, L_Q)$, a data graph $G = (V, E, L)$, the graph pattern matching problem is to find all the matches of Q in G .

Subgraph pattern queries. Traditional graph pattern queries are defined by subgraph isomorphism (Ullmann 1976): (1) each node in Q has a unique label, and (2) the matching function F specifies a subgraph isomorphism, which is an injective function that enforces an edge-to-edge matching and label equality.

The subgraph isomorphism problem is NP complete. Ullmann proposed a first practical backtracking algorithm for subgraph isomorphism search in graphs (Ullmann 1976). The algorithm enumerates exact matches by incrementing partial solutions and prunes partial solutions when it determines that they cannot be completed. A number of methods such as VF2 (Cordella et al. 2004), QuickSI (Shang et al. 2008), GraphQL (He and Singh 2008), GADDI (Zhang et al. 2009), and SPATH (Zhao and Han 2010) are proposed for graph pattern queries defined by subgraph isomorphism. These algorithms follow the backtracking principle as in (Ullmann 1976) and improve the efficiency by exploiting different join orders and various pruning techniques. Lee et al. conducted an experimental study (Lee et al. 2012) to compare these methods, and experimentally verified that QuickSI designed for handling small graphs often outperforms its peers for both small and large graphs.

The major challenge for querying big graphs is twofold: (1) The query models have high complexity. For example, subgraph isomorphism is NP hard. (2) It is often hard for end users to write accurate graph pattern queries. Major research effort has been focused on two aspects: (a) developing computationally efficient query models and algorithms, and (b) user-friendly graph search paradigms.

Key Research Findings

Computationally Efficient Query Models

Graph simulation. The class of simulation-based query models includes graph simulation and bounded simulation (Fan et al. 2010), strong simulation (Ma et al. 2011), and pattern queries

with regular expressions (Fan et al. 2011). A graph simulation $R \subseteq V_Q \times V$ relaxes subgraph isomorphism to an edge-to-edge matching relation. For any node $(u, v) \in R$, u and v have the same label, and each child u' of u must have at least a match v' as a child of v , such that $(u', v') \in R$. Strong simulation (Ma et al. 2011) enforces simulation for both parents and children of a node in Q . Regular expressions are posed on edges in Q to find paths with concatenated edge labels satisfying the regular expression (Fan et al. 2011). All these query models can be evaluated with low polynomial time.

Approximate pattern matching. Approximate graph matching techniques make use of cost functions to find approximate ($\text{top-}k$) matches with fast solutions. The answer quality is usually characterized by aggregated proximity among matches determined by their neighborhood, which is more effective to cope with ambiguous queries with possible mismatches in data graphs. Traditional cost measures include graph edit distance, maximum common subgraph, number of mismatched edges, and various graph kernels. Index techniques and synopses are typically used to improve the efficiency of pattern matching in large data graphs (see chapter “Graph Indexing and Synopses”).

Notable examples include PathBlast (Kelley et al. 2004), SAGA (Tian et al. 2006), NetAlign (Liang et al. 2006), and IsoRank (Singh et al. 2008) that target bioinformatics applications. G-Ray (Tong et al. 2007) aims to maintain the shape of the query via effective path exploration. TALE (Tian and Patel 2008) uses edge misses to measure the quality of a match. NESS and NeMa (Khan et al. 2011, 2013) incorporate more flexibility in graph pattern matching by allowing an edge in the query graph to be matched with a path up to a certain number of hops in the target graph. Both methods identify the top- k matches. This is useful in searching knowledge graphs and social networks.

Making Big Graphs Small

When the query class is inherently expensive, it is usually nontrivial to reduce the complex-

ity. The second category of research aims to identify a small and relevant fraction G_Q of large-scale graph G that suffice to provide approximate matches for query Q . That is, the match $Q(G_Q)$ is same or close to its exact counterpart $Q(G)$. Several strategies have been developed for graph pattern matching under this principle.

Making graph query bounded. Bounded evaluability of graph pattern queries aims to develop algorithms with provable computation cost that is determined by the small fraction of graph. Notable examples include query preserving graph compression (Fan et al. 2012a) and querying with bounded resources (Fan et al. 2014b; Cao et al. 2015). (1) Given a query class \mathcal{Q} , query-preserving compression applies a fast once-for-all preprocessing to compress data graph G to a small, query-able graph G_Q , which guarantees that for any query instance from \mathcal{Q} , $Q(G) = Q(G_Q)$. Compression schemes have been developed for graph pattern queries defined by reachability and graph simulation. (2) Querying with bounded resource adds additional size bound to G_Q . The method in Cao et al. (2015) makes use of a class of access constraints to estimate and fetch the amount of data needed to evaluate graph queries. When no such constraints exist, another method (Fan et al. 2014b) dynamically induces G_Q on the fly to give approximate matches. Both guarantee to access G_Q with bounded size. (3) Graph views are also used to achieve bounded evaluability, where query processing only refers to a set of materialized views with bounded size (Fan et al. 2014a).

Incremental evaluation. When data graph G bear changes ΔG , bounded evaluability is achieved by applying *incremental pattern matching* (Fan et al. 2013). While ΔG is typically small in practice, G_Q is induced by combining ΔG and a small fraction of G (called “affected area”) that are necessarily visited to update $Q(G)$ to its counterparts in the updated graph. An algorithm guarantees bounded computation if it incurs cost determined by the neighbors of G_Q (up to a certain hop) and Q only, independent of

the size of G . Bounded incremental algorithms are identified for several graph pattern queries including reachability and graph simulation (Fan et al. 2013).

Parallelizing sequential computation. When data graph G is too large for a single processor, bounded evaluability can be achieved by distributing G to several processors. Each processor copes with a fragment G_Q of G with a manageable size and bounded evaluability, guaranteed by partition, load balancing, and other optimization techniques. Existing models include bulk (synchronous and asynchronous) vertex-centric computation and graph-centric model , which are designed to parallelize node and graph-level computations, respectively (see chapter “► Parallel Graph Processing”).

Several characterizations of such models have been proposed. Notable examples include *scale independence* (Armbrust et al. 2009), which ensures that a parallel system enforces strict invariants on the cost of query execution as data size grows, and *parallel scalability* (Fan et al. 2014c, 2017), which ensures that the system has polynomial speed-up over sequential computation as more number of processors are used. A notable example is the techniques that aim to automatically parallelize sequential graph computation without recasting (Fan et al. 2017). The declarative platform defines parallel computation with three core functions for any processor – to support local computation, incremental computation (upon receiving new messages), and assembling of partial answers from workers. Several parallel scalable algorithms are developed under this principle for graph pattern queries including reachability and graph simulation (Fan et al. 2012b, 2014c).

User-Friendly Pattern Matching

A third category of research aims to develop algorithms that can better infer the search intent of graph queries, especially when end users have no prior knowledge of underlying graph data. We review two approaches specialized for graph pattern matching.

Graph keyword search. Keyword search over graphs allows users to provide a list of keywords and returns subtrees/subgraphs as interpretable answers. Various ranking criteria also exist to find the top- k answers, e.g., sum of all edge weights in the resulting tree/graph, sum of all path weights from root to each keyword in the tree, maximum pairwise distance among nodes, etc. Notable examples include BANKS (Aditya et al. 2002) and BLINKS (He et al. 2007) (see chapter “► Graph Exploration and Search” for details). Several keyword searches find answers that are connected subgraphs containing all the query keywords. Examples include r -clique (Kargar and An 2011), where the nodes in an r -clique are separated by a distance at most r . Query refinement and reformulation techniques are studied to convert the keyword queries to structured queries such as SPARQL. Beyond keyword queries, Zheng et al. (2017) develop a more interactive way of answering natural language queries over graph data. For more details of graph queries, see chapters “► Graph Query Languages” and “► Graph Query Processing.”

Graph query by example. A relatively new paradigm for user-friendly graph querying is graph-query-by-example. Query-by-example (QBE) has a positive history in relational databases, HTML tables, and entity sets. Exemplar query (Mottin et al. 2014) and GQBE (Jayaram et al. 2015) adapted similar ideas over knowledge graphs. In particular, the user may find it difficult how to precisely write her query, but she might know a few answers to her query. A graph query-by-example system allows her to input the answer tuple as a query and returns other similar tuples that are present in the target graph. The underlying system follows a two-step approach. Given the input example tuple(s), it first identifies the query graph that captures the user’s query intent. Then, it evaluates the query graph to find other relevant answer tuples. Major techniques of graph query by example are introduced in chapter “► Graph Exploration and Search.”

Key Applications

Graph pattern matching has been widely adopted in accessing and understanding network data. Representative applications include community detection in social networks, attack detection for cyber security, querying Web and knowledge bases as knowledge graphs, pattern recognition in brain and healthcare, sensor network in smart environment, and Internet of Things.

Future Directions

The open challenges remain to be the designing of efficient and scalable graph pattern query models and algorithms to meet the need of querying big graphs that are heterogeneous, large, and dynamic. Another challenge is the lack of support for declarative languages for more flexible graph pattern queries beyond SPARQL. A third challenge is to enable fast and scalable pattern matching with quality guarantees in incomplete and uncertain graphs, with applications in data fusion and provenance of high-value graph data sources. These call for new scalable techniques for graph pattern query evaluation.

Synonyms

Graph parallel computation API; Graph processing library; Large-scale graph processing system

Definitions

A graph processing framework (GPF) is a set of tools oriented to process graphs. Graph vertices are used to model data and edges model

relationships between vertices. Typically, a GPF includes an input data stream, an execution model, and an application programming interface (API) having a set of functions implementing specific graph algorithms. In addition, some GPFs provide support for vertices and edges annotated with arbitrary properties of any kind and number.

Graphs are being used for modeling large phenomena and their relationships in different application domains such as social network analysis (SNA), biological network analysis, and link analysis for fraud/cybercrime detection. Since real graphs can be large, complex, and dynamic, GPFs have to deal with the three challenges of data growth: volume, velocity, and variety.

The programming API of GPFs is simple enough to facilitate efficient algorithm execution on graphs while abstracting away low-level details. On the one hand, the basic computation entity in a GPF can be graph-centric, vertex-centric, or edge-centric. On the other hand, as big data drives graph sizes beyond memory capacity of a single machine, GPFs partition and distribute data among computing nodes implementing a communication model.

Overview

There is a growing number of GPFs. Doekemeijer and Varbanescu (2014) review 83 different frameworks. To briefly explain the most relevant

aspects of GPFs, 11 proposals, shown in Table 1, have been selected in this entry. Four main dimensions can be used to classify GPF frameworks: (1) the target platform, (2) the computation model, (3) the graph processing approach, and (4) the communication model.

The target platform is one of the major distinctions between frameworks. Most of the GPFs are distributed memory frameworks (DMF), but there are some shared-memory frameworks (SMF) that exploit the parallel capabilities of a single machine.

Many graph processing algorithms need to traverse the graph in some way, and they are iterative until a global state is reached. Because of that, the computation model can be seen as a sequence of MapReduce invocations requiring to pass the entire state of the graph from one stage to the next. DMFs, like Surfer, Pegasus, and GBase, are based on MapReduce.

The bulk-synchronous process (BSP) model was created to simplify the design of software for parallel systems. BSP is a two-step process: perform task computing on local data and communicate the results. Both are performed iteratively and synchronously repeating the two step as many iterations needed. Each compute/communication iteration is called a superstep, with synchronization of the parallel tasks occurring at the superstep barriers.

DMFs, like Pregel, GraphX, Giraph, and GiraphX, and the hybrid framework, Totem, are based on the BSP model of computation.

Graph Processing Frameworks, Table 1 Frameworks for processing large-scale graphs

Framework	Year	Platform	Computation	Approach	Communication
Surfer	2010	Distributed memory	MapReduce	Graph-centric	Message passing
Pegasus	2009	Distributed memory	MapReduce	Matrix-centric	Dataflow
GBase	2011	Distributed memory	MapReduce	Matrix-centric	Dataflow
Pregel	2010	Distributed memory	BSP-based	Vertex-centric	Message passing
GraphX	2013	Distributed memory	BSP-based	Graph-centric	Dataflow
Giraph	2012	Distributed memory	BSP-based	Vertex-centric	Dataflow
GiraphX	2013	Distributed memory	BSP-based	Vertex-centric	Shared memory
Gelly	2015	Distributed memory	Delta iterative/GSA	Vertex-centric	Message passing
GraphLab	2010	Single machine/Distributed memory	GAS model	Vertex-centric	Shared memory
GraphChi	2012	Single machine	Sequential model	Vertex-centric, PSW	Shared memory
Totem	2012	Hybrid CPU + GPU	BSP-based	Graph-centric	Hybrid CPU + GPU

The Gelly framework supports two different alternative computation models: the delta iterative model and the Gather, Sum, and Apply (GSA) model. The delta model supports incremental iterations, in which only selected elements of the solution are updated and only the dependent elements are recomputed.

According to the GSA model, a vertex pulls information from its neighbors, contrary to the conventional vertex-centric approach where the information is pushed to the neighbors.

GraphLab is based in the gather, apply, and scatter (GAS) model, similar to BSP but having a synchronous or asynchronous execution mode. A different framework is GraphChi, a single-machine implementation framework relying on a parallel sliding window mechanism for processing large graphs from disk. Pegasus and GBase follow a matrix representations of graphs paying attention on the matrix computations and storage.

Regarding the graph processing approach, most frameworks employ a vertex-centric one, also known as the “think like a vertex” (TLAV) approach, in which user-defined programs center on a vertex rather than a graph. TLAV improves locality and scalability and provides a natural way to express many iterative graph algorithms. In contrast, frameworks like Surfer, GraphX, and Totem use a graph-centric approach performing computations on graph partitions.

GPFs can be classified also according to their memory model to share information. GiraphX, GraphLab, and GraphChi are based on a global shared-address memory space. Surfer and Pregel are elaborations of a pure message-passing model in which state is local and messages flow through the system to update external entities. Totem’s hybrid model is a combination of both shared-memory and message-passing models.

In the dataflow communication model, the flow of information goes from a vertex to its neighbors. In DMFs, the dataflow communication model is also to indicate that state flows through the system toward the next phase of computation.

The next sections are devoted to describe in more detail each of the GPFs listed in Table 1.

Review of Graph Processing Frameworks

MapReduce-Based Graph Processing Frameworks

Surfer is one of the first attempts to create a large-scale graph processing engine. It is based upon to basic primitives for programmers: MapReduce and propagation (Chen et al. 2010). MapReduce is used to process key-value pairs in parallel, and propagation is used to transfer information along edges.

Surfer employs a partition strategy dividing the large graph into many partitions of similar sizes. Each computer node in the distributed system holds several graph partitions and manages propagation doing as many local operations as it can before exchanging messages with other nodes in the system.

Pegasus is a large-scale graph mining library that has been implemented on top of the Hadoop framework (Kang et al. 2011b). Pegasus has built-in functions to perform typical graph mining tasks such as computing the diameter of a graph, performing a graph traversal, and finding the connected components. Pegasus uses the matrix-vector algebraic approach to perform most of its operations.

Pegasus has been utilized to discover patterns on near-cliques and triangles in large-scale graphs by MapReduce-based applications.

GBase is also a MapReduce-based framework focused in partitioning the graph into blocks and using block compression to store each block (Kang et al. 2011a). Vertex distribution is done by placing vertices belonging to same partition near to each other.

BSP Graph Processing Frameworks

Pregel system (Malewicz et al. 2010), introduced by Google, is the first BSP implementation providing an API specifically tailored for graph algorithms following the TLAV model. Each vertex executes the user-defined vertex function and then sends results to neighbors along graph edges. Pregel is a DMF where graph vertices are allocated in the different machines achieving that

all associated neighbors are assigned to the same node.

Pregel deals with the underlying organization of resource allocation of the graph data and splits computation into BSP-style supersteps. Supersteps always end with a synchronization barrier, which guarantees that messages sent in a given superstep are received at the beginning of the next superstep.

Vertices may change states between active and inactive, depending on the overall state of execution. Pregel terminates when all vertices halt and no more messages are exchanged.

GraphX is a distributed graph engine built on top of Spark, which is a MapReduce-like general data-parallel engine currently released as an Apache project (Xin et al. 2013). Spark’s programming model consists of:

1. An in-memory data abstraction called resilient distributed datasets (RDD), and
2. A set of deterministic parallel operations on RDDs that can be invoked using data primitives such as map, filter, join, and group by.

A Spark’s program is a directed acyclic graph (DAG) of Spark’s primitives, which are applied in a set of initial or transformed RDDs.

GraphX extends Spark’s RDD abstraction to introduce resilient distributed graph (RDG) which associates records with vertices and edges and provides a collection of expressive computational graph primitives.

GraphX relies on a flexible vertex-cut partitioning to encode graphs as horizontally partitioned collections. A vertex-cut partitioning promotes to evenly assign edges to machines leaving vertices to span multiple machines. A vertex-data table is used to represent each vertex partition; an edge table is used to represent each edge partition, i.e., those vertices having an edge crossing from one partition to another. A vertex map indexes all copies for each vertex.

Apache Flink is a stream processing framework developed by the Apache Software Foundation. Flink’s runtime provides support for the

execution of iterative algorithms natively. Gelly is Apache Flink’s graph processing API and library.

Gelly’s programming model exploits Flink’s delta iteration operators. Delta iterations enable Gelly to minimize the number of vertices that need to be recomputed during an iteration as the iterative algorithm. This can enhance performance when some vertices converge to their final value faster than others.

Gelly also supports the GSA model functions defined by the user and wrapped in map, reduce, and join operators. GSA also makes use of delta iteration operators.

Apache Giraph is an open-source project which uses Java to implement the Pregel specification, rather than C/C++, on the top of the Hadoop framework infrastructure (Avery 2011).

Giraph uses a vertex-centric programming abstraction adapting the BSP model. Giraph runs synchronous graph processing jobs as map-only jobs and uses Hadoop (HDFS) for storing graph data. Giraph employs Apache Zookeeper for periodic checkpointing, failure recovery, and coordinating superstep execution. Giraph is executed in-memory which can speed up job execution; however, it can fail processing a workload beyond the physical available memory.

Single-Machine Graph Processing Frameworks

An important issue of TLAV frameworks is how data is shared between vertex programs. In shared memory, vertex data are shared variables that can be directly read or modified by other vertex programs.

Shared memory is often implemented by TLAV frameworks developed for a single machine. Instead of dealing with consistency accessing remote vertices, using a mutual exclusion protocol, access to vertices stored in shared memory can be serialized.

GiraphX is a synchronous shared-memory implementation following the Giraph model (Tasci and Demirbas 2013). Serialization of shared vertex is provided through locking of border vertices, without local cached copies.

GiraphX showed a reduced overhead compared to message-passing in Giraph.

GraphLab is an open-source GPF implemented in C++, formerly started at CMU and currently supported by GraphLab Inc. GraphLab is a shared-memory abstraction using gather, apply, and scatter (GAS) model similar to BSP model employed in Pregel (Low et al. 2012) but with some differences. In the GAS model, a vertex collects information about its neighborhood in the gather phase, performs the computations in the apply phase, and in the scatter phase updates its adjacent vertices and edges.

GraphChi is a centralized system, implemented in C++, that can process massive graphs from secondary storage in a single machine (Kyrola et al. 2012). It uses a parallel sliding window (PSW) mechanism to process very large graphs from disk moving a fraction of the graph to memory and requiring a small number of sequential disk accesses.

GraphChi partitions the input graph into subgraphs where edges are sorted by the source id. A sequential stream is used to load the edges in memory. Using CSR and CSC graph representations, GraphChi avoids finding graph cuts which is a costly operation.

Modern single-node systems use both CPU and graphical processing units (GPUs) to accelerate the processing of large graphs. Host processing units are optimized to fast sequential processing, while GPUs bring massive hardware multithreading able to mask memory access latency.

Totem is the most representative hybrid framework combining GPU and CPU processing (Gharaibeh et al. 2013). Totem is also a BSP-based framework in which each processing element executes computations asynchronously on its local memory during the computation phase.

Totem's important contribution is that, for some real-world graphs, the communication overhead between CPUs and GPUs can be significantly reduced becoming negligible relative to the processing time.

Example of Application

The degree distribution is a useful tool to characterize the topology of real-world graphs. A power law degree distribution implies that a network has only a few vertices with very high degree, called hubs.

The following example illustrates the procedure to obtain the degree distribution of a large-scale social network by exploiting the API of a GPF in a distributed computing environment. The example shows how to obtain the degree distribution of the LiveJournal social network dataset, a graph with four million vertices and around 68 million links.

The degree distribution of a graph G can be defined as $P(k)$, the fraction of vertices in a graph that have degree k for all different k .

A general distributed computing strategy to calculate the degree distribution $P(k)$ with a GPF is as follows:

- Step 1: Use the GPF API to load and distribute the graph to all computing nodes.
- Step 2: Use the GPF API to calculate the total number of vertices n .
- Step 3: Obtain the list of all vertex degrees by letting each vertex to calculate its own degree in a distributed fashion with the help of the GPF API.
- Step 4: Calculate the degree histogram n_k , the frequency of each different degree in the list, by applying a distributed group by degree operation.
- Step 5: Calculate the degree distribution $P(k)$ by letting each degree frequency n_k to divide itself by the total number of vertices in the graph n , again in a distributed fashion.
- Step 6: Collect all the $P(k)$ data in a single computing node.

As the reader may notice, steps 1 through 3 are performed with the help of the graph processing abstractions provided by the GPF, whereas steps 4 through 6 can be expressed by using a conventional MapReduce approach. The following is the implementation of the previously described

steps with the Gelly framework API in the Scala language:

```

import org.apache.flink.api.scala._
import org.apache.flink.graph.scala._
import org.apache.flink.types.NullValue

object DegreeDistribution {
  def main(args: Array[String]) {

    // Set up the execution environment
    val env = ExecutionEnvironment.getExecutionEnvironment

    // Step 1: load and distribute the graph data
    val graph = Graph.fromCsvReader[Long, NullValue](
      NullValue]()
    pathEdges = "data/soc-LiveJournal1.csv",
    env = env)

    // Step 2: calculate the number of vertices
    val n = graph.numberOfVertices()

    // Step 3: calculate (vertex ID, degree) for all vertices
    val degrees = graph.getDegrees()

    // Steps 4 and 5: calculate the degree distribution
    val degreeDist = degrees
      .map { degreeTuple =>
        degreeTuple._2
      }
      .map { (_, 1) }
      .groupBy(0)
      .sum(1)
      .map { degreeCount =>
        (degreeCount._1, degreeCount._2 / n.toDouble)
      }

    // Step 6: collect and print out the result
    degreeDist.print()

  }
}

```

Step 1 is implemented with the `GraphCsvReader` method, which enables Gelly to load and build a Gelly graph dataset from an edge list CSV file of the LiveJournal graph, where the first field is the source vertex u , the second field is the target vertex v , and the third optional field is the edge value.

The `numberOfVertices` method is used to retrieve the number of vertices, implementing step 2. Likewise, the `getDegrees` method is used to compute the nodes degrees, implementing step 3. `getDegrees` builds a Flink dataset of vertex-degree pairs (u, k_u) for all vertices.

Steps 4–6 are implemented in a MapReduce style by using Flink's dataset methods to map, group, aggregate, and collect data. To implement step 4, the degree field of the (u, k_u) pairs dataset is separated to keep only the sequence of all vertex degrees $k_1, k_2 \dots k_n$. Then, each degree

k is paired with the value “1” through the `map` method to obtain a dataset of pairs $(k, 1)$. Next, the $(k, 1)$ pairs dataset is grouped by the degree field, summing up the value field to compute the degree frequencies with the `groupBy` and `sum` methods. This produces a new dataset of degree frequency pairs (k, n_k) .

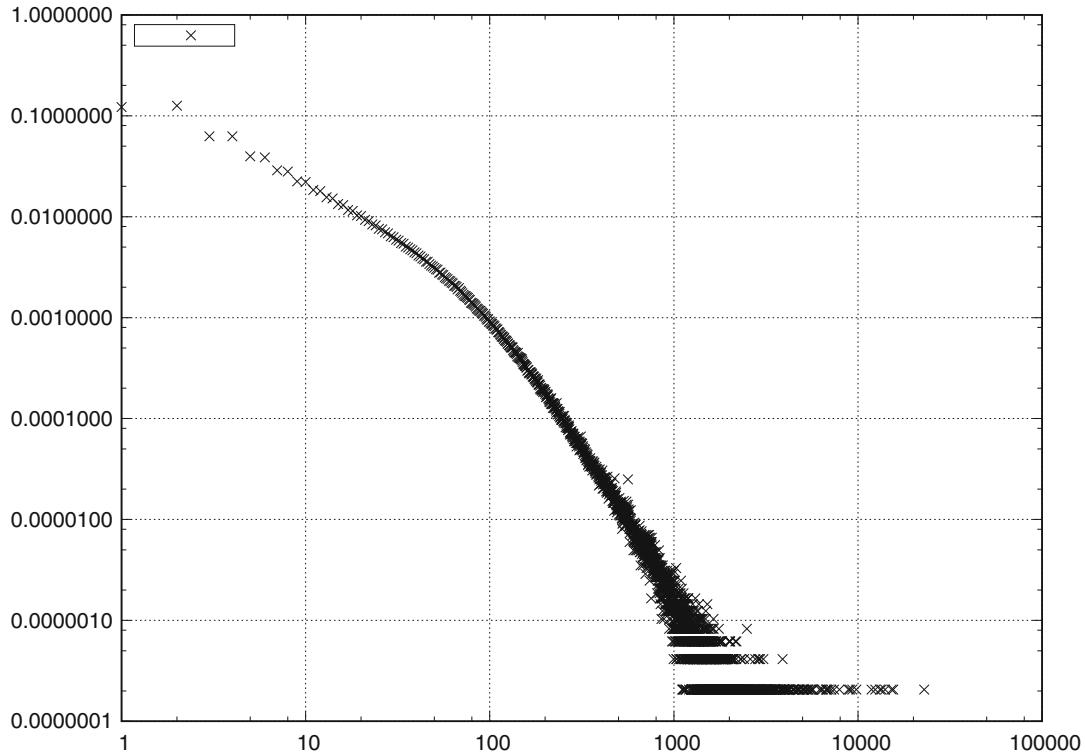

As for step 5, the frequency field of the (k, n_k) pair dataset is divided by the total number of vertices n , again through the `map` method, to obtain the final dataset of degree-probability pairs $(k, P(k))$, which represents the graph degree distribution. Step 6 collects and prints out the $(k, P(k))$ pairs dataset by making use of the `print` dataset method.

Figure 1 shows the log-log plot of the LiveJournal social network degree distribution obtained with the Gelly example. The close to linear plot shows that the graph degree distribution might follow a power law suggesting that the LiveJournal graph topology encodes relevant properties of the underlying social phenomenon.

Figure 2 shows the results of an experimental evaluation of the degree distribution Gelly application. All experiments were executed in a server including 32 cores (Intel Xeon 2.5 GHz), 64 RAM in which Centos 7, Java8, Scala 2.1.8, SBT 1.0.4, and Flink 1.4.0 were installed. Vertical axis shows the speedup and millions of TEPS (traversed edges per second) achieved by Gelly when using different numbers of threads (horizontal axis). The performance of Gelly is nonlinear improved in proportion to the number of threads. The speedup values for 2, 8, 16, and 32 cores were 1.93, 5.86, 7.39, and 7.58, respectively.

Future Directions for Research

Because of the increasing number and variety of available GPFs, users now face the challenge of selecting an appropriate platform for their specific application and requirements. First, a user might search for efficient implementations of graph algorithms. However, there exists a large variety of graph processing algorithms which can

Graph Processing Frameworks, Fig. 1 Plot of the LiveJournal social network degree distribution obtained with the Gelly GPF. The horizontal axis represents the degree

k . The vertical axis represents the degree distribution $P(k)$. Both axes are in logarithmic scale

be categorized into several groups by functionality and consumption of resources.

Efficient low-level implementation of such algorithms is subject to substantial implementation effort. Parallelizing graph algorithms with efficient performance is a very challenging task.

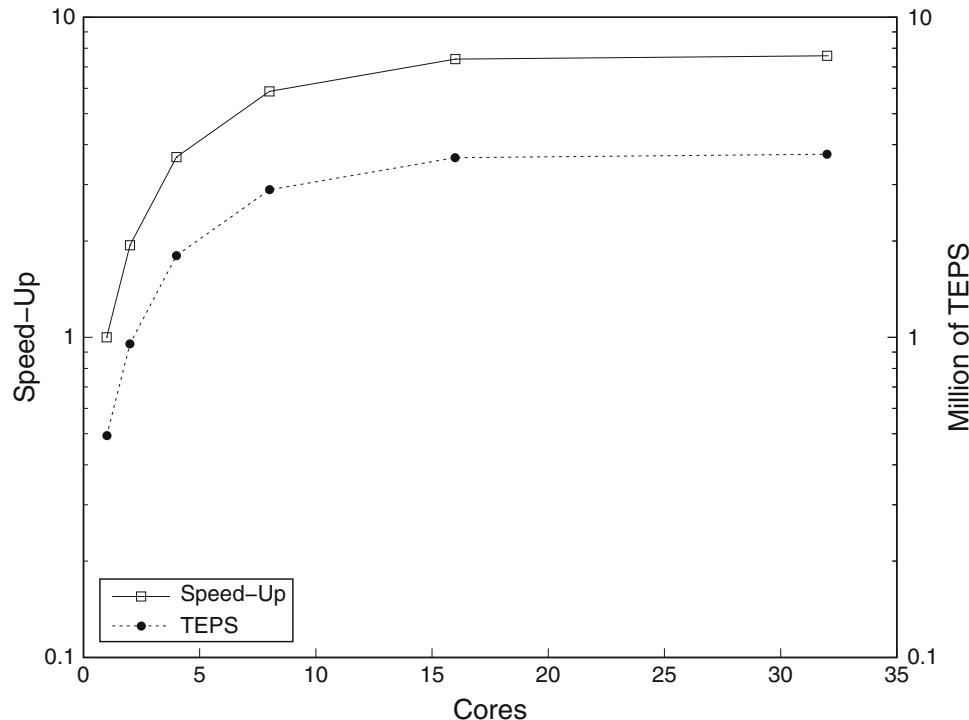

Although TLAV is a simple and easy to use approach to build graph processing applications, their implementation often leads to a significant amount of overhead. Efficient computing of graph partitions remains as a relevant topic in GPFs.

GPF performance is also a key aspect. Identifying the systems parameters to be monitored and the metrics that can be used to characterize GPF performance might be a difficult task. The general performance aspects can be raw processing power, resource usage, scalability, and processing overheads. These aspects can be observed by monitoring traditional system parameters like

lifetime of each processing job, the CPU and network load, the OS memory consumption, and the disk I/O, to name some parameters. Those observed parameters should be translated to relevant performance metrics such as vertices per second, edges per second, horizontal and vertical scalability, computation and communication time, and time overhead.

Datasets need to be considered also. In general, designing a good benchmark is challenging task due to the many aspects that should be considered which can influence the adoption and the usage scenarios of the benchmark. Unfortunately, there is clear lack of standard benchmarks that can be employed in GPF evaluation.

Finally, building GPFs to hybrid architectures is still under development. The main challenge in heterogeneous computing frameworks is to partition the graph in such a way that resulting partitions are mapped to processing elements

Graph Processing Frameworks, Fig. 2 Speed-up and TEPS produced by Gelly by using different numbers of threads of the LiveJournal Social Network degree distribution

according to their different architectural characteristics. In heterogeneous computing the power of different processors varies, so the load assigned to each processor should not be the same. Graph partitioning for hybrid architectures should focus on minimizing computation time rather than minimizing communications.

ture types of a data model, in any combination desired.

In the context of graph data management, a *graph query language* (GQL) defines the way to retrieve or extract data which have been modeled as a graph and whose structure is defined by a graph data model. Therefore, a GQL is designed to support specific graph operations, such as graph pattern matching and shortest path finding.

Graph Query Languages

Renzo Angles¹, Juan Reutter², and Hannes Voigt³

¹Universidad de Talca, Talca, Chile

²Pontificia Universidad Católica de Chile, Santiago, Chile

³Dresden Database Systems Group, Technische Universität Dresden, Dresden, Germany

Overview

Research on graph query languages has at least 30 years of history. Several GQLs were proposed during the 1980s, most of them oriented to study and define the theoretical foundations of the area. During the 1990s, the research on GQLs was overshadowed by the appearance of XML, which was arguably seen as the main alternative to relational databases for scenarios involving semi-structured data. With the beginning of the new millennium, however, the area of GQLs gained new momentum, driven by the emergence of applications where cyclical relationships naturally occur, including social networks, the Semantic Web, and so forth. Currently GQLs are a fundamental tool that supports the manipulation and analysis of complex big data graphs. Detailed survey of graph query language research can be found in Angles et al. (2017b).

Key Research Findings

Most of the languages that have been proposed are based on the idea of matching a *graph pattern*. In designing a GQL one typically starts with graph patterns, to which several other features are added. Examples of these features include set operations, relational algebra operations, the addition of path queries, closing graph patterns through recursion, etc. In the following we describe how graph pattern matching works, as well as the most typical features commonly added to graph patterns.

Definitions

A query language is a high-level computer language for the retrieval and modification of data held in databases or files. Query languages usually consist of a collection of operators which can be applied to any valid instances of the data struc-

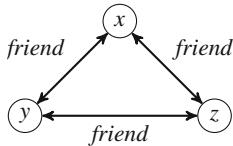

This work was supported by Iniciativa Científica Milenio Grant 120004.

Since our focus is on the fundamentals of GQLs, we concentrate on the simplest data model for graphs, i.e., directed labeled graphs. Later on, we review how these fundamentals are translated into practical query languages in more complex graph data models.

Let Σ be a finite alphabet. A *graph database* G over Σ is a pair (V, E) , where V is a finite set of nodes and $E \subseteq V \times \Sigma \times V$ is a set of edges. That is, we view each edge as a triple $(v, a, v') \in V \times \Sigma \times V$, whose interpretation is an a -labeled edge from v to v' in G .

Graph Pattern Matching

The idea of patterns is to define small subgraphs of interest to look for in an input graph. For example, in a social network one can match the following pattern to look for a clique of three individuals that are all friends with each other:

Let $V = \{x, y, z, \dots\}$ be an infinite set of variables. In its simplest form, a graph pattern is simply a graph $P = (V_P, E_P)$ where all the nodes in V_P are replaced by variables. For example, the pattern above can be understood as a graph over alphabet $\Sigma = \{\text{friend}\}$ whose set of nodes is $\{x, y, z\}$ and whose edges are $\{(x, \text{friend}, y), (y, \text{friend}, x), (x, \text{friend}, z), (z, \text{friend}, x), (y, \text{friend}, z), (z, \text{friend}, y)\}$.

The semantics of patterns is given using the notion of a match. A match of a pattern $P = (V_P, E_P)$ over a graph $G = (V_G, E_G)$ is a mapping μ from variables to constants, such that the graph resulting from replacing each variable for the corresponding constant in the pattern is actually a subgraph of G , i.e., for every pattern node $x \in V_P$, we have that $\mu(x) \in V_G$, and for each edge $(x, a, y) \in E_P$, we have that $(\mu(x), a, \mu(y))$ belongs to E_G .

The problem of pattern matching has been extensively studied in the literature, and several other notions of matching have been considered. The basic notion defined above is known as a

homomorphism and constitutes the most common semantics. Additionally, one could also consider *simple path semantics*, which does not permit repeating nodes and used in, e.g., the languages G (Cruz et al. 1987b) and $G+$ (Cruz et al. 1989), *injective homomorphism*, that disallow variables to be mapped to the same element or semantics based on graph simulations (see, e.g., Miller et al. 2015 for a survey).

Although the set of matchings from P to G can be already seen as the set of answers for the evaluation of P over G , one is normally interested in tuples of nodes: if P uses variables x_1, \dots, x_n , then we define the result of evaluating P over G , which we denote by $P(G)$, as the set of tuples $\{(\mu(x_1), \dots, \mu(x_n)) \mid \mu \text{ is a match from } P \text{ to } G\}$.

Extensions. Graph patterns can be extended by adding numerous features. For starters, one could allow variables in the edge labels of patterns or allow a mixture between constant and variables in nodes or edges. In this case, mappings must be the identity on constant values, and if an edge (x, y, z) occurs in a pattern, then $\mu(y)$ must be a label in Σ , so that $(\mu(x), \mu(y), \mu(z))$ is an edge in the graph upon we are matching. Patterns can also be augmented with *projection*, and since the answer is a set of tuples, we can also define set operations (*union*, *intersection*, *difference*, etc.) over them. Likewise, one can define *filters* that force the matches to satisfy certain Boolean conditions such as $x \neq y$. Another operator is the left outer join, also known as the *optional* operator. This operator allows to query incomplete information (an important characteristic of graph databases).

Graph Patterns as Relational Database Queries.

Graph patterns can also be defined as *conjunctive queries* over the relational representation of graph databases (see, e.g., Abiteboul et al. 1995 for a good introduction on relational database theory). In order to do this, given an alphabet Σ , we define $\sigma(\Sigma)$ as the relational schema that consists of one binary predicate symbol E_a , for each symbol $a \in \Sigma$. For readability purposes, we identify E_a with a ,

for each symbol $a \in \Sigma$. Each graph database $G = (V, E)$ over Σ can be represented as a relational instance $\mathbf{D}(G)$ over the schema $\sigma(\Sigma)$: The database $\mathbf{D}(G)$ consists of all facts of the form $E_a(v, v')$ such that (v, a, v') is an edge in G (for this we assume that \mathbf{D} includes all the nodes in V). It is then not difficult to see that graph patterns are actually *conjunctive queries* over the relational representation of graphs, that is, formulas of the form $Q(\bar{x}) = \exists \bar{y} \phi(\bar{x}, \bar{y})$, where \bar{x} and \bar{y} are tuples of variables and $\phi(\bar{x}, \bar{y})$ is a conjunction of relational atoms from σ that use variables from \bar{x} to \bar{y} . For example, the pattern shown above can be written as the relational query $Q(x, y, z) = \text{friend}(x, y) \wedge \text{friend}(y, x) \wedge \text{friend}(x, z) \wedge \text{friend}(z, x) \wedge \text{friend}(y, z) \wedge \text{friend}(z, y)$.

The correspondence between patterns and conjunctive queries allows us to reuse the broad corpus on literature on conjunctive queries for our graph scenario. We also use this correspondence when defining more complex classes of graph patterns.

Path Queries

The idea of a path query is to select pairs of nodes in a graph whose relationship is given by a path (of arbitrary length) satisfying certain properties. For example, one could use a path query in a social network to extract all nodes that can be reached from an individual via friend-of-a-friend paths of arbitrary length.

The most simple navigational querying mechanism for graph databases is a *regular path query (RPQ)* (Abiteboul et al. 1999; Cruz et al. 1987a; Calvanese et al. 2002), which allows to specify navigation by means of regular expressions. Formally, an RPQ Q over Σ is a regular language $L \subseteq \Sigma^*$, and it is specified using a regular expression R . Their semantics is defined in terms of paths. A *path* ρ from v_0 to v_m in a graph $G = (V, E)$ is a sequence $(v_0, a_0, v_1), (v_1, a_1, v_2), \dots, (v_{m-1}, a_{m-1}, v_m)$, for some $m \geq 0$, where each (v_i, a_i, v_{i+1}) , for $i < m$, is an edge in E . In particular, all the v_i 's are nodes in V and all the a_j 's are letters in Σ . The *label* of ρ is the word $a_0 \dots a_{m-1} \in \Sigma^*$.

The idea behind regular path queries is to select all pairs of nodes whose labels belong to the language of the defining regular expression. That is, given a graph database $G = (V, E)$ and an RPQ R , the evaluation of R over G , denoted $\llbracket R \rrbracket_G$, is the set of all pairs $(v, v') \in V$ such that there is path ρ between v and v' and the label of ρ is a word in the language of R .

More Complex Path Queries. RPQs have been extended in a myriad of ways. For example, we have *two-way regular path queries* (2RPQs) (Calvanese et al. 2000) that add to RPQs the ability to traverse edge backward via inverse symbols a^- , *nested* regular path queries (Barceló et al. 2012b) that further extend 2RPQs with node tests similar to what is done with propositional dynamic logic or XPath expressions, and several proposals adding variables to path queries (Wood 1990; Santini 2012; Fionda et al. 2015). There are also proposals of more expressive forms of path queries, using, for example, context-free languages (Hellings 2014), and several formalisms aimed at comparing pieces of data that may be associated with the nodes in a graph (see, e.g., Libkin and Vrgoč 2012). Another type of path queries, called *property paths*, extends RPQs with a mild form of negation (Kostylev et al. 2015).

Adding Path Queries to Patterns. Path queries and patterns can be naturally combined to form what is known as *conjunctive regular path queries*, or CRPQs (Florescu et al. 1998; Calvanese et al. 2000). Just as with graph patterns and conjunctive queries, we can define CRPQs in two ways. From a pattern perspective, CRPQs amount to replacing some of the edges in a graph pattern by a regular expression, such as the following CRPQ, which looks for two paths with an indirect friend n in common:

However, a CRPQ over an alphabet Σ can also be seen as a conjunctive query over a relational representation of graphs that includes a predicate for each regular expression constructed from Σ .

In our case, the corresponding conjunctive query for the pattern above is written as $Q(x, y) = \text{friend}^+(x, n) \wedge \text{friend}^+(y, n)$. Note that here we are using n as a constant; since CRPQs are again patterns, they can be augmented with any of the features we listed for patterns, including constants, projection, set operations, filters, and outer joins. We can also obtain more expressive classes of queries by including more expressive forms of path queries: using 2RPQs instead of RPQs gives rise to C2RPQs, or conjunctive 2RPQs, and using nested regular expressions gives rise to CNREs, which are also known as *conjunctive nested path queries*, or CNPQs (Bienvenu et al. 2014; Bourhis et al. 2014). Finally, Barceló et al. (2012a) consider restricting several path queries in a CRPQ at the same time by means of regular relations. The resulting language is capable of expressing, for example, that the two paths of friends in the pattern above must be of the same length.

Algorithmic Issues. The most important algorithmic problem studied for GQLs is *query answering*. This problem asks, given a query Q with k variables, a graph G and a tuple \bar{a} of k values from G , whether \bar{a} belongs to the evaluation of Q over G . All of the classes of path queries we have discussed can be evaluated quite efficiently. For example, all of RPQs, 2RPQs, and NREs can be evaluated in linear time in the size of Q and of G . Barceló (2013) provides a good survey on the subject.

When adding path queries to patterns, one again hopes that the resulting language will not be more difficult to evaluate than standard patterns or conjunctive queries. And indeed this happens to be the case: The evaluation problem for CRPQs, C2RPQs, and CNREs is NP-complete just as patterns. In fact, one can show this for any pattern augmented with a form of path query, as long as the evaluation for these path queries is in PTIME.

The second problem that has received considerable attention is *query containment*. This problem asks, given queries Q_1 and Q_2 , whether the answers of Q_1 are always contained in the

answers of Q_2 . Since all queries we presented are based on graph patterns, the lower bound for this problem is NP, as containment is known to be NP-complete already for simple graph patterns. In contrast to evaluation, adding path queries to patterns can significantly alter the complexity of containment: for CRPQs the problem is already EXPSPACE-complete (Calvanese et al. 2000), and depending on the features considered, it may even become undecidable.

Beyond Patterns

For the navigational languages, we have seen, thus far, paths are the only form of recursion allowed, but to express certain types of queries, we may require more expressive forms of recursion. As an example, suppose now our social network admits labels *friends* and *works_with*, the latter for joining two nodes that are colleagues. Now imagine that we need to find all nodes x and y that are connected by a path where each subsequent pair of nodes in the path is connected by both *friend* and *works_with* relations. We cannot express this query as a regular expression between paths, so instead what we do is to adopt *Datalog* as a framework for expressing the repetitions of patterns themselves. Consider, for example, a rule of the form:

$$P(x, y) \leftarrow \text{friend}(x, y), \text{works_with}(x, y).$$

This rule is just another way of expressing the pattern that computes all pairs of nodes connected both by *friend* and *works_with* relations. In this case, P represents a new relation, known as an *intensional predicate*, that is intended to compute all pairs of nodes that are satisfied by this pattern. We can then use P to specify the rule:

$$\text{Ans}(x, y) \leftarrow P^+(x, y).$$

Now both rules together form what is known as a *regular query* (Reutter et al. 2015) or nested positive 2RPQs (Bourhis et al. 2014, 2015). The idea is that $P^+(x, y)$ represents all pairs x, y connected by a path of nodes, all of them satisfying the pattern P (i.e., connected both by *friend* and *works_with* relations). Regular queries can be understood as the language resulting of extending

graph patterns with edges that can be labeled not only with a path query but with any arbitrary repetition of a binary pattern.

The idea of using Datalog as a graph query language for graph databases comes from Consens and Mendelzon (1990), where it was introduced under the name GraphLog. GraphLog opened up several possibilities for designing new query languages for graphs, but one of the problems of GraphLog was that it was too expressive, and therefore problems such as query containment were undecidable for arbitrary GraphLog queries. However, interest in Datalog for graphs has returned in the past few years, as researchers started to restrict Datalog programs in order to obtain query languages that can allow expressing the recursion or repetition of a given pattern, but at the same time maintaining good algorithmic properties for the query answering problem. For example, the complexity for evaluating regular queries is the same as for C2RPQs, and the containment problem is just one exponential higher. Besides regular queries, other noteworthy graph languages follow by restricting to monadic Datalog programs (Rudolph and Krötzsch 2013), programs whose rules are either guarded or frontier-guarded (Bourhis et al. 2015; Bienvenu et al. 2015), and first-order logic with transitive closure (Bourhis et al. 2014).

Composability

A particularly important feature of query languages is *composability*. Composable query languages allow to formulate queries with respect to results of other queries expressed in the same language. Composability is an important principle for the design of simple but powerful programming languages in general and query languages in particular (Date 1984). To be composable, the input and the output of a query must have the same (or a compatible) data model.

CQs (and C2RPQs) are not inherently composable, since their output is a relation and their input is a graph. In contrast, RPQs (and 2RPQs) allow query composition, since the set of pairs of nodes resulting from an RPQ can be interpreted as edges obviously. Regular queries

are composable for the same reason. In general, Datalog-based graph query languages are composable over relations but not necessarily over graphs.

In the context of modern data analytics, data is collected to a large extent automatically by hardware and software sensors in fine granularity and low abstraction. Where users interact with data, they typically think, reason, and talk about entities of larger granularity and higher abstraction. For instance, social network data is collected in terms of *friend* relationship and individual messages sent from one person to another, while the user is often interested in communities, discussion threads, topics, etc. User-level concepts are often multiple abstraction levels higher than the concepts in which data is captured and stored. The query language of database systems is the main means for users to derive information in terms of their user-level concepts for a database oblivious of user's concepts. To offer a capability of conceptual abstraction, a query language has to (1) be able to create entirely new entities within the data model to lift data into higher-level concepts and (2) be composable over its data model, so that the users can express a stack of multiple such conceptual abstraction steps with the same language.

RPQs (and 2RPQs) and regular queries allow conceptual abstraction for edges. For instance, *ancestor* edges can be derived from sequences of *parent* edges. Conceptual abstraction for nodes has been considered only recently (Rudolf et al. 2014; Voigt 2017) and allows to derive (or construct) an entirely new output graph from the input graph. In the simplest form of *graph construction*, a new node is derived from each tuple resulting from a pattern match (C2RPQs, etc.), e.g., deriving a *marriage* node from every pair of persons that are mutually connected by *married – to* edges. The more general and more expressive variant of graph construction includes aggregation and allows to derive a new node from every group of tuples given a set of variables as grouping keys, e.g., deriving a *parents* node from every group of adults all connected by *parent – to* the same child.

Key Applications

There is a vast number of GQLs that have been proposed and implemented by graph databases and an even larger number of GQLs that are used in specific application domains (see, e.g., Dries et al. 2009; Brijder et al. 2013; Martín et al. 2011). In the following we focus on GQLs designed for the two most popular graph data models: property graphs and RDF.

Property Graph Databases

A property graph is a directed labeled multigraph with the special characteristic that each node or edge can maintain a set (possibly empty) of properties, usually represented as key-value pairs. The property graph data model is very popular in current graph database systems, including Neo4j, Oracle PGX, Titan, and Amazon Neptune.

There is no standard query language for property graphs although some proposals are available. Blueprints (<http://tinkerpop.apache.org/>) was one of the first libraries created for manipulating property graphs. Blueprints is analogous to the JDBC, but for graph databases. Gremlin (Rodriguez 2015) is a graph-based programming language for property graphs developed within the TinkerPop open-source project. Gremlin makes extensive use of XPath to support complex graph traversals. Cypher is a declarative query language defined for the Neo4j graph database engine, originally, and by now adopted by other implementers. Cypher supports basic graph patterns and basic types of regular path queries (i.e., paths with a fixed edge label or paths with any labels) with a no-repeating-edges matching semantics. The development of Cypher is a still ongoing community effort (<http://www.opencypher.org/>).

PGQL (van Rest et al. 2016) is a query language for property graphs recently developed as part of Oracle PGX, an in-memory graph analytic framework. PGQL defines a SQL-like syntax that allows to express graph pattern matching queries, regular path queries (with conditions on labels and properties), graph construction, and query composition.

G-CORE (Angles et al. 2017a) is a language recently proposed by the Linked Data Benchmark Council (LDBC). G-CORE advertises regular queries, nested weighted shortest path queries, graph construction with aggregation, and composability as the core feature of future graph query languages on property graphs.

RDF Databases

The Resource Description Framework (RDF) is a W3C recommendation that defines a graph-based data model for describing and publishing data on the web. This data model gains popularity in the context of managing web data, giving place to the development of RDF databases (also called triplestores). Along with these database systems, several RDF query languages were developed (we refer the reader to a brief survey by Haase et al. 2004). Currently, SPARQL (Prud'hommeaux and Seaborne 2008) is the standard query language for RDF. SPARQL was designed to support several types of complex graph patterns and, in its latest version, SPARQL 1.1 (Harris and Seaborne 2013), adds support for negation, regular path queries (called *property paths*), subqueries, and aggregate operators. The path queries support reachability tests.

Definitions

While being eminently useful in a wide variety of application domains, the high expressiveness of graph queries makes them hard to optimize and, hence, challenging to process efficiently. We discuss a number of state-of-the-art approaches which aim to overcome these challenges, focusing specifically on planning, optimization, and execution of two commonly used types of declarative graph queries: subgraph queries and regular path queries.

Overview

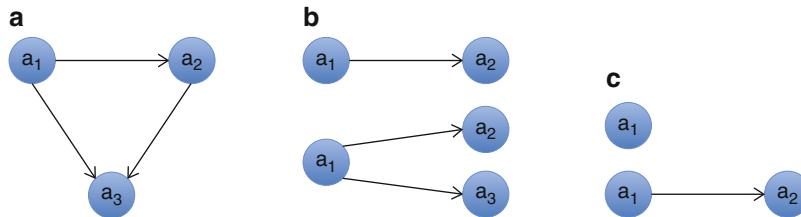

In this chapter, we give a broad overview of the general techniques for processing two classes of graph queries: *subgraph queries*, which find instances of a *query subgraph* in a larger input graph, and *regular path queries* (RPQs), which find pairs of nodes in the graph connected by a path matching a given regular expression. Certainly, software that manage and process graph-structured data, such as RDF

triple stores (Neumann and Weikum (2010), Virtuoso), graph database management systems (GDBMSes) (Kankamamge et al. (2017), neo4j), XML databases (Gou and Chirkova (2007)), or extensions of relational databases that support graphs (Färber et al. 2012), also process other types of queries over graph-structured data. For example, some GDBMSes and RDF triple stores have query languages, such as Cypher and SPARQL, which can express typical relational operations on data, such as group-by-and-aggregates, filters, projections, ordering, as well as graph-specific queries such as *shortest path queries*. We focus on subgraph queries and RPQs as they are two of the most commonly appearing graph-specific queries in these systems. We note that some systems, such as Pregel (Malewicz et al. 2010) and some linear algebra software, have APIs to express other graph algorithms, such as PageRank, algorithms to find connected components, or BFS traversals, which we also do not cover in this chapter.

The high-level pipeline in existing systems to process subgraph queries and RPQs follows the classic pipeline in RDBMSes and consists of two steps: (1) a logical query plan generation and optimization and (2) a physical query plan generation, which outputs a physical plan that is evaluated on the actual graph data. We focus more on techniques to generate logical plans, which we think depict more commonality across systems than physical plans which are highly system-dependent.

Subgraph Queries

We consider the most basic form of subgraph queries in which the goal is to find instances of a directed subgraph Q , without any filters on its nodes or edges, in an input graph G . As a running example, consider the triangle query in Fig. 1a. Any subgraph query Q can be equivalently written as a relational multiway self-join query as follows. We label each vertex in Q with a distinct attribute a_i . The equivalent multiway join query contains an edge (a_i, a_j) relation

Graph Query Processing, Fig. 1 Triangle query and example edge-at-a-time and vertex-at-a-time plans. (a) Triangle Query. (b) Edge-at-a-time Plan. (c) Vertex-at-a-time Plan

for each edge (a_i, a_j) in Q . For example, in Datalog syntax, the triangle query is equivalent to:

$$tri(a_1, a_2, a_3) :=$$

$$edge(a_1, a_2), edge(a_1, a_3), edge(a_2, a_3)$$

Each edge table is a replica of each other and contains each edge (u, v) in G . Therefore, we think of subgraph queries as complex self-joins of replicas of an edge table.

Numerous approaches to evaluating subgraph queries exist in literature. We review two of these approaches, which we refer to as *edge-at-a-time* and *vertex-at-a-time* approaches. Then, we review two techniques which handle two scalability issues: (1) query decompositions, which are used when Q is large, i.e., contains many edges and vertices and (2) compressed output representations, which are used when the number of output instances is large. Large input graphs are a third scalability issue and are often handled by resorting to distributed systems. We omit a detailed discussion of this topic.

Edge-at-a-time Approaches

One of the most common approaches to evaluate subgraph queries is to match Q in G one edge at a time. This approach is equivalent to binary join plans. For example, one can evaluate the triangle query by first matching two of the edges and finding open triangles in G and then matching the third edge and closing these open triangles. This is equivalent to performing the following binary joins:

$$\begin{aligned} open-tri(a_1, a_2, a_3) &:= \\ edge(a_1, a_2), edge(a_2, a_3) & \\ tri(a_1, a_2, a_3) &:= \\ open-tri(a_1, a_2, a_3), edge(a_3, a_1) & \end{aligned}$$

The partial subgraphs matched by this plan are shown in Fig. 1b. Many RDF triple stores (Neumann and Weikum 2010), GDBMSes (neo4j), research prototype systems (Lai et al. 2016, 2017), as well as most RDBMSes (The only exception we are aware of is the LogicBlox system (Aref et al. 2015)), use this approach. There is a rich body of work on picking binary join plans. Systems first enumerate a set of join plans to pick from, such as left-deep or bushy plans, and then pick an actual plan using standard techniques. For example, TwinTwigJoin (Lai et al. 2017) considers only left-deep plans, while RDF-3x (Neumann and Weikum 2010) also considers bushy plans, and both systems use cost-based techniques that assign a cost to each possible plan, e.g., by estimating the sizes of intermediate tables that a plan generates and pick the lowest cost plan.

Vertex-at-a-time Approaches

Another approach is to match Q in G one vertex-at-a-time. Suppose Q contains m vertices a_1, \dots, a_m . This approach first picks an order of these m vertices, which we assume for simplicity to be a_1, \dots, a_m . We first compute $\Pi_{a_1} Q$, so match only vertex a_1 of Q in G . Then, these partial matches are extended by one vertex to compute $\Pi_{a_1, a_2} Q$, so and so forth, until finally a_1, \dots, a_{m-1} partial matches are extended to

compute $\Pi_{a_1, \dots, a_m} Q = Q$. Partial subgraphs to a new vertex a_i by effectively intersecting all of the edges that are incident on a_i in Q from already matched vertices a_1, \dots, a_{i-1} . Figure 1c shows the partial subgraphs that are matched when evaluating the triangle query vertex-at-a-time.

Readers might find the difference between vertex-at-a-time and edge-at-a-time approaches superficial. Indeed depending on how the intersections are computed, these approaches can even be equivalent. As an example, suppose a “vertex-at-a-time” algorithm takes (a_1, a_2) partial matches, e.g., $(1, 2)$, and for each outgoing edge of the vertex matching a_2 , in our case vertex 2, checks if the destination of that edge has an edge back to a_1 , in our case vertex 1. This effectively computes the intersection of 2’s out- and 1’s in-neighbors but is also equivalent to the edge-at-a-time join plan in Fig. 1b. Surprisingly, if the intersections are done in a particular way, there can be significant differences between these approaches. In particular, when extending a partial match (a_1, \dots, a_{i-1}) to a_i , the cost of intersecting all of the adjacent neighbor lists of a_i must take time proportional to the smallest adjacency list size, *for each partial match* (This can be achieved, for example, by first checking the sizes of the adjacency lists that need to be intersected and starting intersecting the elements in the smallest list in others.). Recent theoretical results have shown that using such fast intersections can make vertex-at-a-time approaches asymptotically faster than edge-at-a-time approaches (Ngo et al. 2012). For example, one can construct input graphs with N edges such that any edge-at-a-time plan will take $\Omega(N^2)$ time to compute the triangle query, yet vertex-at-a-time approaches will take $O(N^{3/2})$ time. These results were shown in the context of the new *worst-case optimal* join algorithms, such as NPPR (Ngo et al. 2012) and Leapfrog Triejoin (Veldhuizen 2012) algorithms, which evaluate queries one attribute at a time by such fast intersections.

Vertex-at-a-time approaches are used by many systems and algorithms, such as the Turbo_{ISO} (Han et al. 2013) and VF₂ (Cordella et al. 2004) algorithms, which do not necessarily

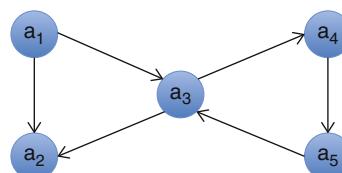

perform fast intersections, and the Empty-Headed (Aberger et al. 2016), LogicBlox (Aref et al. 2015) and Graphflow (Kankamamge et al. 2017) systems, which use worst-case optimal multiway join algorithms.

Query Decompositions

Queries that contain many vertices and edges are a common scalability challenge for evaluating subgraph queries. A popular technique used by both edge-at-a-time and vertex-at-a-time strategies is to decompose a query Q into smaller subqueries, SQ_1, \dots, SQ_k , evaluate each subquery separately, and then join them, instead of matching the edges or vertices of the query one by one. Bushy binary join plans are one type of decomposition. Decomposition has two main benefits:

- *Caching*: Decomposition avoids recomputing partial matched subgraphs SQ_i multiple times by caching and reusing them.
- *Filtering*: If the results of an SQ_i in the decomposed query is (partially) empty, we can (partially) avoid evaluating some SQ_j . As a simple example, consider the *bow tie query* in Fig. 2, which consists of an asymmetric triangle (a_1, a_2, a_3) and a symmetric triangle (a_3, a_4, a_5) sharing vertex a_3 . Suppose a vertex u is not part of any asymmetric triangles for a_3 , then we can skip computing the symmetric triangles of u for a_3 .

Decomposition is used by many systems and algorithms (Aberger et al. 2016; Lai et al. 2016; Neumann and Weikum 2010; Zhao and Han 2010). There are many possible decompositions of large queries, and different systems use different decompositions. For

Graph Query Processing, Fig. 2 Bow Tie Query

example, SEED (Lai et al. 2016) and SPath (Zhao and Han 2010), precompute and index several subgraphs, such as triangles or some paths, and pick decompositions that use these subgraphs. As another example, EmptyHeaded picks a special type of decomposition called *generalized hypertree decomposition* (GHD) and aims to have small number of edges in each SQ_i , which are evaluated using a vertex-at-a-time approach, but then joined using binary joins.

Compressed Output Representations

Another scalability challenge for systems and algorithms is the possibly very large outputs. On a graph with N edges, the number of matches of a query Q can be as large as $N^{\rho^*(Q)}$, where $\rho^*(Q)$ a quantity called the *fractional edge cover* of Q (Atserias et al. 2013). For example, there can be $\Omega(N^{3/2})$ triangles and $\Omega(N^3)$ bow ties. As a simple demonstrative example, an input graph that contains a clique of size 1000, will contain at least $\binom{1000}{5}$, roughly a quadrillion, many 5 cliques, which no system can effectively output in a reasonable time.

Several systems and algorithms handle this problem by using a compressed representation of the outputs for some queries. The techniques are varied, and we give high-level descriptions of several examples from literature. These compression techniques are closely related to the technique of *factorized databases* from the relational systems that have been used in several systems (Olteanu and Schleich 2016).

- *Clique compression:* SEED (Lai et al. 2016) detects maximal cliques in input graphs as a preprocessing step to avoid matching exponentially many instances of subgraphs in these cliques. Instead, these cliques are returned as output, and applications can enumerate the instances in them.
- *Cartesian Product-based Representation:* Reference (Qiao et al. 2017) proposes a technique to decompose Q into multiple subqueries (based on the vertex cover of Q) such that matches to the entire query can be represented as the union of a set of

Cartesian products of the matches of these subqueries. For example, a directed two-path query $edge(a_1, a_2), edge(a_2, a_3)$ can be represented as the union of Cartesian products of incoming and outgoing edges of each vertex.

G

Some systems and algorithms also compress the intermediate partial matches instead of the outputs. For example, TurboISO (Han et al. 2013) compresses two nodes a_i and a_j in Q that have the same neighborhoods into a single supernode (called *neighbor equivalence class*) and constructs a smaller query Q' . That is because if in an output a_i matches u and a_j matches v , there must be another output in which a_i matches v and a_j matches u . The algorithm evaluates Q' in a way that supernodes match sets of vertices in the graph. These sets are then expanded in different permutations to get outputs of Q . This technique effectively compresses the intermediate results that the algorithm generates.

Regular Path Queries

Regular path queries (RPQs) extend subgraph queries with nontrivial navigation on a graph. This navigation is performed by returning pairs of vertices in a graph such that paths between the vertices in a pair match a given regular expression. Formally, given a graph G as a tuple $\langle V, \Sigma, E \rangle$ for which V is a set of vertices, Σ is a set (alphabet) of labels, and $E \subseteq V \times \Sigma \times V$ is a set of directed, labeled edges; a regular path query Q is a tuple $\langle x, r, y \rangle$, where x and y are free variables which range over vertices and r is a regular expression. An *answer* to Q over a graph G is a vertex pair $\langle s, t \rangle \in V \times V$ such that there exists a path p from vertex s to vertex t such that it matches r . A *result* of a query Q on graph G is a collection of all answers of Q over G .

The semantics of regular path queries play an important role in their evaluation. Specifically, matching paths can be *simple* (no vertex is visited twice) or *arbitrary* (no such restriction). Further,

the result of the query can be *counting* (\forall), i.e., a query returns a *bag* of vertex pairs with each pair appearing in the result for each different matching path in a graph. On the other hand, the result can be *existential* (\exists , non-counting), i.e., a query returns a *set* of vertex pairs with each pair being an evidence that a matching path exists in a graph. Therefore, depending on the variations above, four types of semantical configurations for RPQs are distinguished: *simple*/ \exists , *simple*/ \forall , *arbitrary*/ \exists , and *arbitrary*/ \forall .

Intuitively, *simple* semantics have an implicit mechanism of dealing with cycles in a graph, while *arbitrary* configuration needs to deal with cycles explicitly to avoid unbounded computation. Further, \forall -semantics is very useful in SQL-style aggregation queries which \exists -semantics cannot handle.

It has been shown that *arbitrary*/ \exists is the only tractable configuration for a full fragment of regular expressions. Hence, a vast majority of systems which evaluate RPQs do so under *arbitrary*/ \exists semantics. SPARQL, a widely used graph query language, adopted *arbitrary*/ \exists RPQs in its *property paths* feature introduced as a part of SPARQL 1.1 specification. However, other semantical configurations are also used. For example, Cypher, a graph query language used in a popular neo4j graph database, is based on CHAREs (regular expressions with limited use of Kleene expressions) and semantics similar to *simple*/ \forall , but with paths with no repeated edges.

Graph Query Processing,

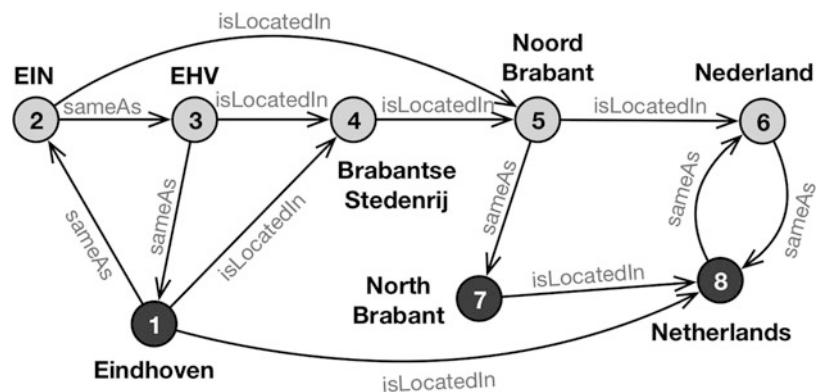

Fig. 3 Example of an interlinked English and Dutch DBpedia graph G_{DBP}

In the following subsections, we give a brief overview of different methods used in the evaluation of regular path queries. In literature, we identify three main groups of approaches: relational algebra-based, Datalog-based, and automata-based RPQ evaluation methods. Note that, due to lack of space, we do not discuss a wide body of work which uses specialized data structures (e.g., *reachability* indexes) in the evaluation of RPQs (e.g., see Gubichev et al. 2013; Fletcher et al. 2016). These methods are, in general, complementary to the methods we discuss below.

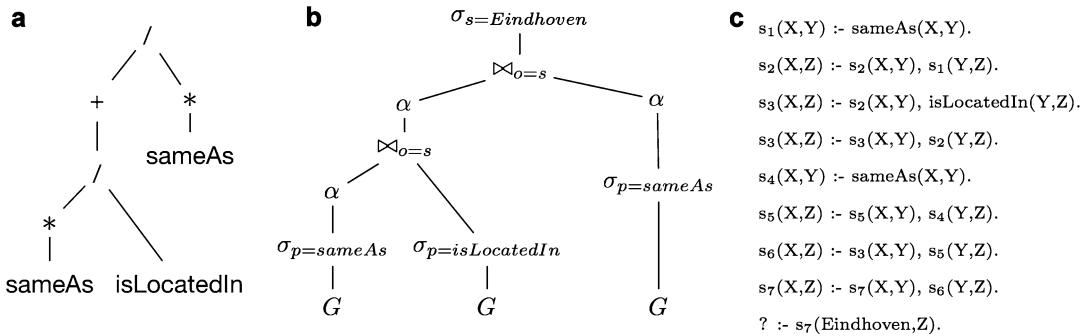

As a running example, consider a graph G_{DBP} and a query Q_{DBP} as shown in Fig. 3. Graph G_{DBP} contains information from both English and Dutch DBpedia datasets. Query Q_{DBP} aims to find all places p in both Dutch and English datasets in which the city of Eindhoven is located in. This query demonstrates the usefulness of RPQs in the navigation of unknown graphs, as it uses succinct but nontrivial Kleene transitive expressions to concurrently resolve both equivalence and geographical closures without prior knowledge of an underlying graph.

Relational Algebra and Datalog-Based Approaches

Authors of (Losemann and Martens 2012) proposed an RPQ evaluation algorithm based on a dynamic programming paradigm. Their approach

$$Q_{DBP} = \langle \text{Eindhoven}, (\text{isLocatedIn}/\text{sameAs}^*)^+/\text{sameAs}^*, p \rangle$$

Graph Query Processing, Fig. 4 A parse tree for a regular expression in Q_{DBP} , an α -RA tree and a Datalog program for Q_{DBP} . (a) A parse tree. (b) An α -RA tree (c) A Datalog program

G

can be modeled by the *relational algebra* extended by an additional operator α which computes the *transitive closure* of a given relation. This algebra, called α -RA (Agrawal 1988), can be then used to construct an α -RA expression tree (e.g., see Fig. 4b) based on the bottom-up traversal of a parse tree of the regular expression (Fig. 4a) in a given query.

Many GDBMSes implement RPQ evaluation by adapting the α -RA approach since it models relational techniques well and, thus, can be easily and efficiently implemented in most relational databases which support SQL-style recursion (e.g., PostgreSQL, Oracle, IBM DB2, and others) and relational triple stores (e.g., Virtuoso, IBM DB2 RDF store, and others). Evaluation based on α -extended relational algebra is also considered in (Dey et al. 2013; Yakovets et al. 2013).

Native support of recursion makes Datalog a suitable language to express regular path queries. For example, authors of (Consens et al. 1995) propose a simple strategy to convert an α -RA tree into a Datalog program (e.g., as shown in Fig. 4c). Then, this program can be submitted to any Datalog-compliant engine (e.g., LogicBlox) in order to evaluate a given RPQ.

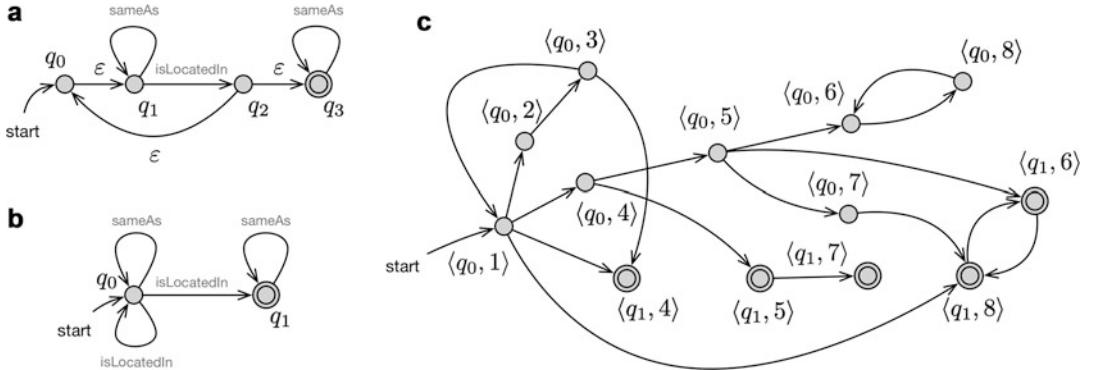

Note, however, that both α -RA tree and a corresponding Datalog program obtained by the translation procedure are not necessarily the most efficient as all the issues related to query planning apply to the tree and its translation as well (e.g., translation methods, join orders, query rewrites,

sideways information passing, and many others) (Consens et al. 1995; Yakovets et al. 2016).

Finite Automata-Based Approaches

Research on regular expressions, of course, well precedes the introduction of regular path queries. Specifically, regular expressions have been introduced in formal languages theory as a notation for patterns which *generate* words over a given alphabet. The dual problem to generation is *recognition* – and *finite state automata* (FA) are the recognizers for regular expressions. Specifically, given a regular expression r , there exists a number of methods to construct a corresponding automaton which recognizes the language of r . Note that there exist infinitely many FA which can recognize r , and many approaches exist which aim to construct an automaton deemed efficient for a particular scenario, e.g., finite automata obtained by using *minimization*.

Implementation of a **G+** query language (Mendelzon and Wood 1995) includes the first method which uses FA for evaluation of regular path queries on graphs. The algorithm works as follows. First, an automaton AQ_{DBP} (e.g., see Fig. 5a) which recognizes given regular expression r is constructed by using standard methods (e.g., Thompson's construction (Thompson 1968) and then, optionally, minimized (Fig. 5b). Then, a graph database G_{DBP} is converted into finite automaton AG_{DBP} with graph vertices becoming automaton states and

Graph Query Processing, Fig. 5 Example of automata for Q_{DBP} and a corresponding product automaton. (a) An ϵ -NFA for Q_{DBP} . (b) A minimized NFA for Q_{DBP} . (c) A product automaton $P_{DBP} = A_{Q_{DBP}} * A_{G_{DBP}}$

graph edges becoming automaton transitions in $A_{G_{DBP}}$. Given $A_{Q_{DBP}}$ and $A_{G_{DBP}}$, a product automaton $P_{DBP} = A_{Q_{DBP}} \times A_{G_{DBP}}$ (Fig. 5c) is constructed. Finally, automaton P_{DBP} is then tested for non-emptiness by checking whether any accepting state(s) can be reached from the starting state(s). Then, pairs of starting and corresponding reachable accepting states in P_{DBP} form the answer pairs for Q_{DBP} . The idea of using FA in evaluation of RPQs is used in Kochut and Janik (2007), Koschmieder and Leser (2012), Mendelzon and Wood (1995), Pérez et al. (2010), Yakovets et al. (2016), and Zauner et al. (2010). We briefly summarize some of these approaches below.

To avoid construction of a full product automaton, authors of Kochut and Janik (2007) propose to evaluate RPQs by running a bidirectional breadth-first search (biBFS) in the graph. Specifically, given a *reachability* query (i.e., an RPQ where variables are bound to constants on both ends), two FA are constructed. First automaton recognizes the regular language defined by the original expression, and the second automaton accepts the reversed language, which is also regular. The algorithm uses the steps of the biBFS to expand the search frontiers and to connect paths. Before each vertex in a graph is placed on the search frontier for the next expansion, the check is performed whether the partial path leading up to this vertex is not rejected by the appropriate (direct or reverse) automaton.

Authors of Koschmieder and Leser (2012) present an RPQ evaluation method which executes the search simultaneously in the graph and the automaton. This is achieved by exploring the graph using a BFS while marking the vertices in the graph with the corresponding states in the automaton. Essentially, in this method, edges in the graph are traversed only if the corresponding transition in the automaton allows it. This way, the construction of a full product automaton is avoided, and the automaton essentially acts as an evaluation plan for a given RPQ.

WaveGuide system (Yakovets et al. 2016) takes the idea of using an FA as an evaluation plan further. Authors show that effective plan spaces that result from FA-based and α -RA-based approaches are, in fact, incomparable. Hence, to find the best plan, both implicit plan spaces have to be considered. With this in mind, authors design a cost-based optimizer for RPQs which subsume and extend FA and α -RA-based approaches. Query plans in WaveGuide are based on the notion of *wavefronts* – stratified automata extended with seeds, append, prepend, and view transitions.

Research Directions

One important research direction in evaluating subgraph queries is understanding when the vertex-at-a-time algorithms perform better

than edge-at-a-time algorithm. For example, some early work in the area Nguyen et al. (2015) suggest that the worst-case optimal join algorithms outperform some systems that use binary join plans for some cyclic queries, but the topic requires a more thorough study.

Often applications do not just find subgraphs but perform other computations on the found subgraph outputs. Studying what kind of queries can be further executed on these outputs, when the outputs are compressed, is another research direction.

Finally, while it has been shown that RPQs allow for a rich plan space, it is still a challenge to generate *good* query evaluation plans with lowest execution costs. More research is needed to come up with accurate cost and cardinality estimation techniques used in graph query processing. This task is further complicated by the limited and often correlated structure of graph data.

³SAP SE, Berlin, Germany

Definitions

Graph representation concerns the layout of graph data in the linearly addressed storage of computers (main memory, SSD, hard disk, etc.). General objectives for graph representations are (1) to use little storage space (space-efficiency) while (2) allowing operations and queries on the graph to be executed in a short time (time-efficiency). Hence, every graph representation technique is subject to a specific space–time trade-off. It depends on the particular scenario (data, workload, available resources, etc.) whether the space–time trade-off of a certain representation technique is worthwhile.

Overview

Graph data comes with a large variation of graph data models, with RDF and the property graph model (PGM) being the most prominent ones. The specific graph representation depends on the data model. We introduce the most important concepts for graph representations as data-model-agnostic as possible. The discussion is structured in (1) primary representation of the graph adjacency, (2) primary representation of properties (i.e., data) associated with graph objects (nodes and edges), and (3) indexing, i.e., the secondary representation of graph data.

Key Research Findings

Adjacency Representation

The adjacency representation concerns only the graph topology, i.e., the structure of the graph, specifically the pairs of nodes that are connected by an edge. Here, we assume a simple, directed graph $G(V, E)$ where V is the set of vertices and $E \subseteq V \times V$ is the set of edges.

Adjacency Matrix. An adjacency matrix, the most basic storage structure for graphs, stores the topology as a binary matrix representing each edge in the graph by an individual bit stored at coordinates (u, v) for vertices $u, v \in V$ (Cormen et al. 2001). With a quadratic space complexity of $\mathcal{O}(|V|^2)$, an adjacency matrix is only space-efficient for very dense graphs. However, often graphs are sparse in practice; therefore a pure adjacency matrix representation is rather uncommon in graph data management and graph processing systems.

Adjacency List. Being more suitable for sparse graphs, an adjacency list stores for each vertex a linked list of adjacent vertices and has a space complexity of $\mathcal{O}(|V| + |E|)$. Technically, an adjacency list can be implemented either by a pointer array to represent vertices and a set of linked lists to represent adjacent vertices or by an array of arrays. While a list-based adjacency data structure allows higher in-place update rates, an array-based adjacency list exhibits a better CPU

cache utilization for retrieving the adjacency of a vertex through a strictly sequential and contiguous memory access pattern. This is particularly important when the graph is stored in memory.

CSR. The *compressed sparse row* (CSR) data structure is a variation of the adjacency list. It has been developed in the context of sparse matrix multiplications and is widely used in graph processing systems (Gustavson 1978). The CSR data structure represents the graph topology as an *edge array* consisting of the target vertices of all edges in sequential order. To retrieve the adjacency of a single vertex, the *offset array* is used to compute the boundary values of the adjacency. In comparison to the adjacency list and the adjacency matrix, a CSR is more compact since the entire topology is represented in a single, large, continuous chunk of memory. The downside is that adding and removing vertices/edges is expensive and results in a partial reconstruction of the CSR to maintain the ordering. A detailed experimental analysis of several graph representations is given in Blandford et al. (2004).

Adjacency Compression. Various works consider succinct representations of the graph topology (Boldi and Vigna 2004; Apostolico and Drovandi 2009; Claude and Navarro 2010a,b; Boldi et al. 2011; Grabowski and Bieniecki 2011). Brisaboa et al. (2014) that provides a good overview. Currently, the most compact graph representation that still allows fast edge existence checks is based on k^2 -ary tree structures (Brisaboa et al. 2014). Specifically, this representation exploits the sparseness of the adjacency matrix and stores a graph in a compact tree structure of height $\lceil \log_k n \rceil$. The tree consists of nodes, where each node has a single bit assigned indicating whether there is at least one edge in the corresponding submatrix. A node assigned zero means that it has no child nodes and all elements in the submatrix are zero. The authors use the parameter k to configure the height of the tree at the cost of larger internal nodes with more child nodes. Internally, a k^2 -tree is represented by two bit sets, one for the internal nodes (except leaves) and one for the leaves

only. Bits are assigned according to a level-wise traversal of the tree, i.e., first all bits of level one, then all bits of level two, and so on. Although the data structure provides a concise representation of the graph topology, multi-relational graphs, i.e., multiple edges between a pair of vertices, are not supported. Additionally, the k^2 -ary tree is not designed for dynamic graphs with frequent edge insertions/deletions as each of these operations might trigger a rewriting of multiple internal nodes in the tree.

G

Adaptive Bit Set Representations. Aberger et al. (2016) propose to represent edges in an immutable and adaptive CSR data structure, which allows storing a single neighborhood either in a dense or a sparse representation. The actual representation is selected by an optimizer based on collected statistics about the density and the cardinality of the neighborhood set. The authors define the *density* of a neighborhood set as the cardinality of the set divided by the value range of the set. Real-world graphs tend to have a large skew in their neighborhood density distribution.

Property Representation

Property representation concerns approaches to represent all triples of the form (s, p, o) , where s is an entity, p is a property key, and o is a value. These properties can be node attributes and edge attributes. However, outgoing edges (or their label) can be treated as properties of a node. Likewise, source and target node of an edge can be treated as properties of an edge. Hence, approaches for property representation are often also used for adjacency representation. In general, techniques for the property representation are becoming more relevant in the presence of attributed or labeled graphs, as prevailing in RDF and the PGM.

Triple Table. A generic, straightforward approach for storing triple data is a relational data representation. A triple set can be easily stored in a single, universal *triple table* with three columns, S, P, and O (Chong et al. 2005). This approach is very common for RDF data. Typically, a triple table is combined with dictionary compression

to reduce the storage overhead implied by reoccurring, long identifiers. The addition of indexes allows for faster lookups. The downside is that a triple table requires many join operations to read an entity and its accompanying properties.

Universal Table. Alternatively, triples can also be stored in a universal table. The universal table maps each distinct property key to a separate column, and each object is represented as a single record in the table. Precisely, each row represents an s , each column a p , and each cell o so that $s[p] = o$ if there is triple (s, p, o) and $s[p] = \text{NULL}$ otherwise. This approach is very common for PGM data. In typical PGM data, nodes and edges do not share many property keys so that it is beneficial to use two universal tables, a *vertex table* and an *edge table* (Rudolf et al. 2013; Paradies et al. 2015). This approach allows the join-free reconstruction of a vertex/an edge through a selection and a subsequent attribute projection. Both, vertices and edges, can have an arbitrary number of attributes, though. Hence, universal tables require an efficient handling of NULL values.

Emerging Schemas. A solution that reduces the number of joins without introducing too many NULL values tries to exploit the schema inherent in the graph data. Since graph data usually has no upfront defined and rigid database schema, finding a suitable normalized database design for it is a nontrivial and tedious task. The simple *property-class* pattern partitions entities by class (RDF) or label (PGM) (Abadi et al. 2007). More general *property tables* cluster properties that frequently occur together into a table. Individual entities may be represented in many of these property tables, depending on which property cluster they fully or partially instantiate (Abadi et al. 2007). For a given dataset, a good set of property tables can be found automatically. Approaches are (1) utilizing standard clustering algorithms such as k-means (MacQueen 1967), cf. (Chu et al. 2007), (2) starting from every distinct property set and merge infrequent ones (Pham et al. 2015), or (3) partitioning entities on the fly based on

their schema similarity into small fix-sized partitions, such as memory blocks or disk pages (Herrmann et al. 2014a,b). The latter approach is lightweight, does not require any upfront computation, and can readapt if the inherent schema changes over time.

Schema Hashing. Another technique for NULL value reduction in universal tables is *schema hashing* (Bornea et al. 2013). Here, the universal table consists of n column groups. One column group consists of a **property** column and a **value** column, i.e., one column group represents a predicate–object pair or a property key–value pair from RDF or PGM, respectively. A hash function maps a predicate/property to one of the n column groups. With a well-designed hash function, properties are packed densely into the table with only few collisions. In case of a collision, the entity has to spill into an additional row. The same principle can be applied to labeled edges; then a column group consists of three columns, **edge-id**, **label**, and **target-vertex** (Sun et al. 2015). In this way, the complete neighborhood of a vertex can be represented in a single row.

Separate Property Storage. Instead of storing schema-flexible properties in the same data structure as the graph topology, some systems store properties in a separate data structure. For instance, it is possible to utilize a document store or the JSON (Crockford 2006) extension of a relational DBMS, to store all properties of an entity as a single JSON document in a single table cell of a separate vertex or edge attribute table (Sun et al. 2015). Another approach is to separate properties into a key–value table. By doing so, vertices and edges can be stored as fixed-length records in a vertex and an edge table, respectively. Fixed-length records can be directly addressed, which allows $O(1)$ access complexity to adjacent vertices.

Indexing

Exhaustive Indexing. State of the art in RDF representation is sixfold indexing, which

exhaustively indexes every permutation of the three triple elements, S, P, and O (Neumann and Weikum 2008; Weiss et al. 2008). In total, this approach results in six indexes: SPO, SOP, PSO, POS, OSP, and OPS. Likewise, every graph can be indexed on the source (S) and target (T) of the edges exhaustively by storing the adjacency once in forward order (ST) and once in reverse order (TS) (Hauck et al. 2015; Shun and Blelloch 2013). Exhaustive indexing of graphs is feasible since dictionary and delta compression allow for compact index representations. Furthermore, exhaustive indexing provides considerable performance gains since it facilitates direct neighborhood access over incoming as well as outgoing edges and efficient sort merge join operations on every combination of incident edges.

Aggregate Indexing. Additionally, aggregate indexes provide direct access to degree information (Neumann and Weikum 2008; Shun and Blelloch 2013). An aggregate index on S provides out-degrees; one on T provides in-degrees. RDF systems can maintain up to nine aggregate indexes: SP, SO, PS, PO, OS, OP, S, P, and O. Aggregate indexes can be stored even more compactly than regular graph indexes. They are useful for queries that project to a subsets of query variables, where only the existence of not fully qualified triples needs to be checked. Further aggregate indexes provide useful statistics, which allow choosing more efficient query plans (Neumann and Weikum 2008) or processing strategies (Shun and Blelloch 2013).

Reachability and Distance Indexing. A large body of work concerns index structures supporting reachability and distance queries. Given a graph, reachability queries answer whether for a given pair of nodes u and v there is a path between them and distance queries return the minimum length of the path connecting a given pair of nodes u and v . Distance is measured either in number of edges or as sum of edge weights along the path. Most approaches index a graph by

computing a label for each node, which encodes the reachability or the distance to other nodes in the graph.

For instance, a classic approach computes *2-hop labels*, where each node v is assigned a label $L(v) = (L_{\text{in}}(v), L_{\text{out}}(v))$ such that $L_{\text{in}}(v)$ and $L_{\text{out}}(v)$ are a set of nodes from which v can be reached and a set of nodes that are reachable from v , respectively. The labels are chosen in such a way that for any given pair of nodes u and v , the intersection of $L_{\text{out}}(u)$ and $L_{\text{in}}(v)$ is not empty if and only if v is reachable from u . The approach can be generalized to distance queries by storing a distance $d(x, v)$ and $d(v, x)$ together with every x in $L_{\text{in}}(v)$ and $L_{\text{out}}(v)$, respectively, such that the minimum of $d(u, x) + d(x, v)$ among all $x \in L_{\text{out}}(u) \cap L_{\text{in}}(v)$ is equal to (or sufficiently approximates) the distance between u and v . The challenge is to efficiently compute a minimal set of such labels.

For reachability indexes, another common approach uses ranges to encode reachable nodes in a label. Therefore, all nodes are assigned a label identifier by (1) collapsing all strongly connected components into single nodes, (2) traversing the resulting graph depth-first from some (artificially introduced) root node, and (3) numbering all nodes in post-order. Then, all nodes x reachable from a given node v can be succinctly listed in $L(v)$ as a set of ranges of label identifiers so that a node u is reachable from v if $u \in L(v)$ (Yu and Cheng 2010). The size of these labels can be further reduced by just storing approximations that can answer most negative reachability query (resulting in *false*) and efficiently steer a depth-first search in the graph for the remaining queries.

For more details on reachability and distance indexing, we refer the reader to surveys on reachability queries (Yu and Cheng 2010; Su et al. 2017) and distance queries (Sommer 2014; Bast et al. 2016).

Structural Indexing. It is also possible to store a summarization of a graph, which can help to speed up conjunctive and regular path queries. For this topic we refer the reader to the entry on graph indexing and synopses.

Partitioning of Big Graphs

Very large graphs can be partitioned to distribute processing or a query workload across multiple workers (e.g., machines in a cluster or CPUs in a NUMA system). The objective is to maximize parallel execution of the given workload and therefore equally distribute the load to a maximum number of workers while minimizing the synchronization needs between these workers. Obviously, these are conflicting goals. Additionally, the optimal partitioning strategy depends on the workload, the graph topology, the hardware setup (worker capabilities, communication cost, etc.), and the processing model.

Possible strategies can be categorized by the *partitioning criterion*, the *balancing criterion* they apply (Krause et al. 2017), and the *redundancy level* they permit. The partitioning criterion is the domain whose elements are considered atomic in the partitioning. The balancing criterion is the domain of which the resulting partitions should contain a balanced number of elements. For both criteria, domains are either edges, vertices, or components (connected subgraphs). The redundancy level is the amount of overlap that is permitted between partitions. The possible redundancy level ranges from completely disjoint partitions to full redundancy, where each worker receives a complete copy of the graph. For each strategy there are multiple algorithms. For an overview, we refer the reader to the entry on graph partitioning.

Given the large number of possibilities, it is not obvious which is the optimal partitioning strategy for a given setup. In consequence, many systems rely on hash partitioning of nodes (or edges), which is the simplest of all options. Any more sophisticated solution should perform better than hash partitioning to justify extra effort. Various works improve hash partitioning of node on graphs with skewed degree distribution by hash partitioning low-degree nodes and hash partitioning the edges high-degree nodes, e.g., LeBeane et al. (2015) and Chen et al. (2015). Also adaptive strategies have been proposed, e.g., Khayyat

et al. (2013). As of now, however, no graph partitioning strategy showed to be superior for a wide range of use cases (Verma et al. 2017; Krause et al. 2017), neither are cause–effect relations between graph partitioning and performance of parallel system clearly understood.

Examples of Applications

Graph data management systems implement the discussed graph representation techniques in a variety of combinations. For many systems, the implemented graph representation is not publicly known; hence the following is just a sample and not meant to be complete.

RDF Database Systems. RDF-3X (Neumann and Weikum 2008) builds on exhaustively indexed triple table storage with a set of lightweight compression techniques, namely, dictionary compression, delta encoding, and variable byte encoding to keep each index small and space-efficient. Additionally, RDF-3X uses aggregate indexes. Virtuoso (Erling and Mikhalov 2007), Hexastore (Weiss et al. 2008), and RDFox (Nenov et al. 2015) build on an exhaustively indexed triple table with slight variations in how the exhaustively is precisely implemented.

PGM Database Systems. Neo4j stores the property graph essentially in three tables, a node and an edge table each with a fixed record length and a triple table for node and edge properties. SAP HANA Graph (Rudolf et al. 2013) represents a graph in a pair of vertex and edge table following the universal table approach. Additionally, SAP HANA Graph employs CSR structures to exhaustively index the adjacency. IBM’s SQLGraph utilizes schema hashing for edges and a separated property storage by leveraging the JSON extension of a relational DBMS for property storage (Sun et al. 2015). ArangoDB builds a PGM store on top of a JSON document store, storing nodes and edges as JSON documents.

Definitions

Graph visualization is an area of mathematics and computer science, at the intersection of geometric graph theory and information visualization. It is concerned with visual representation of graphs that reveals structures and anomalies that may be present in the data and helps the user to understand and reason about the graphs.

Overview

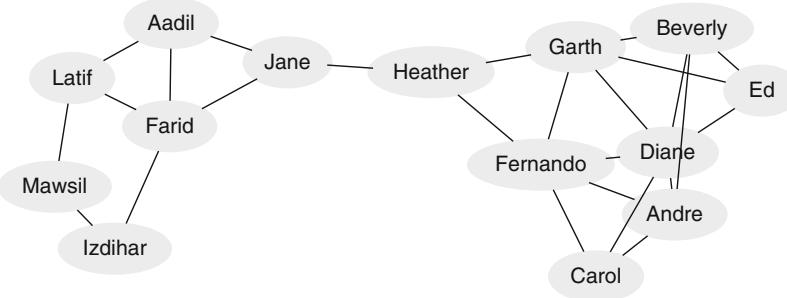

Graph visualization is concerned with visual representations of graph or network data. Effective graph visualization reveals structures that may be present in the graphs and helps the users to understand and analyze the underlying data.

A graph consists of nodes and edges. It is a mathematical structure describing relations among a set of entities, where a node represents an entity, and an edge exists between two nodes if the two corresponding entities are related.

A graph can be described by writing down the nodes and the edges. For example, this is a social network of people and how they relate to each other:

$\{Andre \leftrightarrow Beverly, Andre \leftrightarrow Diane, Andre \leftrightarrow Fernando, Beverly \leftrightarrow Garth, Beverly \leftrightarrow Ed, Carol \leftrightarrow Andre, Carol \leftrightarrow Diane, Carol \leftrightarrow Fernando, Diane \leftrightarrow Beverly, Diane \leftrightarrow Garth, Diane \leftrightarrow Ed, Farid \leftrightarrow Aadil, Farid \leftrightarrow Latif, Farid \leftrightarrow Izdihar, Fernando \leftrightarrow Diane, Fernando \leftrightarrow Garth, Fernando \leftrightarrow Heather, Garth \leftrightarrow Ed, Garth \leftrightarrow Heather, Heather \leftrightarrow Jane, Izdihar \leftrightarrow Mawsil, Jane \leftrightarrow Farid, Jane \leftrightarrow Aadil, Latif \leftrightarrow Aadil, Mawsil \leftrightarrow Latif\}.$

This social network tells us that “Farid” is a friend of “Aadil,” “Latif” is a friend of “Aadil,” and so on. However, this mathematical notation of the network does not convey immediately the structure of the network. On the other hand, Fig. 1 shows a visualization of this graph. We can see at a glance that this graph has two clusters. This example illustrates that graph visualization can give us an overall sense of the data. It reveals structures and anomalies and helps us to ask questions that can in turn be answered through interacting with the visualization itself or by

Graph Visualization, Fig. 1 Graph visualization of a small social network

G

writing algorithms to mine the data for evidence seen in the visualization.

In this chapter, a graph $G = (V, E)$ consists of a set of nodes (vertices) V and a set of edges E , which are pairs of nodes. Denote by $n = |V|$ and $m = |E|$ the number of nodes and edges, respectively. If there is an edge from node i to node j , we denote that as $i \rightarrow j$. If the graph is undirected, then we denote the edge as $i \leftrightarrow j$ and call i and j neighboring (or adjacent) nodes.

Node-Link Diagrams and Layout

Aesthetics

By far the most common type of graph layout is the so-called *node-link diagram* as seen in Fig. 1. Here nodes are represented by points or simple geometric shapes like ellipses or rectangles, whereas edges are drawn as simple curves linking the corresponding pair of nodes. In this chapter we restrict our attention to node-link diagrams; for alternative types of graph representations, see the survey of von Landesberger et al. (2011).

The algorithmic graph layout problem consists in finding node positions in the plane (or in three-dimensional space) and edge representations as straight lines or simple curves such that the resulting layout faithfully depicts the graph and certain aesthetic quality criteria are satisfied and optimized. We list the most common criteria. The influence of most of them on human graph reading tasks has been empirically confirmed (Purchase 1997).

- **crossings:** the fewer edge crossings the better (a layout without crossings exists only for *planar* graphs)

- **bends:** the fewer edge bends the better; ideally edges are straight-line
- **edge lengths:** use as uniform edge lengths as possible
- **angular resolution:** angles between edges at the same node should be large
- **crossing angles:** angles of pairs of crossing edges should be large
- **area and aspect ratio:** the layout should be as compact as possible
- **edge slopes:** few and regularly spaced edge slopes should be used (e.g., *orthogonal* layouts use only horizontal and vertical edges)
- **neighborhood:** neighbors of each node in the graph should be neighbors in the layout as well

The above list is not comprehensive, and there may be additional application-specific constraints and criteria or global aspects such as displaying symmetries. Moreover, some criteria may contradict each other. Typically only a subset of criteria is optimized by a graph layout algorithm, and trade-offs between different criteria need to be considered.

Key Research Findings

Undirected Graph Drawing

The layout algorithms and techniques presented in this section do not make use of edge directions, but they can obviously be applied to both undirected and directed graphs. Undirected graphs are often represented by node-link diagrams with

Algorithm 1 ForceDirectedAlgorithm(G, x, tol, K)

```

1 input: graph  $G = (V, E)$ , initial positions  $x$ , tolerance  $tol$ , and nominal edge length  $K$ 
2 set  $step$  = initial step length
3 repeat
4    $x^0 = x$ 
5   for ( $i \in V$ ) {
6      $f = 0$  //  $f$  is a 2/3D vector
7     for ( $j \leftrightarrow i, j \in V$ )  $f \leftarrow f + F_a(i, j)$  // attractive force, see equation (1)
8     for ( $j \neq i, j \in V$ )  $f \leftarrow f + F_r(i, j)$  // repulsive force, see equation (2)
9      $x_i \leftarrow x_i + step * (f / \|f\|)$  // update position of node  $i$ 
   }
10  until ( $\|x - x^0\| < tol * K$ )
11  return  $x$ 
```

straight-line edges. We denote by x_i the location of node i in the layout. Here x_i is a point in two- or three-dimensional Euclidean space.

Spring embedders (Eades 1984; Fruchterman and Reingold 1991; Kamada and Kawai 1989) are the most widely used layout algorithms for undirected graphs. They attempt to find aesthetic node placement by representing the problem as one of minimizing the energy of a physical system. The guiding principles are that nodes that are connected by an edge should be near each other, while no nodes should be too close to each other (cf. neighborhood aesthetic). Depending on the exact physical model, we could further divide the spring embedders into two types. For convenience, we call the first type spring-electrical model and the second type spring/stress model.

Spring-Electrical Model

This model was first introduced by Peter Eades (1984). A widely used variant, which is given below, is due to Fruchterman and Reingold (1991). The model is best understood as a system of springs and electrical charges; therefore we name this as the spring-electrical model, to differentiate the spring/stress model that relies on springs only, even though historically both are called spring embedders.

In this model, each edge is replaced by a spring with an ideal length of 0, which pulls nodes that share an edge together. At the same time, imagine that nodes have the same type of

electrical charges (e.g., positive) that push them apart. Specifically, there is an attractive spring force exerted on node i from its neighbor j , which is proportional to the squared distance between these two nodes:

$$F_a(i, j) = -\frac{\|x_i - x_j\|^2}{K} \frac{x_i - x_j}{\|x_i - x_j\|}, \quad i \leftrightarrow j, \quad (1)$$

where K is a parameter related to the nominal edge length of the final layout. The repulsive electrical force exerted on node i from *any* node j is inversely proportional to the distance between these two nodes:

$$F_r(i, j) = \frac{K^2}{\|x_i - x_j\|} \frac{x_i - x_j}{\|x_i - x_j\|}, \quad i \neq j. \quad (2)$$

The spring-electrical model can be solved with a force-directed procedure by starting from an initial (e.g., random) layout, calculating the combined attractive and repulsive forces on each node, and moving the nodes along the direction of the force for a certain step length. This process is repeated, with the step length decreasing every iteration, until the layout stabilizes. This procedure is formally stated in Algorithm 1.

The spring-electrical model as described by Eqs. 1 and 2 cannot be used directly for large graphs. The repulsive force exists on all pairs of nodes, so the computational complexity is quadratic in the number of nodes. Force

approximation techniques based on space decomposition data structure, such as the Barnes-Hut algorithm, can be used to approximate the repulsive forces efficiently (Tunkelang 1999; Quigley 2001; Hachul and Jünger 2004).

For large graphs, the force-directed algorithm, which uses the steepest descent process and repositions one node at a time to minimize the energy locally, is likely to be stuck at local minima, because the physical system of springs and electrical charges can have many local minimum configurations. This can be overcome by the multilevel technique. In this technique, a sequence of smaller and smaller graphs are generated from the original graph; each captures the essential connectivity information of its parent. The force-directed algorithm can be applied to this sequence of graphs, from small to large, each time using the layout of the smaller graph as the start layout for the larger graph. Combining the multilevel algorithm and the force approximation technique, algorithms based on the spring-electrical model can be used to layout graphs with millions of nodes and edges in seconds (Walshaw 2003; Hu 2005).

Spring/Stress Model

The spring model, also known as the stress model, assumes that there are springs connecting all pairs of nodes in the graph, with the ideal spring length equal to the graph theoretical distance between the nodes. The spring energy, also known as the stress, of this spring system is

$$\sum_{i \neq j} w_{ij} (\|x_i - x_j\| - d_{ij})^2, \quad (3)$$

where d_{ij} is the ideal distance between nodes i and j . The layout that minimizes the above stress energy is an optimal layout of the graph. Typically $w_{ij} = 1/d_{ij}^2$.

The spring model was proposed by Kamada and Kawai (1989) in graph drawing, although it dates back to multidimensional scaling (MDS) (Kruskal 1964; Kruskal and Seery 1980), and the term MDS is sometimes used to describe the embedding process based on the stress model.

There are several ways to minimize the spring energy (3). A force-directed algorithm could be applied, where the force exerted on node i from all other nodes j ($j \neq i$) is

$$F(i, j) = -w_{ij} (\|x_i - x_j\| - d_{ij}) \frac{x_i - x_j}{\|x_i - x_j\|}. \quad (4)$$

In recent years the stress majorization technique (Gansner et al. 2004) became a preferred way to minimize the stress model due to its robustness.

In the stress majorization process, systems of linear equations are repeatedly solved:

$$L_w X = L_{w,d} Y \quad (5)$$

here X and Y are matrices of dimension $n \times 2$, and the weighted Laplacian matrix L_w is positive semi-definite and has elements

$$(L_w)_{ij} = \begin{cases} \sum_{l \neq i} w_{il}, & i = j \\ -w_{ij}, & i \neq j \end{cases} \quad (6)$$

and the right-hand-side $L_{w,d} Y$ has elements

$$(L_{w,d} Y)_i = \sum_{l \neq i} w_{il} d_{il} (y_i - y_l) / \|y_i - y_l\|. \quad (7)$$

Here matrix Y is the current best guess of the optimal layout in 2D. The solution X serves as Y in the next iteration. A good initial layout Y is often helpful to achieve a good final layout.

On large graphs, the stress model (3) is not scalable. Formulating the model requires computing the all-pairs shortest path distances and a quadratic amount of memory to store the distance matrix. Furthermore the solution process has a computational complexity at least quadratic in the number of nodes. In recent years there have been attempts (Brandes and Pich 2007; Gansner et al. 2013; Ortmann et al. 2016) at developing more scalable ways of drawing graphs that still satisfy the user-specified edge length as much as possible, without having to carry out the all-pairs shortest path distances.

Directed Graph Drawing Algorithms

Directed graphs express relations that have a source and a target, e.g., senders and recipients of messages or hierarchical relationships in an organization. Using arrowheads to indicate directions, any undirected graph layout algorithm can be used for visualizing directed graphs. Yet, often the edge directions carry important information that should directly influence the layout geometry. In this section we discuss layout algorithms that make use of edge directions.

Layered Graph Layout

Layered graph layout is particularly useful for hierarchical graphs, which have no or only few cyclic relationships. For such graphs it is natural to ask for a drawing, in which all or most edges point into the same direction, e.g., upward. A classic algorithmic framework for upward graph layouts is layered graph drawing, often also known as Sugiyama layout named after the fundamental paper by Sugiyama et al. (1981). Each node is assigned to a layer, and for each edge it is required that the layer of the source node is below the layer of the target node. For a detailed survey of layered graph layout methods, see Healy and Nikolov (2014).

The process of computing layered graph layouts consists of a series of four steps. Each step influences the input to the subsequent steps and thus also the achievable layout quality.

1. **Cycle removal.** If the graph contains directed cycles, this step determines a small set of so-called *feedback edges* whose reversal yields an *acyclic* graph. The subsequent steps will draw this acyclic graph and in the end of the process the original edge directions are restored. Finding a minimum set of edges to reverse is equivalent to finding a so-called *minimum feedback arc set*, a classical NP-hard problem (Karp 1972). Several heuristics and approximation algorithms can be used to find small feedback edge sets in practice (Gansner et al. 1993; Eades et al. 1993).
2. **Layer assignment.** This step assigns each node to a horizontal layer, which can be thought of as an integer y-coordinate, such

that all edges point upward. Multiple nodes can be assigned to the same layer. Typical goals in this phase are to find compact layer assignments that use few layers and distribute nodes evenly to the layers, while ensuring that all edges point from a lower layer to a higher layer. After the layer assignment, some edges may span several layers. Such long edges are usually subdivided by dummy nodes to guarantee that for the next step, all edges connect nodes in neighboring layers. In order to keep edges short, a natural goal is to minimize the number of dummy nodes needed. Suitable layer assignments can be computed efficiently for most optimization goals, e.g., minimizing the number of layers based on topological sorting of the graph. For compact layouts with few dummy nodes and bounds on the number of nodes per layer, the ILP-based algorithm of Gansner et al. (1993) provides good results.

3. **Crossing minimization.** The crossing minimization step needs to determine the node order in each layer such that the number of edge crossings among the edges between two neighboring layers is minimized. Crossing minimization between two layers is again an NP-hard optimization problem (Eades and Wormald 1994). Several heuristics and (non-polynomial) exact algorithms for minimizing crossings between neighboring layers are known and evaluated in the experimental study by Jnger and Mutzel (1997). For computing node orders in all layers, usually a layer-by-layer sweep method is applied that cycles through all layers and optimizes node orders in neighboring layers, but global multilevel optimization methods exist as well (Chimani et al. 2011).
4. **Edge routing.** Once layers and node orders in each layer are fixed, it remains to assign x-coordinates to all nodes (including dummy nodes) that respect the node orders and optimize the resulting edge shapes. A typical optimization goal is to draw edges as vertical as possible with few bends for long edges (or with at most two bends with a strictly vertical middle segment) while

maintaining a minimum node spacing in each layer and avoiding node-edge overlaps. Algorithms for coordinate assignment either use mathematical programming (Sugiyama et al. 1981; Gansner et al. 1993) or a linear-time sweep method (Brandes and Kpf 2002).

Layouts for Specific Graph Classes

Previous sections covered visualization algorithms for general undirected and directed graphs. There is a variety of tailored algorithms for more specific graph classes, including prominent examples such as trees and planar graphs. These algorithms exploit structural properties when optimizing certain layout aesthetics. It is beyond the scope of this chapter to cover such specific graph classes and their visualization algorithms. Rather we refer to Rusu (2013) for a survey on tree layout and to Duncan and Goodrich (2013) and Vismara (2013) for surveys on planar graph layout. Further general books on graph drawing algorithms (Di Battista et al. 1999; Tamassia 2013) contain chapters on specific layout algorithms.

Examples of Application: Graph Visualization Software

There are many software packages and frameworks for visualizing and drawing graphs. A non-exhaustive list of noncommercial ones is given below. We divide the list into two parts. The following are packages that can handle relatively large graphs:

- Cytoscape is a Java-based software platform particularly popular with the biology community for visualizing molecular interaction networks and biological pathways.
- Gephi is a Java-based network analysis and visualization software package which is able to handle static and dynamic graphs. It is supported by a consortium of French organizations.
- Graphviz is one of the oldest open-source graph layout and rendering engines, developed at AT&T Labs. It is written in C and

C++ and hosts layout algorithms for both undirected (multilevel spring-electrical and stress models) and directed graphs (layered layout), as well as various graph theory algorithms. Graphviz is incorporated in Doxygen and available via R and Python.

- OGDF is a C++ class library for automatic layout of diagrams. Developed and supported by German and Australian researchers, it contains spring-electrical algorithms with fast multipole force approximation, as well as layered, orthogonal, and planar layout algorithms.
- Tulip is a C++ framework originating from the University of Bordeaux I for developing interactive information visualization applications. One of the goals of Tulip is to facilitate the reuse of components; it integrates OGDF graph layout algorithms as plugins.

G

The following are a few other free software each with its own unique merit, but not designed to work on very large graphs. For example,

- Dunnart is a C++ diagram editor developed at Monash University, Australia. Its unique feature is the ability to layout diagrams with constraints.
- D3.js is a popular JavaScript library for manipulating web documents based on data. It contains spring-electrical model-based layout modules solved by a force-directed algorithm. Since D3 works with SVG, it cannot scale beyond a few thousand graphical objects. However, a WebGL-based JavaScript library Viva-Graph could be used for larger graph visualization in the browser.

Future Directions for Research

Since the 1980s, a great deal of progress has been made in laying out graphs. The key enabling techniques are fast force approximations, the multilevel approach, and techniques for the efficient solution of the stress models. In addition, progress in the speed of GPU and graphics

library also made it possible to display graphs with millions of nodes and edges. Furthermore, there has also been progress in abstracting the visual complexity of large graphs, for example, by grouping similar nodes together, and representing certain subgraphs such as cliques as a motif. But as graphs become increasingly large, complex, and time-dependent, there are a number of challenges to be addressed.

The Increasing Size of the Graphs

The size of graphs is increasing exponentially over the years (Davis and Hu 2011). Social networks are one area where we have graphs of unprecedented size. As of late 2017, Facebook, for example, has over 2.07 billion monthly active users, while Twitter has over 330 million. Other data sources may be smaller but just as complex. For instance, Wikipedia currently has 5.5 million interlinked articles, while Amazon offers around 400 million items, with recommendations connecting each item to other like items. All these pale in comparison when we consider that there are 100 billion interconnected neurons in a typical human brain and trillions of websites on the Internet. Each of these graphs evolves over time. Furthermore, graphs like these tend to exhibit the small-world characteristic, where it is possible to reach any node from any other in a small number of hops. All these features present challenges to existing algorithms (Leskovec et al. 2009).

The unique features of these networks call for rethinking of the algorithms and visual encoding approaches. The large size of some networks means that finding a layout for such a graph can take hours even with the fastest algorithms available. There have been works on using GPUs and multiple CPUs, e.g., (Ingram et al. 2009), to speed up the computation by a factor of 10–100.

Even though state-of-the-art graph layout algorithms can handle graphs with many millions of nodes and billions of edges, with so many nodes and edges, the traditional node-link diagram representation is at its limit. A typical computer screen only has a few million pixels,

and we are running out of pixels just to render every node.

One solution is to use a display with high resolution, including display walls, and various novel ways to manipulate such a display (e.g., gesture- or touch-based control). But even the largest possible display is unlikely to be sufficient for rendering some of the largest social networks. One estimate puts human eyes as having a resolution of just over 500 million pixels. Therefore even if we can make a display with higher resolution, our eyes can only make partial use of such a display at any given moment.

Since the purpose of visualization is to help us to understand the structures and anomalies in the data, for very large graphs, it is likely that we need algorithms to discover structures and anomalies first (Akoglu et al. 2010) and display these in a less cluttered form, but allowing the human operator to drill down to details when needed.

Node-link diagram representation, while most common, may not be the most user-friendly to the general public, nor is it the most pixel-efficient. Other representations, such as a combination of node-link diagrams and matrices (Henry et al. 2007), have been proposed.

Large complex networks call for fast and interactive visualization systems to navigate around the massive amount of information. A number of helpful techniques for exploring graphs interactively, such as link sliding (Moscovich et al. 2009), have been proposed. Further research in this area, particularly at a scale that helps to make sense out of networks of billions of nodes and edges, are essential in helping us to understand large network data.

Finally, the stress model is currently the best algorithm for drawing graphs with predefined edge length. Improving its high computation and memory complexity is likely to remain an active area of research as well.

Time-Varying and Complex Graphs

All the large and complex networks mentioned earlier are time-evolving. How to visualize such dynamic networks is an active area of research (Frishman and Tal 2007), both in terms of graph

layout (van Ham and Wattenberg 2008), and in displaying such graphs. For example, time-varying graph can be displayed as an animation or as small multiples. Researchers have been studying Archambault and Purchase (2016) whether to use one form or the other, when measured in terms of preservation of the users' mental maps, and in improving comprehension and information recall. Dynamic network visualization will likely continue to be an area of strong interest.

Visualizing multivariate graphs is another challenging area. In a multivariate graph, each node and edge may be associated with several attributes. For example, in a social network, each node is a person with many possible attributes. Each edge represents a friendship which could entail multiple attributes as well, such as the type of friendship (e.g., school, work, church) and the length and strength of the friendship. Displaying these information in a way that helps our understanding of all these complex attributes is a challenge. It requires careful consideration of both visual design and interaction techniques (Wattenberg 2006; Kerren et al. 2014).

Synonyms

Hadoop ecosystem; Hadoop software; HDFS; MapReduce

Definition

Apache Hadoop is an open-source platform for storage and efficient processing of large datasets on a cluster of computers. The framework provides fault tolerance, high availability, and scalability, being able to process petabytes of data. Its principal components are MapReduce and HDFS.

Overview

Introduction

Apache Hadoop is a distributed framework used to tackle Big Data. It is a software platform in a master/worker architecture with three main components: HDFS, YARN, and MapReduce. The HDFS (Hadoop Distributed File System) is an abstraction layer responsible for the storage of data. MapReduce is the data processing framework

designed specifically to scale and run distributed. YARN (Yet Another Resource Negotiator) is a management platform responsible for handling resources in the cluster. Hadoop's open-source software was written in Java and distributed under Apache license 2.0.

The Hadoop framework can be implemented on a cluster of relatively inexpensive computers since it already works with the premise that machines fail and the system should be prepared to handle that. Besides fault tolerance, it provides high availability and scalability while hiding most distributed computing details from the user. These qualities made Hadoop a well-adopted solution in the industry (White 2015).

It is important to note that Hadoop is not a replacement for relational databases. The reason for this is that Hadoop was conceived for batch processing, where higher latency is acceptable. Data in Hadoop is not indexed; therefore seeking specific patterns can be a time-consuming task. Nevertheless, real-time analytics is a possibility in Hadoop together with some other Apache components such as HBase, Kafka, and Spark. Apache HBase is a no-sql column table database that runs on top of HDFS. Apache Kafka is a stream processing platform that enables handling real-time data. Apache Spark offers a component, Spark Streaming that works together with Kafka for building streaming applications.

Currently, Hadoop is a term used to express an entire toolset of softwares that provide services related to Data Science and Big Data used mostly alongside or on top of Hadoop software

itself. Each tool has its own application and advantages. The Hadoop ecosystem comprises softwares for data processing such as Apache Hive, Apache Spark and Apache Drill, Apache Oozie for jobs orchestration, Apache Mahout and Apache Spark's MLlib for machine learning applications, and many others.

Hadoop History

The Apache Hadoop project started as a part of the Apache Nutch, a scalable open-source web crawler project. Nutch was created in 2002 as a component of the Apache Lucene initiative. Doug Cutting was the creator of Apache Lucene and started Nutch trying to build a web crawler to democratize search engine algorithms. He soon realized that in order to do that he would need to scale Nutch to the complexity of the Internet. Hadoop was the answer to this quest.

Doug Cutting conceived Hadoop inspired by Google's 2003 and 2004 papers on Google's distributed file system (GFS) (Ghemawat et al. 2003) and distributed programming paradigm MapReduce (Dean and Ghemawat 2008). The GFS paper described the foundations of distributed storage for data intensive applications used by the company. It explained how to deploy such a platform on commodity hardware while providing fault tolerance and scalable performance. The MapReduce paper introduced a straightforward paradigm to do distributed programming using the GFS architecture. The programmer would be responsible for providing a Map and a Reduce function to process the data, while all resource allocation and application management were handled by the platform. These two components put together made possible to scale Nutch, and Doug soon realized that Hadoop scalability had great applicability to other areas.

In 2006, Hadoop emerged as an independent Apache project, and around that same time, Doug Cutting joined Yahoo!. The company saw the tool potential and created a dedicated team to develop it. The name Hadoop was chosen by Doug inspired in his kid's toy, a yellow stuffed elephant. By 2008, Hadoop was already a top-level Apache project, and by 2010 a whole ecosystem of tools

was created around Hadoop, such as Apache HBase, Hive, and Pig.

The first version of Hadoop, known as Hadoop 1, consisted of two main components: MapReduce and HDFS. In this initial version, MapReduce was responsible for managing job resources. Around 2012, YARN was introduced in Hadoop 2, making it much more polyvalent and open to new processing engines such as Apache Spark. Currently, the use of MapReduce paradigm for data processing has declined, being replaced by higher-level APIs such as Hive or by more dynamic processing tools like Spark. HDFS remains a widely adopted distributed file system.

Hadoop Components

HDFS

The Hadoop Distributed File System is an abstraction layer between the regular operating system file system and a data processing framework such as MapReduce, Spark, or HBase. It was written in Java in a *shared nothing master-worker architecture*. In Hadoop, computers are nodes in a cluster, and they exchange information through the network (usually using a TCP/IP socket communication). The master node orchestrates the cluster and the workers do the computation. HDFS was thought to handle big datasets providing high availability and fault tolerance.

The master, *NameNode*, is responsible for storing all files and directories metadata such as file access permission and file locations. The file locations are not stored persistently on disk in the NameNode; they stay in memory for quicker access. Note that this limits the amount of data that is possible to store in a Hadoop system: the amount of files cannot be larger than what the NameNode can store in memory. This is also one of the reasons why HDFS deals better with larger files than a large number of small files; small files have greater chances of overloading NameNode's memory. Usually, each file block or directory takes about 150 bytes of memory.

The *Secondary NameNode* exists to help the NameNode, by copying the NameNode file metadata. Note that these copies are not guaranteed

to be updated, so in case of failure, the Secondary NameNode is not a hot standby to the NameNode. With Apache Zookeeper, however, it is possible to arrange the Secondary NameNode to be a hot standby. It is also possible to have multiple NameNodes taking care of multiple clusters together with the so-called HDFS Federation, a concept introduced in Hadoop 2.

The worker DataNodes are responsible for storing and processing data. When storing a file in HDFS, each file is divided into blocks, and each block is replicated and stored separately in different DataNodes. The default replication factor is three and the default block size is 128 MB. The blocks are actually located in the regular OS file system, but one accesses it through HDFS's API.

Replicating data is important for the failover mechanism, for high availability, and for load balancing. Node failures are detected by the Hadoop system with a heartbeat type of signaling. Each DataNode sends heartbeat signals to the NameNode every 3 s. If a DataNode fails, the other two replicas can be used to ensure high availability. In that case, when the NameNode stops receiving the heartbeat signal, it will copy the lost DataNode data into another DataNode to maintain the default replication factor. To replicate the lost data, the NameNode uses one of the other two copies of the data available in HDFS. Now, assume that no DataNode is failing but many of them are overloaded with processing jobs. Having three data replicas helps ensuring that processing power will be available to new jobs, and processing is distributed more or less equally among nodes. Furthermore, it helps ensure the **data locality** principle of sending the job to the data (and not otherwise) so as to not overload the network traffic.

There are three main ways of interacting with HDFS: a command-line interface, a Java API, and a web interface with Apache Hue. The command-line interface is similar to POSIX, presenting commands such as *mkdir*, *ls*, and *cat*.

When writing a file into HDFS with the command-line interface, a file can be inserted in the system with the following command:

```
$ hadoop hdfs -put my_file.txt
```

Under the hood, the client is sending a message to the NameNode asking permission to write a file. If the client's permission is granted, the NameNode answers with DataNode's locations to write the blocks. The file *my_file.txt* is then divided into blocks, and each block is copied to one different DataNode. Note that the file does not pass through the NameNode itself which would cause a bottleneck in the system. Instead, the client sends the block to the closest DataNode, and this DataNode by its turn sends the block to the second closest DataNode and so on.

As mentioned, Hadoop replicates the block three times. This, as it is with most Hadoop parameters, can be configured by the cluster administrator. Two data blocks are copied to different machines on a same rack, trying to reduce as much as possible the network traffic. This feature is called *rack awareness*. A third copy is placed on a different rack to ensure data availability in case of a rack failure. To ensure data integrity, a checksum of the data is calculated every time it is read or written. All of these actions are handled by the system and are transparent to the user.

YARN

YARN was introduced in Hadoop version 2 to separate the resource management function from the processing layer of Hadoop, thus providing a broader framework. Because of YARN, Hadoop was able to support other processing models such as iterative programming or graph processing.

The platform contains a Resource Manager to distribute the resources of the cluster among all applications. YARN provides each application with an ApplicationMaster, which talks with the Resource Manager to negotiate resources. Another important entity is the NodeManager, which is responsible for launching and monitoring each application.

MapReduce

MapReduce is a programming paradigm written in Java to run on top of the HDFS, inspired by Google's MapReduce paper (Dean and Ghemawat 2008). It was mainly envisioned for batch processing on embarrassingly parallel problems where the two functions Map and

Reduce process data in a resilient and distributed manner. Many real-world computer science problems have already been modeled into the MapReduce paradigm (Rajaraman and Ullman 2011).

Suppose that a group of people want to count how many books are there in a library. They decide to divide the work, and each person is responsible for counting books in certain shelves. The group finally gets together and sum up each individual count to obtain an overall amount. This same principle is used in the MapReduce framework. The Map phase applies operations in separated chunks of the dataset, and the Reduce phase can be used to combine results appropriately. The Map and Reduce functions come from functional programming and are easily parallelizable. In this paradigm, the user is responsible for specifying a Map and a Reduce function and the input and output location to read and write data. All distributed programming details such as input partitioning, job failures, and resource scheduling are handled by the system so that the user can focus on processing data. This framework allows user with no distributed programming experience to do distributed computing.

MapReduce operates with key/value pairs. The input of a Map function should be in the key/value format, such as (K1, V1), and the output as a list of key/values, list(K2, V2). The Reduce function should receive as input a tuple (k2, list(v2)) and return as output a list of key/value pairs, for example, list(K3, V3). Note that the input of the Reduce function must match the output of the Map function, being an aggregation on values by key. Other than that, the key/value pairs can be of any kind.

Given a Map and a Reduce function, the system will partition the dataset in blocks, as mentioned before, and create several Map and Reduce tasks to run on the data. The client application will talk to an agent called *Resource Manager* from the YARN component, to ask for resources to run the application. The Resource Manager will try to allocate a resource container in a DataNode close to the data, based on the data locality principle. It will first try to allocate re-

sources for the task in the same DataNode where data is located. If it can't, it will try a node on the same rack, and if that is not available as well, it will go for any other node in the cluster. It is important to highlight that the Resource Manager will execute the Map and Reduce functions in a separate JVM, so in case of any failures, the rest of the system should not be affected.

There will be one Map task per block of data. The tracking of tasks is made by YARN through heartbeat signals sent from the tasks to the Resource Manager. The system executes the tasks in parallel, and if any of the tasks fail, it simply re-executes that single task, and not the entire application program. The intermediate results of Map tasks are written persistently to disk, and not into HDFS. This is done because it would be too expensive to write all intermediate data into HDFS, and in case the data is lost, it is less expensive to just run the Map task again. Intermediate result is written to disk and it is sorted in a phase known as *Shuffle*. All data with the same key is grouped together and fed to a single Reduce task using a hash function. One Reduce task might receive input from many or all Map tasks. The Reduce task might be in the same or in another DataNode in the system; this is determined by the Resource Manager. The Reduce phase doesn't wait for all Map tasks to finish to start shuffling data, but it has to wait all Map tasks to finish to complete the shuffle. The shuffling phase is usually the most time-consuming part of a MapReduce job, since possibly all data has to be ordered. To help optimizing this phase, the MapReduce framework provides *Combiners* to aggregate and reduce data before sending it to the Reduce function. Combiners can be applied in some MapReduce jobs. Finally, once Reduce is done, its output is written to HDFS.

Several packages and libraries were created to support the development of MapReduce applications. The *Hadoop Streaming* component provides an API for users to write Map and Reduce functions in languages other than Java, like Python, Ruby, or C. A library; MRUnit was created with JUnit to support testing in MapReduce.

The Apache Oozie project can be useful for the development of applications that use several Map and Reduce tasks sequentially, since it works as a job orchestrator and scheduler.

MapReduce Limitations

The MapReduce paradigm facilitates distributed programming, with the idea of breaking down a dataset and applying in parallel the same function to all portions of data. There are some drawbacks nonetheless. MapReduce is mainly applicable to embarrassingly parallel programs, where communication between processes is minimal and the algorithm is easily parallelized. When willing to do iterative analysis or communication intensive applications, users have to concatenate several Map and Reduce functions sequentially, which may greatly increasing the running time. The reason for this is that each time a Map function sends data to a Reduce function, it writes data on disk. Therefore, the overhead of writing and reading from disk makes iterative analysis on MapReduce less attractive. Apache Spark was developed to overcome this issue. It processes data in memory, by applying functions sequentially without writing to disk. It creates a directed acyclic graph of tasks, where the state of the transformations applied to the data are saved for fault tolerance. This mechanism together with Spark's simple API made it a great resource for data processing. In 2016, Hadoop's creator Doug Cutting declared that Spark is the evolution of the MapReduce framework (Cutting 2016).

Examples of Application

Several real-world applications can be modeled as MapReduce problems. Recommender systems, a technique used to advertise products to users, have been extensively expressed in terms of MapReduce (Rajaraman and Ullman 2011). The frequent itemset problem, k-mean clustering, and many other machine learning problems were modeled in the MapReduce paradigm in the book *Mining of Massive Datasets* (Rajaraman and Ullman 2011).

Google has publicly announced in 2004 that it used MapReduce on its search engine with more than 20 TB of data, as well as in clustering applications for Google News, construction of graph application, and several others (Rajaraman and Ullman 2008).

Hadoop has also been used extensively by Yahoo!. In 2008, Yahoo! announced that they used a 10,000 core cluster to index its search engine, and in 2009 they could sort 1 terabyte of data in 62 s (White 2015). By 2011, Yahoo! had a 42,000 node Hadoop cluster with petabytes of storage (Harris 2013).

Hardware Reliability Requirements

Wenhai Li

Advanced Computing Research Centre, Data to Decisions Cooperative Research Centre, University of South Australia, Adelaide, Australia

Introduction

The development of big data applications has brought a great amount of opportunities yet challenges to both the IT industry and academia. Supporting platforms and architectures, such as Clouds, supercomputing centers and data centers, must develop corresponding technologies to meet the “4V” requirements of big data applications, which are veracity, velocity, volume, and variety. Serving as the fundamental layer of these platforms and architectures, the hardware, especially storage hardware, are of great importance to the big data applications, where the reliability of storage units not only have significantly influence the reliability of the data, but also have significant impact on the “4V” requirements of the big data applications. In this article, we discuss the hardware reliability requirements, specifically, storage hardware reliability requirements, for current big data platforms and architectures.

Big Data Storage Architecture

A typical big data application contains several terabytes to several petabytes of input/output data and intermediate data in either structured or unstructured formats. It is not surprising that the storage architecture plays the dominating role in the reliability of the data and the functionality of the applications. Traditionally, the data is stored in local storage architectures such as hard disk racks and connected via storage networks. Nowadays, more and more companies are shifting their data into large-scale data centers or public clouds to prevent huge investment into the storage hardware, maintenance of data/redundancy, long-term energy cost, as well as the risk of losing the data. In the foreseeable future, local storage and Cloud/data center storage will coexist due to security and performance reasons. However, instead of network-attached storage (NAS), the local storage is nowadays gradually adopting more advanced technologies, such as private cloud or distributed storage system, to meet the extremely high accessing and processing requirements of the big data applications. In terms of local storage architecture leveraging the latest technologies and the public cloud and large-scale data center, these two storage structure share very similar design, and hence share the same group of factors that affect reliability.

Factors that Affect Reliability

Existing research and industrial reports have shown several factors that could affect the reliability of the hardware for data storage architectures:

- Uncontrollable natural or manmade disasters (Dabrowski 2009; Wood et al. 2010): Natural disasters such as floods, hurricanes, and earthquakes or manmade disasters such as infrastructure failure, disastrous IT bugs, or failed hardware installations could cause serious damage to the IT facilities and hence the loss of data.
- Environmental factors (Gersbach 2012; Loken et al. 2010): Environmental factors such as

- temperature, static electricity, and humidity surrounding the IT facilities could impact the reliability of the hardware, where harsh environment could significantly reduce the durability and raise the failure rates of storage components.
- Storage media (Mielke et al. 2008; Pinheiro et al. 2007; Schroeder and Gibson 2007; Zaman 2016; Furrer et al. 2017): Different storage medias have different reliability characteristics. In modern data storage architectures, commonly used storage media includes hard disk drive (HDD), solid-state drive (SSD), and magnetic tape. These storage medias could coexist in a single data storage architecture for storing different types of data according to the reliability requirement, performance requirement, and cost-effective requirement. Details of the storage medias will be described in section “[Reliability of Storage Medias](#).”
 - Media controller (Zaman 2016; Patterson et al. 1988; Taylor 2014): Above the very bottom storage media, there could be another layer of hardware named media controller that is designed to improve the reliability and performance of the storage facilities. For example, multiple hard disk drives could be grouped by a RAID controller to build a RAID array, in which different configurations can be applied to improve the throughput performance and the reliability of the data, respectively. For solid-state drives, a media controller (or SSD controller) is a part of the SSD firmware, in which error correction is conducted using error correction coding technology and wear leveling is conducted to make sure all the flash cells experience the same amount of erase/write cycles so that the chip ages evenly. Different error correction code and wear leveling algorithms can be applied to the SSD controller by reprogramming it to maximize the reliability of the drive.
 - Processing hardware (Dabrowski 2009; Pinheiro et al. 2007; Schroeder et al. 2016): Unexpected non-storage hardware failure, such as motherboard failure or RAM failure, could also cause loss of data in the data storage architecture, especially when the data writing process is in progress. Compare to the reliability of storage media, these hardware parts cause less impact to the reliability of the data (Pinheiro et al. 2007; Schroeder et al. 2016), and technics regarding this type of failure have been well developed for a fairly long period of time (Dabrowski 2009).
 - Software reliability mechanism: Different reliability assurance approaches are also applied in data management software and operating systems to make sure that hardware malfunction cause minimum impact on the application and the data. In this field, many technics have been developed for decades such as data replication (Li et al. 2015), erasure coding (Rashmi et al. 2014), checkpoint/snapshot(Dabrowski 2009), and recovery(Rashmi et al. 2013). Details of this topic are out of scope of this entry and will be covered in chapter “[▶ Data Replication and Encoding](#)” of the encyclopedia.

Reliability of Storage Medias

The reliability of storage medias is the fundamental factor for a big data storage architecture. Simply, storage medias with lower reliability could cause higher probability and frequency of data loss and cause lower data availability. Given large amounts of data stored, the impact on big data applications is significantly magnified. Even with software reliability mechanism applied to provide certain fault tolerance and data recovery ability to the system, the probability that the data being totally lost can still be significantly increased. Analyses have shown that most server failures in a data center are due to the storage media (Vishwanath and Nagappan 2010). As mentioned earlier, each storage media has its own features. These features include response time, total throughput, failure rate and failure pattern, etc. Therefore, big data storage architectures can apply a mixed storage solution by combining HDD, SSD, and magnetic tape cartridges to provide comprehensive data storage solutions to meet different requirements of different big data

applications. For example, SSD and HDD can be applied as tier 1 storage for newly generated data or data that is frequently accessed and require high access speed and low response time, and magnetic tape can be applied as tier 2 storage for data of very large volume, the so-called cold data that is not accessed very frequently as it takes hours to days to access. In current large-scale data centers, this solution is widely applied (Huang et al. 2012; Harris 2014). However, with the drop of storage cost by using HDD, another combination is getting more and more popular, where SSD serves as tier 1, HDD serves as tier 2, and magnetic tape is not used. In this section, we talk about the reliability features of HDD and SSD.

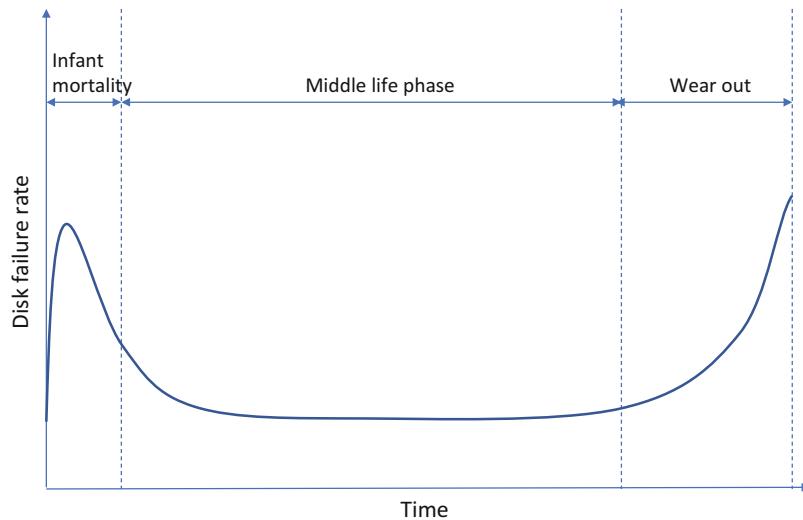

HDD

The reliability of HDDs has been investigated for decades in both academia and industry, where the disk failure rate is considered the main indicator. In a big data storage architecture, environmental factors are maintained to the optimum range, and unexpected dropping to the ground as normal home usage will not happen. However, the worn out of the internal physical parts could still cause a final failure of the drive. A typical hard disk's lifespan in a storage architecture is about 4 years. With the increase of the age of hard disks, existing studies have shown that the disk failure rate follows what is often called a "bathtub" curve, as shown in Fig. 1, where disk failure rate is higher in the disk's early life (infant mortality), drops during the first year, remains relatively constant for the remainder of the disk's useful lifespan (middle life phase), and rises again at the end of the disk's lifetime (wear-out) (Xin et al. 2005). An investigation conducted on a large disk drive population by Google has observed some results very consistent to this model (Pinheiro et al. 2007). For ease of representation, the International Disk Drive Equipment and Materials Association (IDEA) proposed a compromised presentation for disk failure rates, as shown in Fig. 2, where the lifespan of each disk is divided into different life stages with different failure rates, which are 0–3 months, 3–6 months, 6–12 months, and 1 year to the end of design lifespan (the wear-out phase of the disk is con-

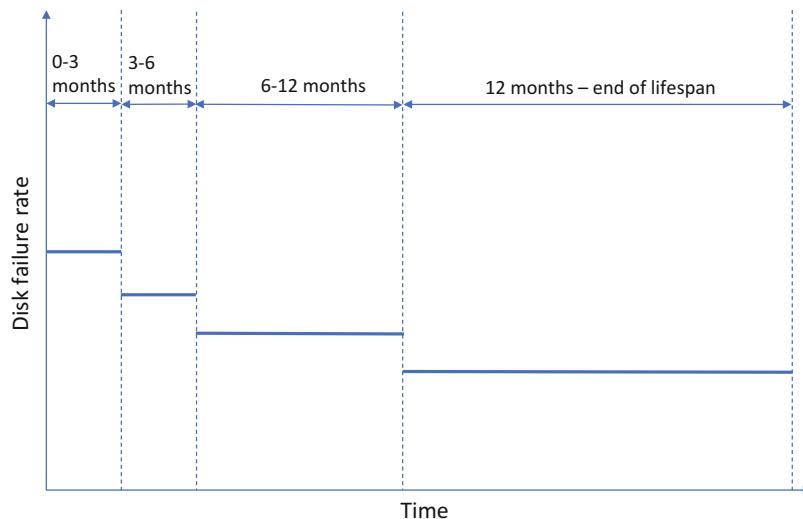

sidered out of useful life of the disk and hence not included in this model) (IDEA 1998). In (Pinheiro et al. 2007), it is reported that the average annual replacement rates of HDD is 2–9%. More recently in the data storage industry, hard disk reliability statistical reports are published regularly that review the disk failure rate of disks with different brands, capacities, performances, and prices, which tracks the reliability of the disks as end users (Klein 2017). The report has shown that the latest models of disks with the sizes ranging from 3 to 8 TB normally have an annual failure rate between 0.33% and 3.25%, where some extreme ones can be as low as 0.15% or as high as 31.58%.

SSD

The outstanding performance in I/O bandwidth and random IOPS (input/output operations per second) has made SSD highly desirable in current big data storage architectures. Current SSDs use NAND flash memory cells to retain data by trapping electrons inside. A process called tunneling is used to move electrons in and out of the cells, but the back-and-forth traffic erodes the physical structure of the cell, leading to breaches that can render it useless (Zaman 2016). Therefore, different from HDD, SSD's capability of storing data fails gradually, and its reliability is evaluated by raw bit error rate (RBER) or sometimes uncorrectable bit error rate (UBER) as it is easier to be observed. There are quite some existing research regarding to the reliability of SSD based on controlled lab tests under synthetic workloads, which predicts an exponential growth between RBER and number of program erase cycles (Mielke et al. 2008; CAI et al. 2012). However, in actual data center environments, it is observed that RBER grow linearly with program erase cycles, and same as HDD, it is also significantly affected by the age of the SSD (Schroeder et al. 2016). Compare to HDD, SSD has a lower replacement rate, which is 4–10% being replaced in a 4-year period compare to the HDD annual replacement rate of 2–9%. However, it also has a higher probability of generating uncorrectable bit, which means that while less likely to fail during usage, SSD is more likely of losing data.

Hardware Reliability Requirements, Fig. 2 IDE MA failure rate curve of hard disk drive

Promising Future Trend

In general, with the big data application getting more and more popular nowadays, several trends can be expected in the near future in the data storage architectures.

1. It tends to share more and more of the same group of software and hardware technics on both local and Cloud/data center storage architectures. Software-wise, Cloud plat-

forms, distributed storage systems, and data processing systems are designed to be flexible and scalable regardless of the scale of underneath hardware, which makes the boundary of local and Cloud/data center storage systems less clear than before. Hardware-wise, both local and Cloud/data center storage architecture uses the so-called commodity hardware to maximize cost-effectiveness, which makes the difference even smaller.

2. In the hardware prospective, specifically, layered storage will become the trend. Firstly, as the unit price of SSD drops, it can be expected that SSD will be more widely used to maximize the I/O throughput, IOPS of the system to meet the high velocity requirement of big data applications. Secondly, HDD will still play a major role in the storage architecture due to its higher capacity, better durability, and less data loss rate to meet the high-volume and reliability requirement of the data. Thirdly, although magnetic tape still provides the lowest unit storage cost and largest storage capacity, the time-consuming accessing of data made it less desirable for many, if not all, big data applications and hence could be less applied in future data storage structures.

Hardware-Assisted Compression

K. Sayood and S. Balkir

Department of Electrical and Computer Engineering, University of Nebraska-Lincoln, Lincoln, NE, USA

Definitions

Video compression: Compact representation of digital video.

Discrete cosine transform (DCT): An orthonormal transform used in many compression applications.

Arithmetic coding: An entropy coding technique that is particularly useful for alphabets with a skewed probability distribution.

LZ77: A dictionary based sequence compression algorithm which adaptively builds its dictionary through an optimal parsing of the “past” of the sequence.

Introduction

The information revolution has resulted in the ubiquity of the use of compression. As the explosion in the spread of information persists, the need for energy efficient compression is driving the development of more and more hardware-assisted compression, despite the increasing power of processors. The need is most where the resource constraints are most severe – where the constraints are relative to the application. Video compression deals with a huge amount of temporally sensitive information and thus is highly time-constrained. As video has become the dominant user of the available internet bandwidth, compression algorithms have become more and more complex in order to satisfy both the bandwidth constraints and the increasing quality requirements. The latter is due to significant improvements in display technology. This makes software implementations of video compression algorithms increasingly insufficient for the task at hand. At the other end of the spectrum, in terms of the volume of data, are wireless sensor networks which generally deal with significantly less data per node but have to process them under severe power constraints.

Because of the opportunistic nature of the deployment of hardware-assisted compression, it is difficult to provide a systematic description of the field; therefore, we will organize our discussion around the most popular applications – video compression, wireless sensor networks, and computer memory – and then take a somewhat meandering path through the other applications that do not fit into these categories. We will not

focus on the specific hardware approaches as each particular application has a specific set of design requirements and performance metrics.

Video and Image Compression

The general approach used in video compression standards is as follows (Sayood 2017): Each frame is divided up into blocks – often of different sizes. For most of the image frames, a prediction for the block is generated using the previous, and sometimes future, reconstructed frames. The difference is transformed using some variant of the discrete cosine transform (Rao and Yip 1990) and the coefficients encoded using some variant of run-length encoding and an entropy coder. The reconstructed frames to be used for prediction are filtered using a loop filter. The need for hardware assistance in video compression was clear from the time of the initial video compression standards, such as H.261 (ITU-T Recomendation H.261 1993) and MPEG-1 (Mitchell et al. 1997); and hardware implementations of each part of the video coding structure have been proposed. The hardware assistance was initially focused on the discrete cosine transform which is computationally expensive and thus tends to be a bottleneck. A survey of early efforts in this direction can be found in Pirsch et al. (1995). The discrete cosine transform (DCT) is a separable transform (Sayood 2017), which means it can be implemented by taking a one-dimensional transform of the rows followed by a one-dimensional transform of the columns or vice versa. As this is significantly simpler than a direct implementation of the two-dimensional DCT, many of the hardware implementations are for one-dimensional DCT (Martisius et al. 2011; Amer et al. 2005), most based on the efficient Loeffler algorithm (Loeffler et al. 1989). There are also designs for the direct implementation of the two-dimensional DCT (Chang et al. 2000; Gong et al. 2004). The latest standard, variously known as High Efficiency Video Coding, H.265, and MPEG H Part 2, uses a mixture of block sizes and an integer approximation to the DCT. A number of implementations for the transform used in HEVC

have been proposed (Pastuszak 2014; Meher et al. 2014; Park et al. 2012).

Other common components of most video coding algorithms are the loop filter (Cho et al. 2015; Khurana et al. 2006), the motion adaptive prediction, and the entropy coder. The latter has been a particular target for hardware-assisted design as the coder has become more and more complex with each succeeding standard. The most widely deployed entropy coder is the context-adaptive binary arithmetic coder (CABAC). The binary arithmetic coder itself is relatively simple to implement; however, the number of contexts and the approaches for generating the contexts using rate distortion optimization have become increasingly complex and computationally expensive. Hence there is an increase in the number of hardware implementations for the CABAC encoder and decoder (Nunez-Yanez 2006; Penge et al. 2013; Chen and Sze 2015).

In recent years, a number of companies have begun marketing complete hardware solutions targeting HEVC applications. To name a few, Pixelworks has developed and is marketing HEVC Ultra HD System-On-Chip solutions for the consumer electronics industry (www.pixelworks.com), while VITEC is providing end-to-end video streaming solutions that are based on compact and portable HEVC hardware encoders (www.vitec.com). System-On-Chip Technologies offers high-performance HEVC IP Cores that are suitable for integration into midrange Xilinx and Intel FPGAs (www.soc technologies.com).

The video coding standards are targeted to the very important broadcast market. However, there are more specific applications for video compression. One application area that has been particularly active has been CMOS imagers with focal plane compression. Because of the freedom from standards, a number of innovative approaches have been proposed such as Olyaei and Genov (2013), Leon-Salas et al. (2006), Leon-Salas et al. (2007), Chen et al. (2011), Oliveira et al. (2013), Estevo Filho et al. (2013), which use differential encoding and vector quantization, while others (Lin et al. 2008; Cardoso and Gomes

2014; Wang and Leon-Salas 2012) use time-frequency multiresolution approaches.

Wireless Sensor Applications

The constraints on wireless sensor applications have more to do with energy than time. Compression is often essential in wireless sensor network applications as communication costs are substantially higher than processing costs (Anastasi et al. 2009). Despite this advantage, the amount of processing required for compression still puts a high cost in terms of energy use. This is particularly true for visual sensor networks where while it is imperative that the video sequence or images be compressed, the processing costs can be prohibitive. Therefore, it is entirely understandable that this area is ripe for the use of hardware-assisted compression. A survey of many different image compression approaches used in wireless sensor networks can be found in Khalaf Hasan et al. (2014). Mobile sensor networks for environmental monitoring tend to be small and miserly in their use of energy making the use of hardware-assisted compression useful (Sarmiento et al. 2010). Physiological sensors are another obvious target for hardware-assisted compression. Wearable devices such as cardiac monitors (Singh Alvarado et al. 2012; Deepu and Lian 2015; Deepu et al. 2016) which need to function over a long period of time have strict energy constraints which can be best satisfied with hardware-assisted compression. This is also true for sensors which need to function inside the body such as capsules used in wireless endoscopy (Karargyris and Bourbakis 2010). In this, a capsule containing a video sensor (Wahid et al. 2008; Turcza and Dupлага 2013) records images of the gastrointestinal tract as it passes through the patient.

Memory Systems

As programs and datasets have increased in size and complexity, computer memory has

become more and more crowded leading to increased levels of paging. Paging in memory systems can cause a considerable increase in many applications. It has long been recognized that compression in memory systems can help alleviate this problem. Issues that are specific to compression in memory include speed and the heterogeneity of the data to be compressed. To address these problems, IBM developed the IBMLZ1 compression chip (Cheng and Duyanovich 1995) which used the LZ77 (Ziv and Lempel 1977) algorithm and a Huffman coder (Sayood 2017) to provide compression. This algorithm uses the patterns contained in the history of the sequence as a dictionary to compress the current values. This makes the compression scheme locally adaptive and addresses the data heterogeneity issue. In their chip (as in other technologies using dictionary-based coding), the dictionary is stored in content-addressable memory. The first commercial system to use compression to help reduce the memory load was the IBM Memory Expansion Technology (MXT) (Tremaine et al. 2001; Franaszek 2001) which again used the LZ77 algorithm for compression. Latency issues were handled by using a 32 MB cache. Since the appearance of the MXT technology, memory sizes have grown considerably, and the complexities of the LZ77 algorithm can result in high latencies. A number of algorithms have been developed to reduce the latency by using modified forms of the algorithm (Kjelso et al. 1996; Benini et al. 2002; Sardashti and Wood 2014) with the most well-known being the Frequent Pattern Compression (FPC) schemes (Ekman and Stenstrom 2005). More recent approaches, such as Zhao et al. (2015), use a multifaceted approach where the data is compressed using one of several simple, low-latency schemes. An excellent primer on compression in memory can be found in Sardashti et al. (2015). An interesting recent proposal is to do away with the requirement that all contents of memory be accurately preserved (Ranjan et al. 2017). In this approach contents of memory that can be approximated are compressed using lossy compression which

provides substantially more compression than lossless compression.

Conclusion

While most hardware-assisted compression applications fall into the three groups mentioned above, they by no means exhaust the applications of hardware-assisted compression. Consider (Schmitz et al. 2017) which describes a recently developed video processing chip that, not constrained by the standards, uses differential decorrelation to allow processing at rates of 1000 frames per second, or (Amarú et al. 2014) which uses logic operations to provide decorrelation, or a hardware-assisted set partitioning in hierarchical trees (SPIHT) (Said and Pearlman 1996) implementation (Kim et al. 2015). As devices become smaller and more functional, the role of hardware-assisted compression is likely to spread much farther.

Definitions

Online transaction processing (OLTP) is one of the most important and demanding database applications. A **transaction** is a unit of work that satisfies the **ACID** properties (Gray and Reuter 1992). Atomicity ensures that when a transaction ends, either all or none of its effects are visible to the other transactions. Consistency guarantees that the effect of a transaction transforms the database from one consistent state to another. Isolation property gives the illusion that transactions do not interfere with each other's effects to the database even if they run concurrently. Durability assures that the effects of complete transactions must be persistent in the database. The maintenance of these properties in the face of many concurrent client requests is a big challenge and complicates the design of transaction processing systems. Multiple components of a transaction processing system are involved in satisfying each of the ACID properties, and a component is usually involved in providing several properties. These tightly coupled components lead to various forms of underutilization on multicore processors.

Multicores refer to processors with two or more independent processing units (i.e., cores). **Many cores** are a specialized type of multicores, where the parallelism is more extensive (100s

or 1000s of cores in a processor). Today's commodity server hardware where majority of data management applications, including OLTP, run on typically has multiple multicore processors. Such hardware is called **multisocket multicore** hardware.

Overview

Transaction processing has been at the forefront of many influential advancements in the data management ecosystem (Diaconu et al. 2013; Exadata 2015; Kongetira et al. 2005; Stonebraker et al. 2007). In the recent years, many of these advancements have been triggered by the developments in the computer architecture community: multicore parallelism, large main memories, hardware transactional memory, nonvolatile memory, remote direct memory access, etc. These developments led to rethinking of the overall system design for transaction processing systems. In turn, several specialized transaction processing systems have evolved adopting a variety of system designs each with their unique pros/cons. The focus of this entry is to survey the techniques proposed in recent years to scale up transaction processing on modern multicore hardware and assess how suitable these techniques are in the context of emerging many-core hardware and trends in the computer architecture community in general.

Up until around 2005, software systems benefited from the advancements in the hardware industry easily. Thanks to Moore's law (Moore 1965), computer architects were able to boost the performance of processors by adding more and more complexity within a core (e.g., aggressive pipelining, super-scalar execution, out-of-order execution, and branch prediction). Around 2005, however, power draw and heat dissipation have prevented processor vendors from leaning on more complex micro-architectural techniques for higher performance. Instead, they have started adding more cores on a single processor, creating multicores, to enable exponentially increasing parallelism (Olukotun et al. 1996). As a result,

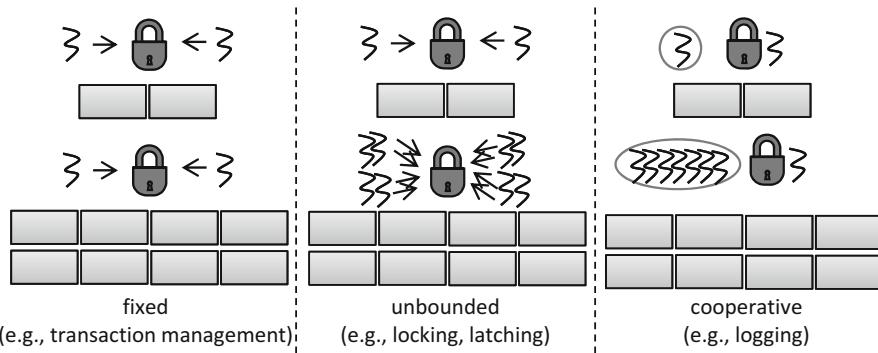

software developers did not have the luxury to be blind to the advancements in hardware. The processors, and in turn software systems, did not automatically get faster with each new generation of hardware. Traditional software systems, including transaction processing, had to go through fundamental design changes to be able to exploit the kind of parallelism offered by having multiple cores in a processor.

The traditional transaction processing systems were not designed with abundant horizontal parallelism in mind. Even though they can handle several concurrent requests very efficiently while satisfying the *ACID* properties on a few single-core processors, their performance suffers on multicore architectures due to the tightly coupled and centralized internal components and unpredictable accesses to the shared data (Johnson et al. 2014). Such components and access patterns lead to various scalability bottlenecks on multicores and hinder the parallel execution of even non-conflicting requests.

In the rest of this entry, we first categorize the communication patterns and, in turn, types of critical sections, in transaction processing to better understand the underlying scalability problems. Then, we review the recent works that tackle the scalability of transaction processing systems proposing novel system designs that are based on data partitioning and that avoid data partitioning. Finally, we discuss the issues that await modern transaction processing systems on emerging hardware and identify the significant research challenges in this context and conclude the entry.

Communication Patterns in Transaction Processing

To analyze the communication patterns of a transaction processing system, we are going to look at the types of critical sections it executes. Transaction processing systems employ several types of communication and synchronization. *Locking* operates at the logical (application) level to enforce isolation and atomicity among transactions.

Hardware-Assisted Transaction Processing, Fig. 1 Communication patterns in transaction processing based on the type of contention they create as the parallelism increases (Johnson et al. 2014)

Latching operates at the physical (database page) level to enforce the consistency of the physical data as concurrent transactions read/write this data. Finally, at the lowest levels, *critical sections* ensure the consistency of the system's internal state. Locks and latches form a crucial part of that internal state and are themselves protected by critical sections underneath. Therefore, analyzing the behavior of critical sections captures nearly all forms of communication in a transaction processing system.

Critical sections, in turn, fall into three categories depending on the nature of the contention they tend to cause in the system as Fig. 1 illustrates. *Fixed* critical sections are the ones where a fixed number of threads use to protect their communication. Therefore, the contention is limited, and it cannot increase as the underlying parallelism increases. Producer-consumer-like communication, mainly found inside the transaction manager component of a transaction processing system, is an example for these types of critical sections. At the other extreme, *unbounded* critical sections are the ones where all concurrent worker threads in the system might contend for. Therefore, as hardware parallelism increases, the degree of contention also has the potential to increase. Such critical sections inevitably grow into a bottleneck. Making them shorter or less frequent provides a little slack but does not fundamentally improve scalability. Locking and latching are good examples for this category of critical sections. Finally, *cooperative* critical sections are

the ones where concurrent worker threads can aggregate their requests and execute them all at once later. They are not as lightweight as the fixed critical sections. However, they allow good resistance against contention, since adding more threads to the system gives more opportunity for threads to combine work rather than competing directly for the critical section. Batching log requests is an example of cooperative communication in a transaction processing system.

The real key to scalability lies in converting all unbounded communication to either the fixed or cooperative type, thus removing the potential for bottlenecks to arise. The following sections analyze the various proposals for building more scalable transaction processing systems in the context of this categorization of communication patterns and critical sections. Note that this categorization is not unique to data management systems and can be used to reason about the scalability of other types of software systems as well.

Key Research Findings

Proposals that depart from traditional transaction processing in order to scale up on multicores can be grouped into two broad categories. The first category applies some sort of data partitioning, physical or logical, to bound the concurrent accesses on data. The second category prefers not depending on data partitioning and in-

stead relies on lighter-weight concurrency control mechanisms, lock-free algorithms, and multiversioning. The former has the potential to eliminate the most problematic critical sections in a system but requires the data to be almost perfectly partitionable. The latter doesn't require the data to be perfectly partitionable but doesn't eliminate the critical sections either; it instead reduces/minimizes their impact. More importantly, both approaches have challenges when it comes to scaling up on multisocket multicore (Porobic et al. 2012) or many-core hardware (Yu et al. 2014).

Scaling Up with Partitioning

There are various ways to partition the data from extreme physical partitioning to lightweight logical partitioning to more hybrid partitioning that combines physical and logical partitioning. This section briefly surveys these partitioning mechanisms going over some of the systems that adopt them.

Physical Partitioning

Shared-nothing systems physically partition the data and deploy multiple database instances. In this setup, one can tune which part of the data belongs to which instance and the number of threads assigned to each instance. Therefore, physically partitioned systems can regulate the data access patterns and contention on the data. Systems like VoltDB (<http://www.voltdb.com>) (commercial version of H-Store (Stonebraker et al. 2007)) apply the idea of physical partitioning to the extreme and deploy single-threaded database instances. When a workload is perfectly partitionable, i.e., all the transactions are handled by a single database instance and data accesses are balanced across the instances, this design eliminates all unbounded communication within the database engine and has the potential to achieve perfect scalability.

When a workload is not amenable to partitioning, though, physical partitioning suffers from multi-partition/distributed transactions (Curino et al. 2010; Helland 2007; Pavlo et al. 2011; Porobic et al. 2012) or load imbalance (Pavlo et al. 2012). Dynamic repartitioning to minimize

distributed transactions or balance load is highly costly due to the amount of data to be moved from one partition to another and reorganization of the index structures (Serafini et al. 2014; Tözün et al. 2013). In addition, traditional physiological logging (Mohan et al. 1992) does not favor this design since maintaining a partitioned log has high overhead, especially for non-partitionable workloads (Johnson et al. 2012). Therefore, physically partitioned systems either use a shared log (Lomet et al. 1992) or eliminate it completely (Stonebraker et al. 2007) and provide durability through replication or adopt more lightweight forms of logging (Malviya et al. 2014).

Logical or Physiological Partitioning

Instead of physically partitioning the data and adopting a shared-nothing design, one can also just logically partition the data in a shared-everything setting to regulate the data access patterns and the contention over the shared data. More specifically, logical partitioning decentralizes the lock manager and enforces each partition to maintain its own lock manager. Each logical partition can be owned by either a single worker thread (Pandis et al. 2010) or a few worker threads (Lahiri et al. 2001). This design eliminates the unbounded communication due to locking. In addition, dynamic repartitioning is cheap under logical partitioning since no data movement is necessary (Tözün et al. 2013).

On the other hand, logical partitioning is not able to regulate the accesses to shared database pages. Therefore, it cannot eliminate the unbounded communication due to latching. Physiological partitioning (Pandis et al. 2011; Schall and Härdler 2015) enhances logical partitioning and partitions physical data page accesses as well. This type of partitioning can eliminate the unbounded communication due to both locking and latching while still reaping the benefits of a shared-everything setting.

However, both logical and physical partitioning introduce multi-partition transactions in a shared-everything system. Such transactions can be handled by some extra fixed communication to coordinate the actions of a transaction that belong to different partitions.

While such fixed communication is usually lightweight and is not a burden for scalability as section “Communication Patterns in Transaction Processing” describes, it has to be handled within a processor socket as much as possible. Otherwise, such fixed communication can easily become a bottleneck as well due to nonuniform memory accesses as Porobic et al. (2014) shows and as section “Future Directions of Research: Toward Many Cores” elaborates.

Scaling Up Without Partitioning

While partitioning-based techniques have been quite popular, the recent years have seen the rise of systems work that relies on lock-free techniques while maintaining the consistency of their internal data structures and optimistic and multiversion concurrency control to ensure isolation and atomicity of concurrent transactions. There are various commercial transaction processing systems that follow this approach: HyPer (Kemper et al. 2013), Hekaton (Diaconu et al. 2013), MemSQL (<http://www.memsql.com/>), SAP HANA (Lee et al. 2013), etc. In addition to typical OLTP workloads, these systems also benefit workloads that have short-running read/write transactions concurrently running with the long-running read-only transactions or queries or workloads that need hybrid transactional/analytical processing (HTAP), since they do not block transactions with pessimistic locking techniques.

However, these systems do not eliminate the unbounded communication at all. They rather minimize the time spent for such communication through optimistic concurrency control, decentralized record locks, frequent use of atomic operations, read-copy-update mechanisms, or hardware transactional memory (Larson et al. 2011; Leis et al. 2014; Levandoski et al. 2013; Sewall et al. 2011; Tu et al. 2013). Even though these mechanisms perform and scale well on architectures with a few (one to four) processor sockets without depending on data partitioning, scaling them up on larger multisocket multicore hardware or emerging many-core processors is not straightforward (David et al. 2013; Porobic et al. 2014; Yu et al. 2014). In addition, similarly to the statically partitioned designs, they suffer under

update-heavy workloads with hotspots (Narula et al. 2014).

Future Directions of Research: Toward Many Cores

Commodity servers that data-intensive applications typically run on have been offering us more and more opportunities for parallelism over the years, thanks to Moore’s law, even though its form and level have been changing over time. As mentioned in section “Overview”, this parallelism has been mainly implicit (more complexity within a core) shortly before the last decade. Multicores, on the other hand, offer explicit parallelism where tasks can run concurrently. *A software system has to exploit both types of parallelism if one wants to utilize modern hardware fully.*

Nowadays we tend to have multiple multicore processors in server hardware, typically two to four sockets on commodity servers. Such hardware does not offer uniform core-to-core communication anymore. Cores within a processor socket tend to communicate at least an order of magnitude faster compared to the cores on different sockets (David et al. 2013) creating nonuniform communication within a server. In the future, we expect even more cores in a processor and even more processors in commodity servers. Core-to-core access latency is going to be nonuniform even within a processor socket. *Therefore, system designs targeting only parallelism and not nonuniformity of communication across cores are not ideal.*

Unfortunately, the traditional multicore hardware design also faces challenges. Even though Moore’s law still holds today, Dennard scaling (Dennard et al. 1974), which enables keeping the power density of the transistors constant, does not. The supply voltage required to power all the transistors up does not decrease at a proportional rate (Esmailzadeh et al. 2011). Putting more cores in a processor rather than putting more complexity within a core helped mitigating this problem up until now, but is not going to help us solve this problem any longer. Even if we end up

incorporating more cores on a single processor, we are not going to be able to use them all at the same time. This trend is called *dark silicon* and fundamentally alters the focus of hardware designs (Hardavellas et al. 2011). *In this new era, the focus has to shift toward optimizing energy per instruction.*

This focus on energy and the ever-growing scale of data-intensive applications has increased the interest in building hardware components that are specialized for data-intensive processing tasks. Most of the efforts in this direction so far has targeted traditional analytics workloads (Balkesen et al. 2018; Wu et al. 2014) or cloud search, machine learning, and AI (Putnam et al. 2014; Jouppi et al. 2017) more recently. There have been efforts for building specialized hardware components for transaction processing as well (Johnson and Pandis 2013). *Even though it might still not be feasible to design a whole chip specifically for a data-intensive application, building hardware components that accelerate frequent operations from an application might be, especially if the accelerator can benefit similar operations from other applications as well. The challenge is to find such operations that would justify the cost to build specialized hardware.*

Alternatively, many hardware vendors have started to ship co-processors. Low power processing units shipped together with power hungry ones or regular CPUs are shipped together with FPGAs or GPUs on the side (<https://www.arm.com/products/processors/biglittleprocessing.php>) (<https://www.altera.com/solutions/acceleration-hub/overview.html>) (<https://www.ibm.com/support/knowledgecenter/en/POWER9/p9hdx/POWER9welcome.htm>). *Finding ways to exploit such heterogeneous platforms is going to be another big challenge for data-intensive systems.*

Conclusions

Despite various advancements both from academia and industry, tackling ever-increasing parallelism and heterogeneity on modern and emerging hardware is still a hot challenge for

transaction processing systems. None of the major proposals for concurrency control are good enough for many-core hardware (~ 1000 cores) (Yu et al. 2014) even when one assumes uniform cores. As long as there is unbounded communication in a system, even the most scalable systems on the current generation of hardware will fail to scale up in the future generations. In addition, scheduling tasks on today's multisocket hardware or on hardware with mild specialization is not straightforward. Focusing on parallelism as the only dimension for scaling up transaction processing systems is insufficient. We have to take nonuniformity and heterogeneity of the underlying hardware into account.

More and more emerging hardware is going to be nonuniform and heterogeneous in terms of the provided functionality. Therefore, it also becomes essential for the emerging transaction processing systems to decide on the optimal design options based on the processor types they are running on. If the system is running on a hardware that has a combination of different processing units (aggressive, low-power, special purpose, etc.), it should be able to automatically decide on which types of requests should run on which types of processors. If the system is running on a hardware that has support for hardware transactional memory, it should be able to know the types of critical sections that would benefit from switching the synchronization primitive to transactions and the ones that should keep its existing synchronization method. If there are tasks that would benefit from running on GPUs or could be accelerated via FPGAs, the system should know when to off-load these tasks to these units. Nevertheless, this requires a thorough understanding of the specific requirements of a system that can exploit the specific features of various hardware types. In addition, it requires interdisciplinary collaborations, especially involving people from data management, computer architecture, and compiler communities. Furthermore, to come up with more economically viable solutions in this area, we need to reach out to cloud providers so that they start building

software and hardware infrastructures with heterogeneity in mind.

Synonyms

Transaction processing on persistent memory;
Transaction processing on storage-class memory

Definitions

A transaction is a demarcated sequence of application operations, for which the following properties are guaranteed by the underlying transaction processing system (TPS): atomicity, consistency, isolation, and durability (ACID). Transactions are therefore a general abstraction, provided by TPS that simplifies application development by relieving transactional applications from the burden of concurrency and failure handling. Apart from the ACID properties, a TPS must guarantee high and robust performance (high transactional throughput and low response times), high reliability (no data loss, ability to recover last consistent state, fault tolerance), and high availability (infrequent outages, short recovery times).

The architectures and workhorse algorithms of a high-performance TPS are built around the properties of the underlying hardware. The introduction of nonvolatile memories (NVM) as novel storage technology opens an entire new problem space, with the need to revise aspects such as the virtual memory hierarchy, storage management and data placement, access paths, and indexing. NVM are also referred to as storage-class memory (SCM).

Overview

Over the last decades, advances in the semiconductor industry regarding novel storage technologies and the resulting disruptive applications have been remarkable. Even though databases or file systems still do not fully exploit NVM properties, nonvolatile memory devices are gradually entering the mass market. There are several promising NVM technologies, such as resistive memory (e.g., HP's memristor), spin-transfer torque memory (STT-RAM), Intel's 3D XPoint, and phase-change memories (PCM). Their characteristics differ considerably from existing storage solutions. Similar to Flash, NVMs wear out and exhibit asymmetric I/O latencies; similar to DRAM, they are byte-addressable, but they are much denser and only consume energy during I/O activity (proportional to the data size to be written), and their I/O latencies are 2–50× slower than DRAM yet about 100× faster than Flash (see Table 1).

Key Research Findings

The advent of modern storage technologies since 2006 resulted in novel approaches and algorithms on virtually all layers of modern DBMS: storage and transaction management, access paths and indexing, and query processing. Since transactions commonly traverse these layers, current research shows the significant impact of using these advances in the DBMS processing stack.

Architectural Considerations

The architectural positioning of NVM alongside DRAM yields complex virtual memory hierarchies (Fig. 1). They comprise block and byte-addressable storage and a combination of wear-prone and wear-immune technologies. Traditional DBMS are designed to compensate for the so-called access gap. Yet, in complex memory hierarchies, this gap turns into an operation-based latency *continuum*, due to read/write asymmetry and different technological combinations. Given all of the above, the research space is extended by fields such as query optimization for asymmetric memories and byte addressability, data placement, and automated advisors, as well as energy efficiency.

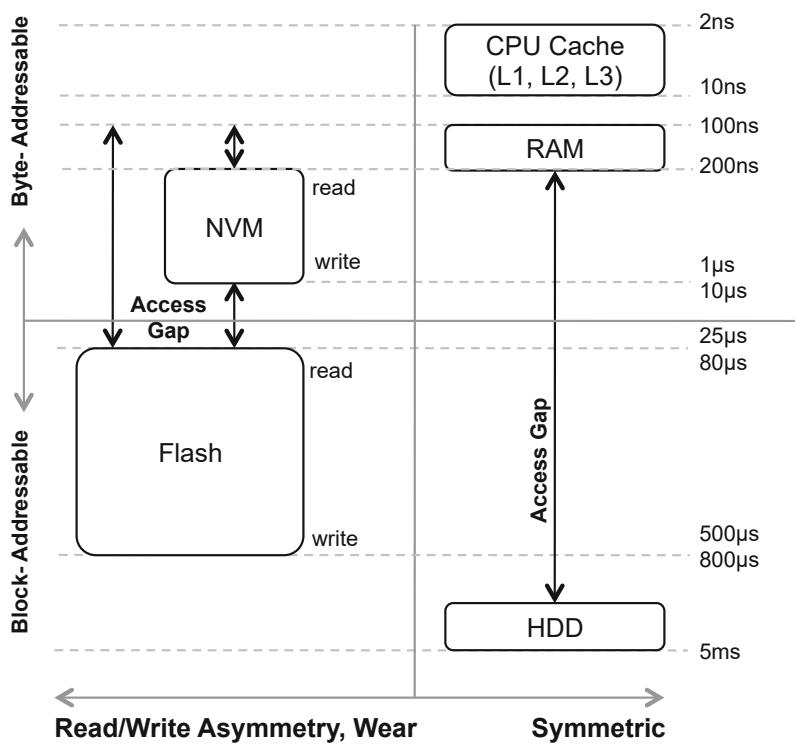

The announced form factors of leading semiconductor manufacturers comprise almost the complete spectrum of currently available peripheral devices and embedded systems. NVM can act as caches in front of NAND Flash (Intel Optane SSD DC P4800X Series), as stand-alone PCIe storage cards (Intel Optane SSD 900P), or even as memory DIMM replacements, directly attached to various processing units (CPU, GPU, FPGA, or ASIC). Besides NVDIMM-F, NVDIMM-N, and various other standards toward novel storage technologies, JEDEC currently defines a new NVDIMM-P standard (JEDEC 2017) for compatibility with traditional DDR4 DIMM slots, which is expected to be released soon. Moreover, its application in computer system either as peripheral, DIMMs, or embedded is widespread and comprises

Hardware-Assisted Transaction Processing: NVM, Fig. 1 Complex memory hierarchy

small IoT devices, smartphones, consumer devices, but also large data centers. However, the definitive position is still unclear. NVM can function as a RAM replacement but can also be exposed as conventional block device. The former calls for persistent memory controllers with a consistent energy-backed write queue (WQ) as well as extended CPU instruction set (e.g., CLWB, CLFLUSH, etc.). The latter promotes faster market introduction at the cost of underutilizing the technological potential and employing suboptimal backward compatibility.

Furthermore, a variety of different and novel interface definitions lately emerged. Depending on the targeted utilization and application, these approaches focus on various aspects of NVM characteristics. A broad range of lightweight file systems (PMFS (Dulloor et al. 2014), NOVA (Xu and Swanson 2016), etc.) including kernel drivers and user mode libraries were proposed in the last half decade. But also a potpourri of novel access mechanisms for nonvolatile storage (PAllocator Oukid et al. (2017), pmemlib Intel (2017), etc.), adapting and extending conventional concepts of

memory management, are topics of the current research. Arulraj et al. (2015) propose a NVM allocator extension providing a naming mechanism that ensures validity of memory address pointers and pointers even after restart, hence, providing *nonvolatile pointers*. The allocators may also offer *atomicity* (Schwalb et al. 2015) by avoiding dangling pointers since NVM leaks upon a restart.

Moreover, CPU instruction set architectures (ISA) have to be extended by new primitives like CLWB, CLFLUSH, or SFENCE (Oukid and Lehner 2017; Arulraj and Pavlo 2017) to handle NVM durability in combination with the WQ. To avoid consistency issues, modified cache lines need to be written *in order*. ISA extensions for this purpose are necessarily needed, since data modifications caused by a transaction may still rely in the CPU caches and may not directly flushed to the NVM, causing durability and consistency issues in case of a power loss. Supporting some type of soft or atomic writes natively on NVM is an intensive research area (Schwalb et al. 2015; Oukid et al. 2017; Intel 2017).

Storage Manager

The interaction with NVM in the context of transaction is in many cases realized as any kind of storage management. The associated research comprises data placement via file systems or allocators, interface extensions, as well as cost models and advisers for these concepts.

Data Placement in Complex Memory Hierarchies

With NVM as novel, persistent but also fast storage layer, data placement emerges as a pressing research question: *Where* should the data of a database object be placed (completely or partially), so that data access patterns match the characteristics of the respective storage technology, to achieve optimal performance under the current workload? DRAM, for instance, can be utilized for rapidly changing data or as a fast NVM cache to achieve write and energy optimizations as well as compression. NVM storage is predestined for large hot persistent data sets due to its high density and low latencies. Flash has higher access latencies but increasing large storage capacity (with the advent of 3D NAND) and can serve as cold or read-intensive storage. HDD can serve as cheap cold storage devices for large sequentially accessed data sets.

The extent to which NVM can function as a DRAM replacement is evaluated in Huang et al. (2014), concluding that a replacement becomes quickly inefficient as soon as transaction-heavy benchmarks like TPC-C, TATP, or TPC-B are executed. To overcome this, novel hybrid NVM-DRAM storage engines like FOEDUS, (Kimura 2015) or SOFORT, (Oukid et al. 2014) and respective data structures, algorithms, and hybrid page layouts are subjects under research.

Hardock et al. (2017) exploit low-level techniques on Flash storage to handle appends to already programmed physical pages. Extending the traditional NSM page layout with a delta record area and proposing a scheme to control the write behavior and space allocation resulted in not only significantly less reads, writes, and erases but also in a higher transactional throughput.

Still, data placement in complex memory hierarchies does not influence exclusively the trans-

action throughput. In addition, a wide array of performance metrics like recovery time, as studied in DeBrabant et al. (2014a). Viglas (2015) and Arulraj et al. (2015) evaluate and identify further open problems in various traditional DBMS, e.g., validating in-place, copy-on-write, and log structured updates. In this context, Ma et al. (2016) explore issues regarding swapping in in-memory databases to overcome data size limitations, especially with NVM. This includes policies for when to evict tuples and how to bring them back. Reconsiderations of the OLTP durability management for NVM is presented in Pelley et al. (2013a). NVM as disk replacement for near-instantaneous recovery and the removal of software-managed DRAM buffering is presented. Mihnea et al. (2017) have already shown an early adoption of NVM within SAP HANA.

Access Paths and Interface Extensions

The use of the file abstraction and lightweight file systems (FS) for NVM is another intensively investigated research area. First approaches to bypass the slow, block-based interface of conventional FS are introduced in Condit et al. (2009). Their new technique *short-circuit shadow paging* supports atomic, fine-grained updates while enabling strong reliability guarantees. Dulloor et al. (2014) set their focus with PMFS likewise on the byte addressability and the avoidance of block-oriented overheads. Thereby, they exploit processor's paging and memory-order features for optimization and use fine-grained logging to ensure consistency. By changing the architecture for user-mode programs to access files without kernel interaction, Volos et al. (2014) present a novel and flexible FS with fewer consistency guarantees but higher performance. Xu and Swanson (2016) adapt commonly used log-structuring techniques with their NOVA FS and provide strong consistency guarantees on hybrid memory systems. Having lightweight characteristics in common, all these FSs are claimed to facilitate storage management on modern architectures.

An alternative approach is In-Page Logging for Flash and NVM, which allocates a small log sector of a page on the same Flash block to

accumulate updates to the respective page. In addition, partial differential logging of Kim et al. (2010) explores the idea of reducing write amplification. Many of these principles have been extended and applied on storage management for NVM (Lee et al. 2010a,b; Gao et al. 2015; Kim et al. 2011). To further minimize the write volume and perform NVM-friendly writes, storage managers use techniques such as epochs, change ordering, and group commit (Pelley et al. 2013b).

Volos et al. (2011) address the interface to modern storage technologies with Mnemosyne and target the creation and management of NVM as well as consistency handling in the presence of failures. Likewise, Intel (2017) defines a set of libraries designed to provide some useful API server applications, e.g., a transactional object store.

REWIND, Chatzistergiou et al. (2015a), proposes a user-mode library to manage transactional updates *directly* in the application to minimize the overhead of the conventional access stack. PAllocator is proposed in Oukid et al. (2017) as a fail-safe persistent NVM allocator with a special focus on high concurrency, capacity, and scalability. Ogleari et al. (2016) presents an approach that goes one step further in that it handles a sort of undo/redo log directly in hardware.

Transaction Management and Logging

Due to their I/O characteristics, both Flash and NVM are claimed to speed up logging. Numerous methods have been developed for Flash (On et al. 2012; Chen 2009) with some concepts (e.g., group commit) being adapted by approaches for NVM. As a consequence, Kim et al. (2016), Gao et al. (2015), and Wang and Johnson (2014) demonstrate how the logging load shifts from I/O-bound to software-bound when utilizing NVM.

In fact, a whole field of persistent programming models for NVRAM as RAM replacement has emerged (Boehm and Chakrabarti 2016; Kolli et al. 2016; Coburn et al. 2011). This includes lightweight logging schemes, (Chatzistergiou et al. 2015b), and approaches for main memory DBMS, DeBrabant et al. (2014b). An alternative approach is KaminoTx, Memaripour et al.

(2017), which avoids copies along the critical I/O path due to logging by permanently maintaining an entire copy of relevant database objects. If a transaction aborts, objects can be recovered from this copy, while updates are handled asynchronously. However, Huang et al. (2014) points out that simply replacing all disks with NVM led to no cost-effective optimum in terms of monetary cost per transaction. As an alternative, the proposed system NV-Logging shows the overheads and scalability limitations of centralized log buffers and therefore enables per-transaction logging.

Liu et al. (2014) first propose the novel unified working memory and persistent store architecture, NVM Duet, which provides the required consistency and durability guarantees. Later, Liu et al. (2017) present DudeTM, a crash-consistent durable transaction system that avoids the drawbacks of both undo and redo logging while providing NVM access directly through CPU load and store instructions.

FOEDUS, Kimura (2015), is a holistic approach addressing OLTP DBMS on novel hardware. FOEDUS exploits OCC and is based on Masstree (Mao et al. 2012) and SILO (Tu et al. 2013). It introduces the concepts of dual pages to exploit NVRAM for large cold data and DRAM for hot data, eliminating the need for mapping tables that reduce the concurrency and scalability. In addition, dual pages are coupled with a technique called stratified snapshots for mirroring.

Recovery and Instant Restart

Since the characteristics of modern storage technologies, especially NVM, can be exploited to reduce the recovery time of data management systems, multiple approaches are proposed. The concept of instant restart is introduced in Oukid et al. (2014, 2015), and Schwalb et al. (2016), while instant recovery is described in Graefe et al. (2015, 2016), Graefe (2015), and Sauer et al. (2015). A novel logging and recovery protocol, write-behind logging, is defined by Arulraj et al. (2016) and represents the key idea of logging *what* parts have changed rather than *how* it was changed and gives the DBMS the opportunity to recover nearly instantaneously from system failures.

Indexing and Index Structures

This research area focuses on hybrid DRAM-NVM settings with the goal of improving write efficiency and utilizing read/write asymmetry and byte addressability. There are numerous proposals for indexing techniques in main memory databases: many are cache-aware, are latch-free, and rely on the symmetry of access. Chen et al. (2011) shows how these are suboptimal for PCM, due to the write operations caused by index updates and instead propose an improved B⁺-Tree algorithm for PCMs. B-Trees on NVM have been explored in Chi et al. (2014), Yang et al. (2015), Chen and Jin (2015), and Chen et al. (2011).

Oukid et al. (2016) with its Fingerprinting Persistent Tree (FPTree) addresses the latency sensitivity issues of current persistent trees approaches for NVM. It only persists leaf nodes on NVM and maintains inner nodes in DRAM, rebuilding them upon recovery. In this manner, the applied technique Fingerprinting limits the expected number of in-leaf probed keys to one. Write optimizations are achieved by keeping leaf node entries unsorted, yielding less cache line writes and lower write amplification. Viglas (2012) and Ben-David et al. (2016) address read/write asymmetry by relaxing the B+Tree balance.

Apart from hybrid DRAM-NVM settings, Sadoghi et al. (2016) demonstrate significant reductions in index maintenance, query processing, and insertion time for multiversion databases by redesigning persistence index structures. Employing an extra level of indirection, stored on Flash storage, the number of magnetic disk I/Os for previous metrics can be reduced dramatically.

Examples of Application

Examples for fully mature DBMSs with focus on transaction processing on NVM include:

Peloton: With the main focus on the autonomous operation of the DBMS, Pavlo et al. (2017) present Peloton. It is designed for HTAP workloads and builds its current architecture on in-memory database concepts. In the view of the authors, these concepts endure even with the introduction of NVM.

SAP HANA: An early adoption of NVM within the SAP HANA database is presented in Mihnea et al. (2017). Here, the architectural choices are explained, and arising challenges with the NVM integration are discussed.

Automated discovery of hierarchical process models

Definitions

Hierarchical process discovery is a family of methods in process mining that starting from an event log focuses on the automated discovery of process models containing one or more subprocesses, also known as hierarchical process models.

Overview

With the increasing availability of business process execution data, i.e., event logs, the use of automated process discovery techniques is becoming a common practice among business process management practitioners as a mean to quickly gain insights about the execution of a business process.

Despite several automated process discovery techniques had been proposed over the years (van der Aalst et al. 2004; Weijters and Ribeiro 2011; Leemans et al. 2013), these techniques fall short when dealing with event logs of processes containing sub-processes. When dealing with this type of event logs, classical automated process discovery often produces flat process models that are highly complex and inaccurate (Li et al. 2011; Weber et al. 2015; Sun and Bauer 2016). Let us consider, for example, the log of a process containing a sub-process that may generate multiple instances running at the same time within the same process instance. An example of the application of classical automated process discovery (Weijters and Ribeiro 2011)

on top of this event log is illustrated in Fig. 1. In this particular case, classical automated process discovery fails to isolate the behavior of the sub-process, resulting in a complex model with a high number of gateways and arcs. To overcome this limitation, hierarchical process discovery techniques which reduce the complexity of a discovered process model by exploiting the use of sub-processes have been proposed.

Hierarchical Process Discovery

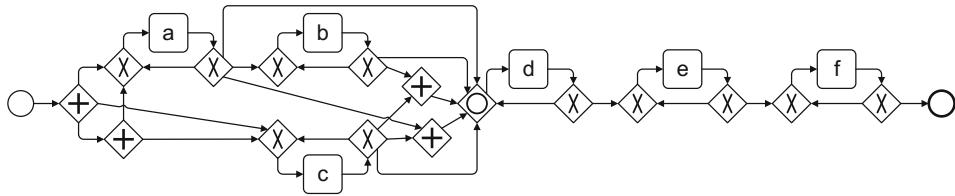

Since the proposal of the first hierarchical process discovery technique by Li et al. (2011), many other techniques followed Maggi et al. (2014), Sun and Bauer (2016), Conforti et al. (2014), Conforti et al. (2016a,b), Wang et al. (2015), and Weber et al. (2015). Despite all these techniques are based on different ideas, the discovery of a hierarchical process model is generally achieved through a two-phase approach (see Fig. 2). Starting from an event log, the first phase involves the extraction of sub-logs from the event log, which leads to a hierarchy of logs with one parent event log and several separate sub-logs (one for each sub-process). In the second phase, a hierarchical process model is discovered by applying classical automated process discovery on top of each (sub-)log.

Sub-logs Extraction

When considering the approach used for the identification and extraction of the hierarchy of logs, hierarchical process discovery techniques can be divided in two major groups: (i) techniques relying on control flow information and (ii) techniques relying on data attributes.

Control-Flow-Based Techniques

Control flow-based techniques are those techniques that identify a sub-log relying uniquely on information that can be derived from the order of the events within an event log. Hierarchical process discovery techniques belonging to this category are the ones proposed by Li et al. (2011), Maggi et al. (2014), and Sun and Bauer (2016).

Hierarchical Process Discovery, Fig. 1 Flat process model (Conforti et al. 2014, 2016b)

Hierarchical Process Discovery, Fig. 2 The two-phase approach

The technique proposed by Li et al. (2011) is based on the idea that the execution of a sub-process leaves a specific *footprint* in an event log. Such a footprint takes the shape of a recurrent execution pattern (Bose and van der Aalst 2009), which can then be used to detect the presence of a sub-process. To detect a sub-process, the authors rely on two patterns: (i) the tandem arrays pattern that corresponds to the execution of loops and (ii) the maximal repeats pattern that corresponds to maximal common subsequence of activities across several process instances. Using these two patterns, sequences of events which could be group together within the same sub-log are identified and several sub-logs extracted. To limit the number of sub-logs generated, only the most frequent patterns out of all patterns detected are considered.

Maggi et al. (2014) consider sub-processes as *pockets of flexibility* within which events of an event log may either be structured (i.e., distributed as a sequence for which the following event can be easily predicted) or unstructured. This concept of structured and unstructured events is used to split the event log in sub-logs. This is achieved by grouping within the same sub-log all subsequent structured events, while unstructured events are grouped together when they are situated in between sequences of structured events.

Finally, the technique proposed by Sun and Bauer (2016) is based on the idea that activities belonging to the same sub-process will be densely connected and their events will

frequently follow each other within the event log. Following this concept, the authors propose to detect densely connected activities by employing graph clustering techniques on top of a causal activity graph, i.e., a graph depicting the causal relation between activities. The resulting clusters are then used to generate several sub-logs (one for each cluster), where each sub-log contains all events belonging to activities within the same cluster.

Data-Based Techniques

In contrast to control flow-based techniques, data-based techniques rely on data attributes belonging to events for the identification of sub-logs and their hierarchical structure. Techniques belonging to this category are the ones proposed by Conforti et al. (2014, 2016b), Wang et al. (2015), and Weber et al. (2015).

The technique proposed by Conforti et al. (2014, 2016a,b) identifies a hierarchy of sub-logs within the event log by relying on approximate functional and inclusion dependency discovery techniques (Huhtala et al. 1999; Bauckmann et al. 2010; Zhang et al. 2010). Additionally, using approximate dependency discovery techniques (Zhang et al. 2010), the technique can identify and filter out noise from the event log, which may be caused by data entry errors, missing event records, or infrequent behavior (Conforti et al. 2016b).

Similarly to Conforti et al. (2014, 2016a,b), the technique proposed by Weber et al. (2015) is based on the idea that a hierarchy between

sub-logs can be identified using data attributes belonging to events. In contrast with the approach by Conforti et al. (2014, 2016a,b), Weber et al. (2015) do not propose a technique for the identification of such data attributes but assume them to be provided in input.

In contrast with these two techniques, the availability of data attributes that can be used to identify a hierarchy between sub-logs is a concern for Wang et al. (2015). To overcome this limitation, they propose a technique that relies on the start and end execution time of each event. Using start and end execution times, they generate an instance tree for each process instance recorded in the log. An instance tree is a tree where events which may occur in parallel are placed on the same level of the hierarchy. These instance trees are then merged together in a hierarchy tree, and events sharing the same ancestor and the same descendants over the union of all instance trees are grouped together within the same sub-log.

The concept of sub-logs extraction is not limited to hierarchical process discovery, and it can be found both in trace clustering as well as in decomposed process discovery.

Trace clustering techniques divide the set of traces of an event log into multiple clusters, where each cluster contains a set of similar traces. These traces correspond to the traces of a variant of a process. The main difference from hierarchical process discovery is that, while in hierarchical process discovery the extracted sub-logs consist of partial traces, in the context of trace clustering, each of the resulting clusters consists of a set of full traces. Additionally, in hierarchical process discovery, a trace at a higher level may refer to a sub-trace at a lower level in the hierarchy.

Similarly, for decomposed process discovery, the goal is to break down each trace in the log into multiple sub-traces. However, in decomposed process discovery, all the sub-traces are at the same level. Moreover, the purpose is different: in hierarchical process discovery, the goal is to discover a modular process model, whereas in decomposed process mining, the goal is to discover a flat process model in a scalable manner.

Sub-process Discovery

When considering the discovery of each sub-process model, all hierarchical process discovery techniques discussed so far rely on classical automated process discovery techniques. Despite this commonality, hierarchical process discovery techniques differ in terms of the features that a discovered process model may contain.

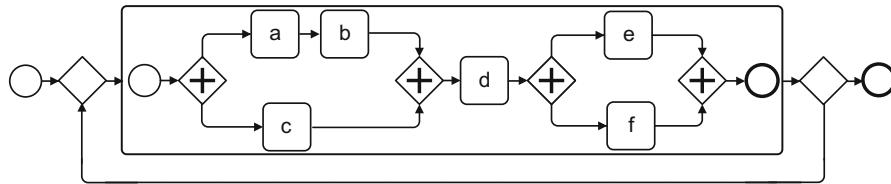

In the following, we provide a comparison of each technique using the set of constructs supported by Business Process Model and Notation (BPMN) (Object Management Group (OMG) 2011) as a reference. When considering hierarchical process discovery and the type of constructs which may be automatically included into a sub-process, we can subdivide these techniques in three groups: (i) techniques supporting the core set of BPMN constructs, (ii) techniques supporting the core set of BPMN constructs and activity markers, and (iii) techniques supporting the complete set of BPMN constructs.

Core BPMN

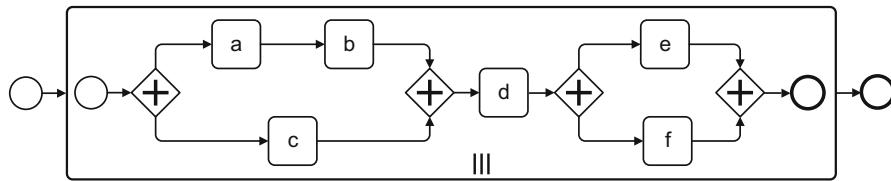

In this category, we find techniques discovering sub-processes which only contain the core set of BPMN constructs, such as start and end events, activities, and gateways. Techniques falling into this category are the ones that outsource the discovery of a sub-process to classical automated process discovery techniques without performing any additional post-processing operation. Models discovered by techniques in this category present a structure similar to the one illustrated in Fig. 3. In comparison to the model presented in Fig. 1, these techniques are able to identify the presence of a sub-process resulting in a simpler process model, despite the model will only allow the sub-process to be executed in a loop (see gateways located externally to the sub-process). In this category, we find the techniques proposed by Li et al. (2011), Maggi et al. (2014), and Sun and Bauer (2016).

Core BPMN and Activity Markers

This category encompasses techniques discovering sub-processes which make use of activity markers in addition to the core set of BPMN constructs. Activity markers are used to

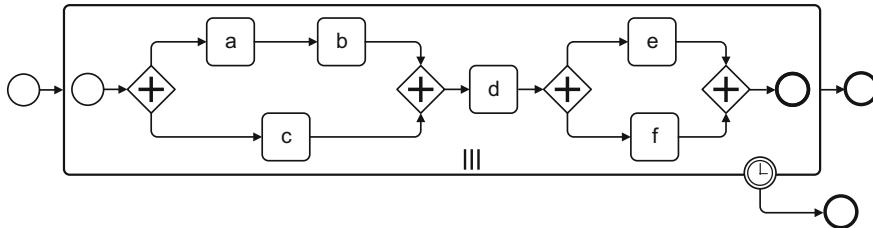

Hierarchical Process Discovery, Fig. 3 Hierarchical process model – core BPMN

H

Hierarchical Process Discovery, Fig. 4 Hierarchical process model – core BPMN with activity markers

Hierarchical Process Discovery, Fig. 5 Hierarchical process model – complete BPMN

differentiate sub-processes which may be executed in a loop or for which several instances of the same sub-process may be spawned at the same time. Techniques falling into this category detect if a sub-process requires an activity marker by using heuristics which are invoked after the discovery of each sub-process. These heuristics generally check if multiple instances of a sub-process are occurring within the same process instance. If this is the case and they overlap in time, the sub-process is marked as multi-instance; otherwise it is marked as loop. In this category, we find the techniques by Wang et al. (2015) and Weber et al. (2015). Process models produced by these techniques will resemble the one illustrated in Fig. 4. In this case, for example, these techniques detect that multiple instances of the sub-process are executed concurrently; hence the use of the multi-instance activity marker in the sub-process replaces the gateways located externally to the sub-process originally used to allow the sub-process to be repeated (Fig. 5).

Complete BPMN

Finally, this category contains techniques able to discover sub-processes that make use of the entire set of BPMN constructs. In this category, we find the technique by Conforti et al. (2014, 2016a,b). In addition to the ability to identify sub-processes that are executed in a loop or that may spawn multiple instances (achieved using similar heuristics as the ones adopted by the techniques presented in the second category), this technique can detect if a given sub-process is subjected to a special condition which forces the premature termination of the sub-process. To achieve this, the technique checks whether the last activity of the sub-process is always executed (i.e., it is present in each instance of the sub-log). The absence of this activity from one of the instances is considered as a sign for a premature termination. Whenever a premature termination is detected, a boundary event is attached to the sub-process. The nature of the premature termination will then determine the type of boundary event,

Hierarchical Process Discovery, Table 1 Hierarchical process discovery techniques: a summary

Technique	Sub-logs extraction based on		Sub-process discovery

i.e., timer event or message event. Specifically, a timer boundary event is used when the duration of a sub-process never exceeds a certain amount of time, while a message boundary event is used in all remaining cases.

Table 1 provides a brief summary of all techniques presented, with the relative subcategory classification.

Conclusion and Final Considerations

In previous sections, we discussed the importance of hierarchical process discovery, we highlighted the advantages that it has over classical automated process discovery, and we presented several techniques that can be used to discover hierarchical process models. In this final section, we will discuss some aspects that should be considered when undertaking the discovery of a hierarchical process model.

Hierarchical process discovery and the quality of a discovered hierarchical process model are influenced by two main factors: the quality of the event log and the effectiveness of the classical automated process discovery technique used for the discovery of each sub-process.

The quality of an event log is a deciding factor over the type of hierarchical process discovery technique that should be adopted. In particular, if data attributes are missing or if the quality of information recorded is inadequate, data-based techniques will fail to identify possible sub-logs within the event log, which in turn will result into the discovery of a flat process model.

Similarly, the quality of a discovered hierarchical process model is affected by the effectiveness of the classical automated process discovery technique used for the discovery of each sub-process. In particular, techniques performing poorly will produce imprecise and complex subprocesses which will still result into imprecise and complex hierarchical process models.

These two aspects should be taken into consideration when attempting to gain insights about a business process. Business process management practitioners should consider hierarchical process discovery techniques only when the quality of the event log is adequate. In scenarios where logs are of poor quality (e.g., logs containing incorrectly recorded events and where data attributes are unreliable or missing), control flow-based hierarchical process discovery techniques should be preferred over data-based hierarchical process discovery techniques. Finally, the discovery of each sub-process should be handled through the use of robust classical automated process discovery techniques for which we refer the reader to the entry on automated process discovery, where a detailed analysis of all available techniques is offered.

Finally, the problem of hierarchical process discovery shares several similarities with the problem of artifact-centric process discovery. Both families of methods aim at discovering a modular process model from an event log. However, they differ in terms of their modularization approach. Specifically, artifact-centric process discovery differs from hierarchical process discovery as it seeks to discover a process model

that consists of a set of interacting artifacts, each one with an independent life cycle. For a detailed discussion on artifact-centric process discovery, we refer to the corresponding entry in this encyclopedia.

Historical Graph Management

Udayan Khurana¹ and Amol Deshpande²

¹IBM Research AI, TJ Watson Research Center, New York, NY, USA

²Computer Science Department, University of Maryland, College Park, MD, USA

Definitions

Real-world graphs evolve over time, with continuous addition and removal of vertices and

edges, as well as frequent change in their attribute values. For decades, the work in graph analytics was restricted to a static perspective of the graph. In recent years, however, we have witnessed an increasing abundance of timestamped observational data, fueling an interest in performing richer analysis of graphs, along a temporal dimension. However, the traditional graph data management systems that were designed for static graphs provide inadequate support for such temporal analyses. We present a summary of recent advances in the field of historical graph data management. They involve, compact storage of large graph histories, efficient retrieval of temporal subgraphs, and effective interfaces for expressing historical graph queries, essential for enabling temporal graph analytics.

Overview

There is an increasing availability of timestamped graph data – from social and communication networks to financial networks, biological networks, and so on. Analysis of the history of a graph presents valuable insights into the underlying phenomena that produced the graph. For instance, the evolution of a graph or community can be seen through the evolution of metrics such as diameter or density; change in the importance of key entities in a network can be done through measuring change in network centrality and so on.

Traditional graph data management systems based on static graphs provide insufficient support for temporal analysis over historical graphs. This is due to a fundamental lack in the modeling of the *change* of information. If performed using the conventional graph systems, such tasks become prohibitively expensive in storage costs, memory requirements, or execution time and are often unfriendly or infeasible for an analyst to even express in the first place. The frequent change of a temporal graph also poses a significant challenge to algorithm design, because the overwhelming majority of graph algorithms assume static graph structures. One would have to design special algorithms for each application

to accommodate the dynamic aspects of graphs. To support general-purpose computations, most of the emerging temporal graph systems adopt a strategy to separate graph updates from graph computation. More specifically, although updates are continually applied to a temporal graph, graph computation is only performed on a sequence of successive *static* views of the temporal graph. For simplicity, most systems adopt a *discretized-time* approach, so that time domain is set of natural numbers, i.e., $t \in \mathcal{N}$. As per the terminology of temporal relational databases, this discussion considers *valid time* (against *transaction time*) as the underlying temporal dimension for historical analyses. Valid time denotes the time period during which a fact is true with respect to the real world. Transaction time is the time when a fact is stored in the database. It is worth noting that there is a related but orthogonal body of work which we do not touch in this chapter. It deals with the need to do *real-time analytics on the streaming data* as it is being generated; here, the scope of the analysis typically only includes the latest snapshot or the snapshots from a recent window. The key challenge there is to be able to deal with the high rate at which the data is often generated.

Broadly speaking, this chapter's focus is to briefly introduce the reader to the recent advances in historical graph data management for temporal graph analytics. There are many different types of analyses that may be of interest. For example, an analyst may wish to study the evolution of well-studied static graph properties such as centrality measures, density, conductance, etc. over time or the search and discovery of temporal patterns, where the events that constitute the pattern are spread out over time. Comparative analysis, such as juxtaposition of a statistic over time or, perhaps, computing aggregates such as *max* or *mean* over time, gives another style of knowledge discovery into temporal graphs. Most of all, even a primitive notion of simply being able to access past states of the graphs and performing simple static graph analytics empowers a data scientist with the capacity to perform analysis in arbitrary and unconventional patterns. Supporting such a diverse set of temporal analytics

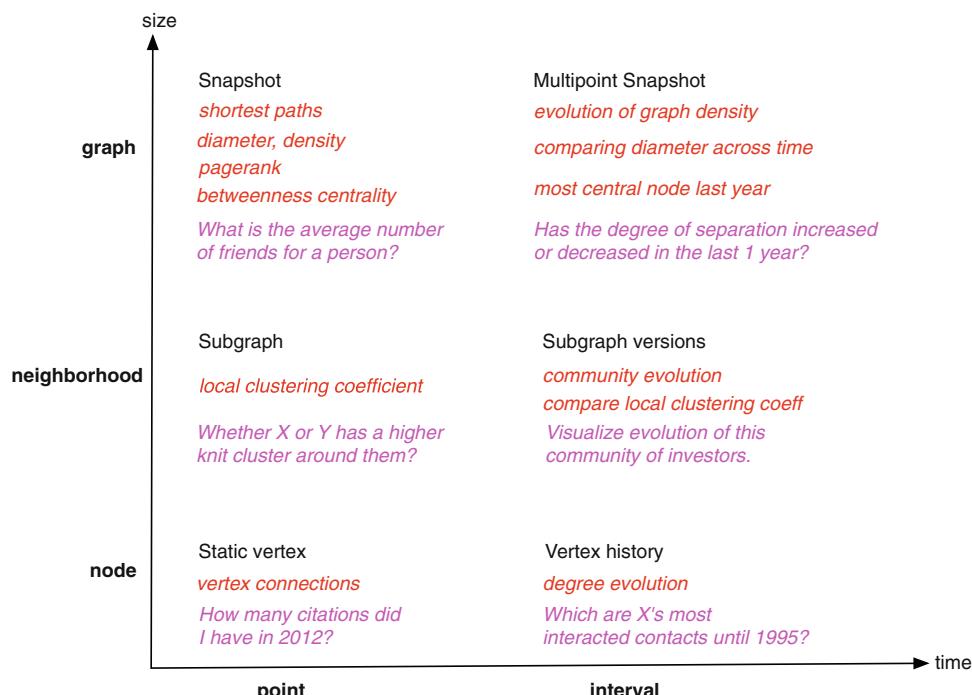

and querying over large volumes of historical graph data requires addressing several data management challenges. Specifically, we need techniques for storing the historical information in a compact manner, while allowing a user to retrieve graph snapshots as of any time point in the past or the evolution history of a specific node or a specific neighborhood. Further the data must be stored and queried in a distributed fashion to handle the increasing scale of the data.

Historical or temporal analyses on graphs span a variety of tasks that vary in the analytical quantity of interest, as well as the scope of the graph locality and time duration being analyzed. Figure 1 provides a classification on those lines and lists a few examples of graph retrieval and analysis tasks. A more exhaustive taxonomy of temporal tasks is provided by Ahn et al. (2014). Finally, there is a need for an expressive, high-level, easy-to-use programming framework that will allow users to specify complex temporal graph analysis tasks in a data-parallel fashion across a cluster.

Key Research Findings

Storage and Retrieval

Storage of large temporal graphs is challenging and requires careful design. An effective storage system for temporal graphs has a twofold objective. First, the storage should be compact such that the invariant information across multiple graph versions is not stored multiple times. Second, it must allow for efficient retrieval of graph primitives such as snapshot(s), temporal range queries of nodes, or neighborhoods, among others, as reflected in Fig. 1. A straightforward use of static graph data stores can lead to an explosion in storage requirements and/or incur high fetch latency times. Consider two basic and extreme approaches from conventional storage methods to support snapshot retrieval queries, referred to as the *Copy* and *Log* approaches, respectively, as described by Salzberg and Tsotras (1999). While the copy approach relies on storing new copies of a snapshot upon every point of change, the log approach relies on storing everything through

Historical Graph Management, Fig. 1 A temporal graph can be represented across two different dimensions – time and entity. It lists retrieval tasks (black), graph

operations (red), example queries (magenta) at different granularities of time and entity size (Khurana 2015)

changes. Their hybrid is often referred to as the *Copy+Log* approach. Copy approach is clearly infeasible for frequently changing graphs because of intractable storage needs; the log approach, while storing minimal information, makes it a hard work to reconstruct any snapshot or temporal subset of the graph.

Delta-Based Encodings

The use of “*deltas*”, or graph differences, is a powerful approach to register the changes in a graph over a period of time. If carefully organized, deltas can provide efficient retrieval at low storage costs. The *DeltaGraph* index (Khurana and Deshpande 2013a), for instance, provides highly efficient retrieval of individual snapshots of the historical graph for specific time instances. It organizes the historical graph data in a hierarchical data structure, whose lowest level corresponds to the snapshots of the network over time and whose interior nodes correspond to graphs constructed by “combining” the lower level snapshots in some fashion; the interior nodes are typically not valid snapshots as of any specific time point. Neither the lowest-level graph snapshots nor the graphs corresponding to the interior nodes are actually stored explicitly. Instead, for each edge, a *delta*, i.e., the difference between the two graphs corresponding to its endpoints, is computed, and these deltas are explicitly stored. In addition, the graph corresponding to the root is explicitly stored. Given those, any specific snapshot can be constructed by traversing any path from the root to the node corresponding to the snapshot in the index and by appropriately combining the information present in the deltas. The use of different “combining” functions leads to a different point in the performance-storage trade-off, with *intersection* being the most natural such function. This index structure is especially effective with *multi-snapshot retrieval* queries, which are expected to be common in temporal analysis, as it can share the computation and retrieval of deltas across the multiple snapshots. While it is efficient at snapshot retrieval, it is not suitable for fetching graph primitives such as histories of nodes or neighborhoods over specified periods of time. However, *Temporal Graph Index*

(*TGI*) (Khurana and Deshpande 2016), is an extension of DeltaGraph which partitions deltas in so-called microdeltas, and uses chaining of related microdeltas across horizontal nodes in the DeltaGraph, allows retrieval of different temporal graph primitives including neighborhood versions, node histories, and graph snapshots. Such a microdelta-based design is great for distributed storage and parallel retrieval on a cloud. This allows efficient retrieval of not only entire snapshots but also of individual neighborhoods or temporal histories of individual neighborhoods.

Storing by Time Locality

Another powerful approach to store and process temporal graphs is based on time locality. *Chronos* (Han et al. 2014) targets time-range graph analytics, requiring computation on the sequence of static snapshots of a temporal graph within a time range. An example is the analysis of change in each vertex’s PageRank for a given time range. Obviously, the most straightforward approach of applying computation on each snapshot separately is too expensive. Chronos achieves efficiency by exploiting locality of temporal graphs. It also leverages the time locality to store temporal graphs on disk in a compact way. The layout is organized in snapshot groups. A snapshot group G_{t_1, t_2} contains the state of G in the time range $[t_1, t_2]$, by including a checkpoint of the snapshot of G at t_1 followed by all the updates made till t_2 . The snapshot group is physically stored as edge files and vertex files in time-locality fashion. For example, an edge file begins with an index to each vertex in the snapshot group, followed by segments of vertex data. The segment of a vertex, in turn, first contains a set of edges associated with the vertex at the start time of the snapshot group, followed by all the edge updates to the vertex. A link structure is further introduced to link edge updates related to the same vertex/edge, so that the state of a vertex/edge at a given time t can be efficiently constructed.

Indexing Using Multiversion Arrays

LLAMA (Macko et al. 2015) presents an approach where an evolving graph is modeled as a time

series of graph snapshots, where each batch of incremental updates produces a new graph snapshot. The graph storage is read-optimized, while the update buffer is write-optimized. It augments the compact read-only CSR representation to support mutability and persistence. Specifically, a graph is represented by a single vertex table and multiple edge tables, one per snapshot. The vertex table is organized as a large multiversioned array (LLAMA) that uses a software copy-on-write technique for snapshotting, and the record of each vertex v in the vertex table maintains the necessary information to track v 's adjacency list from the edge tables across snapshots. The array of records is partitioned into equal-sized data pages, and an indirection array is constructed that contains pointers to the data pages. The indirection array fits in L3 cache. To create a new snapshot, the indirection array is copied, with those references to outdated pages replaced by those to the newly modified pages. Thus, we do not need to copy unmodified pages across snapshots. LAMA stores 16 consecutive snapshots of the vertex table in each file, so that disk space can be easily reclaimed from deleted snapshots. The edge table for a snapshot i is organized as a fixed-length array that stores adjacency list fragments consecutively, where each adjacency list fragment contains the edges of a vertex added in snapshot i . An adjacency list fragment of vertex v also stores a continuation record, which points to the next fragment for v , or *null* if there are no more edges. To support edge deletion, each edge table maintains a deletion vector, which is an array that encodes in which snapshot an edge was deleted.

Analytical Frameworks

Running graph analytics requires dealing with two main aspects – the runtime system components and the interfaces to express the analytical task. Let us discuss the essentials of both.

Runtime Environment Aspects

In-Memory Graph Layouts. Like the storage and indexing of temporal graphs, dealing with temporal redundancy is important in the in-memory data structures on which analytics are

executed. For example, when running a graph algorithm or evaluating a metric on various snapshots of a graph, it might be prohibitively expensive to store all the snapshots in the memory at the same time. However, most graph libraries do require plain isolated version of each graph. The most common solution to this problem is to use an overlaying of multiple versions on one another and using bitmaps and an additional lookup table to establish the validity of a graph component to one or more versions. This reduces any redundancy of nodes, edges, or attributes that occur across multiple versions yet obtaining access to each snapshot as a static graph through a simple interface. GraphPool (Khurana and Deshpande 2013a) and Chronos (Han et al. 2014) among others use variations of this technique. In addition, Chronos also employs such a structure for locality-aware batch scheduling (LABS) of graph computation. More specifically, LABS batches the processing of a vertex across all the snapshots, as well as the information propagation to a neighboring vertex for all the snapshots.

Parallelism. Temporal graph analytics presents opportunities for parallelization in two different ways. First, evaluating a property across multiple snapshots can be easily parallelized, unless. Second, several static graph computation operations, such as PageRank, can be run in parallel themselves. Determining the optimum level of parallelism for an analytical task can be complex and depends on the exact computation steps, nature of graph data, and the resources available. TGAF (Khurana and Deshpande 2016) provides parallelism by expressing all temporal graphs as RDDs of time evolving nodes or subgraphs and letting the underlying Spark infrastructure plan the parallelism. Leveraging Spark parallelism provides abundant benefits, along with simplicity of design. However, there are occasions on which certain tasks can be customized for better results. A major drawback with TGAF is the lack of space saving obtained through overlaid structures such as GraphPool. LABS and Llama show effective locality-based multi-core parallelism.

Incremental Computation. Time-range graph analysis can benefit from incremental or shared computation. First, for iterative algorithms such as PageRank, if the target time range contains a sequence of N snapshots S_0 to S_{N-1} , the result computed on S_0 can be used to initialize the solution for S_1 and so on until S_{N-1} . This reduces the number of iterations needed to converge an algorithm but also serializes the computations because of the newly created dependence. Chronos utilizes a variation of this principle to effectively perform incremental computation.

Analytical Interfaces

There are mainly two kinds of historical graph analytical interfaces. The first one, a programmatic interface involves an abstraction of a temporal graph and various operations that can be performed on it, along with calls to several static (sub-)graph routines. The second kind are the visual exploration tools which are usually targeted to more specific types of analytic options but provide an easier means to express the task through GUI interfaces and provide meaningful visualization of the results. One example of a programmatic interface is TGAF (Khurana and Deshpande 2016), which abstracts the temporal graph through two main primitives – *Set of temporal nodes (SoN)* and *Set of temporal subgraphs (SoTS)*. The entire temporal graph or any part of it may be expressed as one of these primitives. A SoN is best illustrated as a three-dimensional array along the axes of time, nodes, and attributes. The system also defines graph manipulation operations such as *timeslicing*, *selection*, and *filtering*; compute operators such as *node compute map*, *temporal node compute map*, *node compute delta*, and among others; it also provides analytical operators such as *compare*, *evolution*, and such. A rich set of operators enables the expression of complex analytical operations. We omit further details here and refer the interested reader to Khurana and Deshpande (2016) and Khurana (2015).

Visualization is an effective means for exploring and analyzing a temporal graph. The following is a rather brief and non-exhaustive reference to techniques and tools that have demonstrated

such capabilities. Using visualization of different snapshots, Toyoda and Kitsuregawa (2005) study events like appearance of pages, relationship between different pages for a historical dataset of Web archive. *Hinge* (Khurana and Deshpande 2013b) provides a visual timeline-based exploration and search for a temporal graph; it additionally provides the capability to search simple subgraph patterns in a time range. NetEvViz (Khurana et al. 2011) extends NodeXL (a popular graph analysis tool) to study evolving networks. It uses an edge color coding scheme for comparative study of network growth. Ahn et al. (2011) focus on different states of graph components in order to visualize temporal dynamics of a social network. Alternate representations to node-link diagrams have been proposed in order to study temporal nature of social networks, such as TimeMatrix (Yi et al. 2010) that uses a matrix based visualization to better capture temporal aggregations and overlays. A temporal evolution analysis technique based on capturing visual consistency across snapshots can be seen in the work of Xu et al. (2011). A survey by Beck et al. (2014) lists several other approaches for visual analysis of dynamic graphs.

Examples of Application

In recent years, we have witnessed several works of historical graph analyses. Such work could benefit from the new research and systems described above for historical graph data management. Few examples of such applications are as follows. Leskovec et al. (2007) and Kumar et al. (2010) have designed analytical models that capture network evolution, with a focus on social networks and the Web. Studies analyze how communities evolve (Tang et al. 2008), identifying key individuals, and locating hidden groups in dynamic networks (Tantipathananandh et al. 2007), also characterizing the complex behavioral patterns of individuals and communities over time (Asur et al. 2009). Biologists are interested in discovering historical events leading to a known state of a biological network (Navlakha and Kingsford 2011). Change in page rank

(Bahmani et al. 2010), change in centrality of vertices, path lengths of vertex pairs, etc. (Pan and Saramäki 2011), shortest paths evolution (Ren et al. 2011), and such, provide useful analytical algorithms for changing graphs.

Future Directions for Research

The topic of historical graph data management is ripe with research opportunities. In spite of the advances in temporal graph querying, there is a considerable scope for designing a more expressive and rigorous algebra and language. The work in graph pattern matching and mining appears to lack a temporal dimension. A related but important topic is that of finding interesting temporal graphs from timestamped datasets such as system logs. In terms of systems research, integrating a historical graph system and a streaming graph system into one presents interesting challenges and opportunities for researchers in the field.

Hive

Alan F. Gates
 Hortonworks, Santa Clara, CA, USA

Definitions

Apache Hive is data warehousing software that facilitates reading, writing, and managing large data sets residing in distributed storage using SQL (Apache Hive PMC 2017).

Overview

Hive enables data warehousing in the Apache Hadoop ecosystem. It can run in traditional Hadoop clusters or in cloud environments. It can work with data sets as large as multiple petabytes. Initially Hive was used mainly for ETL and batch processing. While still supporting these use cases, it has evolved to also support data warehousing use cases such as reporting, interactive queries, and business intelligence. This evolution has been accomplished by adopting many common data warehousing techniques while adapting those techniques to the Hadoop ecosystem. It is implemented in Java.

Architecture

Hive's architecture is shown in figure 1. Not all of the components in the diagram are required in every installation. LLAP and HiveServer2 are optional; the Metastore can be run embedded in HiveServer2 or in the client's code.

Terms

HDFS: *Hadoop Distributed File System.* HDFS provides adaptors to many distributed file systems and object stores, including cloud object stores (e.g., Amazon's S3), and on-premise distributed systems (e.g., EMC's Isilon). Throughout this article where HDFS is referred to, it means use of the HDFS API. The underlying storage may be HDFS or another system.

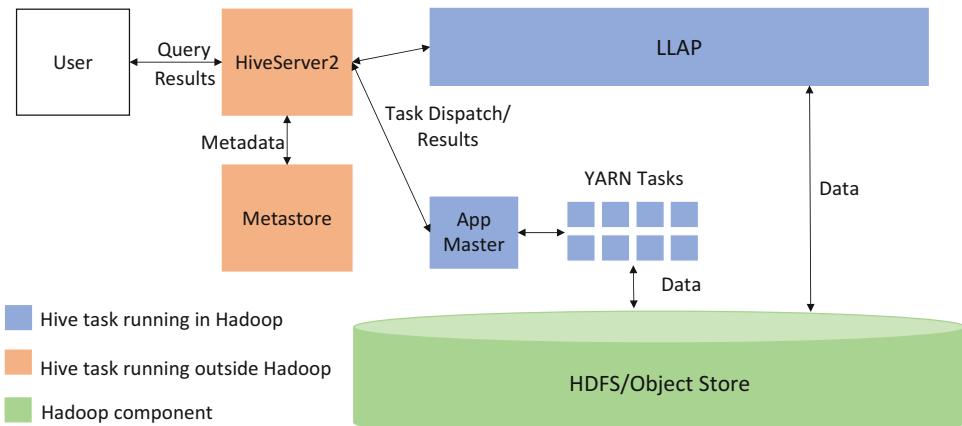

Schema: Hive uses the term schema to refer to the column names and types of data in a relation, also known as table schema. In an RDBMS context, schema often refers to a collection of relations. Throughout this article schema refers to table schema unless otherwise specified.

YARN: *Yet Another Resource Negotiator.* Hadoop's resource allocation and task manager (Vavilapalli et al. 2013). YARN is responsible for finding resources for a job in the Hadoop cluster and interacting with the job to allocate tasks and assuring the tasks and job complete and return to the submitter.

Running on Hadoop, Scalability, and High Availability

Running on Hadoop gives Hive the ability to run over large data sets with a high degree of parallelism. Hadoop clusters vary in size from a few nodes to tens of thousands of nodes. And since Hadoop provides connectors to other distributed storage systems, Hive can be used with these distributed storage systems as well. This allows Hive, on a large cluster or in the cloud, to operate on very large data sets.

Hadoop provides high availability and retry in the face of system failure for the tasks it executes.

Hive, Fig. 1 Hive components

Hive has built HiveServer2 and the Metastore to be highly available, since they do not run as tasks in Hadoop. Multiple instances of these components can be run simultaneously so that any single component failure does not render the system unavailable. Since the Metastore relies on an RDBMS to store the metadata (see below), users must choose a highly available RDBMS in order to avoid a single point of failure.

Columnar Data Storage

For traditional data warehousing queries, it is well known that columnar formats provide superior performance. There are two major columnar formats in the big data ecosystem, Apache ORC (Huai et al. 2014) and Apache Parquet. Hive supports both. ORC was originally a part of Hive and is tightly integrated into a number of Hive's newer features, such as ACID and LLAP. The rest of this section will focus on ORC, but much of what is said here applies to Parquet as well.

Columnar formats often store each column in a separate file. However, HDFS does not support co-location of related files; hence this does not work in Hadoop. Instead, ORC stores all of the columns in a single file. An ORC file is split into stripes. All of the values for a given column are stored contiguously within a stripe. These columns are compressed in type-specific ways (e.g., strings are dictionary encoded), and run length encoding is used for most types. The file

can be further compressed using standard techniques such as zlib or Snappy. Information on column offsets is placed at the end of the file so that a reader can easily read only the desired columns.

ORC also records basic statistics (e.g., minimum and maximum values) per stripe and row group (a collection of 10,000 rows in a stripe) which it uses to support predicate pushdown, allowing it to further trim the data it reads. For example, if a query requests users living in Canada and, when reading a particular row group, ORC discovers that the minimum value in the country column for that row group is Denmark, it will skip reading those rows.

“Unstructured” and Text Data

Hadoop is useful for storing very large quantities of “unstructured” data. Unstructured is a misnomer, in that this data does have structure. It is unstructured in that it has not been normalized and cleansed for storing in an RDBMS. This unstructured data may define its own structure (e.g., JSON, Apache Avro) or be a format with a predefined structure (e.g., MPEG3). It may also be a text file of comma separated values (CSV). Hive can read and write data in JSON, CSV, and Avro. It can also read pre-existing data if a user creates a table with the existing data as its data file(s).

Partitions

Given the large size of many tables, partitioning of tables is an important concept in Hive. At creation time the user specifies whether the table should be partitioned and on what key(s). All partitioning in Hive is based on value, which each partition containing a single value of the partitioning key(s). It is common, though not required, to use a date or time stamp for partitioning, as often data in Hadoop arrives at regular intervals. Each partition is stored in a separate directory in HDFS.

Most data in Hive is stored in files in HDFS. For a given table or partition, there will usually be multiple files, as each writer in a job creates its own file.

Metadata

Hive stores its data catalog in a relational database; it can use Oracle, SQL Server, MySQL, or Postgres. This service is provided by the Metastore module and is exposed via an Apache Thrift API so that other systems and tools can access the metadata. A relational database was chosen rather than storing the data in Hive itself because Hive is not an OLTP system and is not suited for the frequent small reads and writes that the Metastore executes. Fetching all of the metadata and statistics necessary to execute a query can take several seconds when the query spans thousands of partitions. To address this the Hive team is working on effective caching of the metadata so that where possible metadata and statistics can be kept in memory rather than requiring multiple database reads for every Hive query.

Query Optimization

Hive embeds and extends Apache Calcite in its optimizer. Calcite provides several features:

- A cost-based planner which uses dynamic programming as in Volcano-style optimizers. This planner is not exhaustive in its search but rather prunes the search tree to avoid an explosion of plan options.
- An exhaustive planner which explores all options and continues optimizing until no rule results in a transformation.
- A multi-phased approach to planning, where the system groups related rules into a phase. This speeds the optimization process as each phase has fewer alternatives to consider and allows the system to select the cost-based planner for some phases and exhaustive for others.
- Common optimization rules.
- The ability for systems to extend the rule set with their own rules.

Hive makes use of all these features. In particular it has added a large number of its own rules to the planner. Statistics for planning can be gathered automatically as part of data being inserted into Hive, or later by users running ANALYZE over a table or partition.

Hive is currently working on enhancing its optimizer in order to efficiently support cubing-style queries. It will do this by storing aggregate indexes in Druid (a separate open-source project that can very quickly answer many cubing-style queries) and using the optimizer to rewrite queries from the table to the associated index. Work is also underway to support materialized views so that common aggregates can be pre-materialized. Calcite includes an algorithm to help determine the appropriate aggregates to materialize.

Partition Pruning

One of the most important performance optimizations for any distributed data processing system is determining what data to read. Users are encouraged to partition their data such that most of their queries will only require some partitions. This must be balanced against creating too many small

partitions, which puts pressure on HDFS (since it has an upper bound on the number of files it can support in the file system) and the Metastore since it has to store metadata and statistics for each partition.

When a query's WHERE clause includes a predicate on the partition column(s) that can be statically computed, the Metastore can determine which partitions are required for the query. However, in the case where input data is trimmed via a join condition or subquery, Hive cannot statically determine the appropriate partitions to read. This scenario is common with fact and dimension tables. In order to efficiently execute such a query, Hive prunes partitions at runtime. When assigning segments of data to individual tasks, if it determines that the join will drop all records in the partition (based on the partition key or ORC statistics), it will remove that task from the job. This is a crucial performance optimization that allows Hive to efficiently execute data warehousing-style queries.

Query Execution

Hive offers different options for query execution. Originally all queries were executed using Hadoop's MapReduce framework. MapReduce scales very well for large data sets, but it suffers from a number of issues as an execution framework for SQL queries. Queries must be constructed as a chain of MapReduce jobs, each of which writes their results to HDFS in between. MapReduce is a very rigid model. Each job takes one input, applies the map function to it, shuffles the data between machines in order to group the records by key, applies the reduce function, and produces one output. The relational operator set can be pushed into this, but it is neither simple nor efficient.

MapReduce worked well as an engine in Hive's early days when it was focused solely on ETL and large batch jobs. As it began to transition to more data warehousing use cases, Hive needed to support more complex SQL and provide much better latency for query performance.

To address this, Hive was extended to use other Hadoop-based engines, the first of which was Apache Tez. Tez jobs are expressed as a directed acyclic graph (DAG), where nodes are processing tasks and edges are data flows between tasks. Multiple in- and outbound edges per node are supported. Tez also supports modifying the DAG at runtime based on feedback during processing (Saha et al. 2015). These features provide Hive a much simpler and more efficient model for executing its operators.

Another engine chosen was Apache Spark. Spark also supports arbitrary graphs of tasks, with intermediate data being stored in memory of the task machines. This makes it both more flexible and much faster than MapReduce (Zaharia 2010).

Hive currently supports Tez, Spark, and MapReduce, though MapReduce has been deprecated in recent versions.

The use of Tez or Spark addresses many of the performance issues seen with MapReduce, in some cases improving performance by a factor of 100 or more (Shanklin 2014). However, even with these new engines, performance issues remained due to the fact that Hadoop runs each task in a dedicated JVM. This slows down queries in three ways:

- When a job is submitted, it takes a minimum of 2–5 s to spawn the task JVMs.
- Java's just-in-time compiler (JIT) is not invoked until each task is part way through processing its data, even though the task is running the same code as many other tasks before it.
- There are limited options for caching data; each task must read its data from HDFS.

To address these issues, the Hive team developed LLAP (Live Long and Process). LLAP makes use of traditional MPP techniques. A set of long-running YARN tasks is allocated in the Hadoop cluster. Each node has a cache of data. This cache is column and ORC row group aware so that only hot portions of the data are cached.

Any node can cache any segment of the data. This prevents bottlenecks when a portion of the data is very hot and many readers wish to access it. When a job has a task ready for execution, the task is sent to an LLAP node. If the data to be accessed by that task is already cached on an LLAP node and that node has processing capacity, the task will be placed there. If the node does not have capacity, then the task will be placed on a node with capacity, which will then also cache the required data. LLAP nodes can exchange data in the same way that Tez tasks can, thus enabling the whole query to be executed in these standing servers. An area of active development for LLAP is effective workload management, as provided by many mature data warehousing systems.

MPP-like systems such as LLAP perform very well for traditional reporting and BI queries. However, they are not optimal for handling queries that need to read very large amounts of data. Consider a fact to fact join over 1 year of data where each input is a terabyte. The intermediate results will likely be quite large. It is unlikely that a full year of data will be in the cache, since most queries are over more recent data. And reading the full year into the cache will force out more valuable recent data. LLAP will not be able to dynamically add nodes to handle the large intermediate results. In contrast, this is exactly the situation where Hadoop performs well, since it can spawn sufficient tasks to handle reading and shuffling the data in parallel. In order to support interactive queries as well as large batch jobs, Hive allows users to run queries either in LLAP or use Tez, Spark, or MapReduce.

Whether running another engine such as Tez or running in LLAP, Hive provides all of the relational operators to execute its queries. These include standard operators such as projection, filter, group, sort, and join. Hive supports several types of joins:

- Broadcast join. A table, usually small enough to fit into memory, is broadcast to each task and joined against a fragment of the larger table.
- Sort-merge-bucket (SMB) join. This depends on the data already being partitioned and

sorted on the join key. In this case it will materialize the join via a merge join on each segment of data.

- Distributed hash join. This redistributes records from all inputs to a number of tasks based on the join key and then materializes the join in each task. This is by far the most expensive join type since it requires redistributing all the input data across the network. However, it scales much better than a broadcast join and does not require the data to be already sorted to be efficient like SMB join does.

Initially Hive's operators used the textbook database method of building a small set of operators that handle all data types and pull one record at a time through the operator tree. This model does not perform well for data warehousing queries. It does not efficiently make use of pipelining in the CPU, as the need to support multiple data types creates many branches in the code. It also tends to produce CPU cache misses since there is no guarantee that records are co-located in memory, forcing expensive loads from main memory. This can be addressed by operating on records in batches that are sized to fit the CPU's cache and reworking operators to be data-type specific and to minimize branches (Boncz et al. 2005). Hive reworked its operators to conform to this pattern. Hive refers to these new operators as “vectorized.”

SQL

The Hive project has stated a goal of supporting all the segments of ANSI SQL 2011 that are relevant for data warehousing operations. It has not yet achieved that goal but is tracking progress toward it (Apache Hive SQL Conformance 2017).

In addition to supporting standard SQL data types, Hive also supports additional Java-like types. These include strings (unbounded character strings, similar to RDBMS text type, but stored in row), lists (arrays of a given type), structs (a predefined set of names and types; ANSI row types), and maps (a free form mapping

of string names to values). These additional types are frequently used in the big data world as not all data is normalized, especially when first ingested.

Data Ingestion and ACID

Hive provides a LOAD statement to allow users to load external data into the system. It also supports “external tables,” where the data is written and owned by a user external to Hive. At table creation time, the user specifies where the data is located.

Hive can also write data itself via INSERT or CREATE TABLE AS SELECT statements. Originally Hive only supported writing an entire partition or table, or appending rows to an existing partition or table, though with limited ACID guarantees. Recent versions of Hive support standard transactional ACID semantics and UPDATE, DELETE, and MERGE statements. Currently all transactions are limited to a single statement; work on allowing multi-statement transactions is ongoing.

As HDFS provides write-once semantics, supporting ACID requires Hive to store changed records in side files, referred to as delta files, along with information on which transaction wrote the changed record. Transaction state is tracked in the Metastore. Readers are provided with a list of open and aborted transaction as well as their own transaction ID. From this they are able to determine which version of the record they should read. When a table’s or partition’s delta files become too numerous or too large, a compaction process automatically runs in the background to integrate the changed records into the base data files. This compaction process does not prevent simultaneous read and write of the data by users.

Hive can also ingest data from an input stream such as Apache Kafka and store it in a table with transactional semantics so that readers can see very recent data. Currently this only supports insert of new records. Adding support for update and delete of records is an area of future development and is very desirable as it will allow Hive to support change data capture (CDC).

User-Defined Functions

Given its roots in the Hadoop world, Hive has always supported user-defined functions (UDFs). These UDFs are written in Java. They allow the user to provide column transformation functions, aggregate functions (UDAFs), and table operations (UDTFs) that control how data in complex types can be expanded out to one or more rows (referred to as exploding the data).

Security

H

Authentication in Hadoop and related systems is handled by Kerberos. Using components such as Apache Knox, this authentication can be integrated with LDAP or Active Directory. Hive makes use of these features.

Authorization to read and write data in Hadoop is provided by HDFS, using a standard POSIX model. This presents challenges for Hive since it is not useful to secure the data at a SQL level if the user can access the data at the file level. There are several ways to deal with this.

Hive supports deferring all security decisions to HDFS. It refers to this as storage-based authorization. Table read operations (including metadata operations such as describing the table’s schema) are only allowed if the user has read permissions on the underlying data. Similarly, table write operations (including metadata operations such as altering the table) are only allowed if the user has write permissions on the underlying data. In this scenario Hive can only allow access to all of a table or none (i.e., there are no column or row level permissions).

As a second option, Hive supports standard SQL security with roles, grants, and revokes. For this to work properly, the user that the Hive processes are running as must own all of the data stored in HDFS.

Finally, Hive can integrate with Apache Ranger or Apache Sentry. These provide authorization across the Hadoop ecosystem, assuring that a user’s permissions in Hive are coordinated with his or her permissions in HDFS

and other components. Via plug-ins to Hive, Ranger or Sentry can examine the query plan and authorize or reject a query. They can also choose to modify the query plan. For example, Ranger uses this feature to anonymize sensitive data before returning it to the user.

Since Hive runs in Hadoop, it also has to decide what user to execute its jobs as. Traditionally Hadoop jobs run as the user submitting the job. When running with Tez, Spark, or MapReduce, Hive can follow this paradigm, which it refers to as running in “doAs” mode, since it is doing the operations as the user. This works well in environments where a number of different tools are being used to read and write data. It also allows the use of UDFs. However, security options are limited in this scenario, since Hive is dependent on the ability of the user to access the files that store the data.

Hive can also run all jobs as a dedicated user, referred to as the “hive user.” This gives the ability to provide fine-grained security, since Hive owns all of the data and thus controls access to it. However, it is not safe to allow UDFs when running as a super user. Only system-provided functions and administrator “blessed” UDFs are allowed in this scenario.

Client Connections

Hive includes a JDBC driver that works with HiveServer2. The Hive project does not provide an ODBC driver, but there are commercial ones available.

Hive includes a command line tool called beeline which provides an interactive SQL shell. Beeline connects to HiveServer2 via JDBC.

Hive also supports a command line tool that allows for interactive SQL operations. It is not recommended for production environments since it requires direct access to the Hadoop cluster and HDFS files.

Holistic Schema Matching

Erhard Rahm and Eric Peukert
University of Leipzig, Leipzig, Germany

Synonyms

[Collective schema matching](#)

Definitions

Holistic schema matching aims at identifying semantically corresponding elements in multiple schemas, e.g., database schemas, web forms, or ontologies. The corresponding elements from N (>2) sources are typically grouped into clusters with up to N members. Holistic schema matching is usually applied when multiple schemas need to be combined within an integrated schema or ontology.

Overview

Holistic schema matching aims at identifying semantically corresponding elements in multiple (>2) schemas, such as database schemas, web forms, or ontologies. It is to be contrasted with the traditional pairwise schema matching (Rahm and Bernstein 2001; Euzenat and Shvaiko 2013) between two input schemas only that determines a so-called mapping consisting of a set of correspondences, i.e., pairs of elements of the input schemas (table attributes, ontology concepts) that match with each other. Holistic schema matching is applied to more than two input schemas so that matching schema elements are clustered or grouped together.

This form of schema matching is needed to support data integration for more than two data sources and is thus of increasing relevance for big data applications. There is a large spectrum of possible use forms for holistic schema matching depending on the number and complexity of schemas. Traditional approaches for schema and ontology integration (Batini et al. 1986; Raunich and Rahm 2014) are typically limited to few sources with a high degree of manual interaction. The need for automatic approaches has increased by the availability of many web data sources and ontologies. In domains such as the life sciences, there are numerous overlapping ontologies so that there is an increasing need to semantically integrate these ontologies into a combined ontology to consistently represent the knowledge of a domain. An example of such an integration effort is the biomedical ontology UMLS Metathesaurus (Bodenreider 2004) which currently combines more than 3 million concepts and more than 12 million synonyms from more than 100 biomedical ontologies and vocabularies. The integration process is highly complex, and still largely dependent on domain experts, in order to identify the synonymous concepts across all source ontologies as well as to derive a consistent ontology structure for these concepts and their relations. Related to the integration of multiple ontologies is the construction of so-called *knowledge graphs* from different web sources and ontologies (Dong et al. 2014) that requires to holistically integrate

both entities of one or several domains (e.g., countries, cities, presidents, movies, etc.) and schema elements such as attributes, relationships, and concepts.

While the challenges for integrating very large sets of schemas are far from being solved, there are initial approaches for holistic schema matching that we will discuss in this entry, in particular for the following use cases (Rahm 2016):

- Integration of several database schemas or ontologies
- Matching and integrating multiple *web forms*, e.g., for a mediated web search over several databases
- Matching several *web tables* of a certain domain e.g., for improved query processing

Ideally, holistic schema matching is largely automatic with minimal user interaction and achieves a high match quality, i.e., it correctly clusters matching schema elements. Furthermore, holistic match approaches need to be efficient and scalable to many schemas/sources. It should also be easily possible to add and utilize additional schemas and deal with changes in the source schemas.

As we will see, holistic schema matching still uses pairwise matching as a building block before a clustering takes place. However, scalability to many sources is not feasible if a pairwise mapping of all N input schemas is needed since this would result in a quadratic number of mappings, e.g., almost 20,000 mappings for 200 sources (Rahm 2016).

Key Research Findings

In the following, we will discuss main approaches for the mentioned use cases.

Holistic Matching for Schema and Ontology Integration

To match and integrate multiple schemas or ontologies, one can in principle apply a pairwise matching and integration (or merging) multiple

times in an incremental way. For instance, one can use one of the schemas as the initial integrated schema and incrementally match and merge the next source with the intermediate result until all source schemas are integrated. This has the advantage that only $N-1$ match and integration steps are needed for N schemas.

Such binary integration strategies have already been considered in early approaches to schema integration (Batini et al. 1986). More recently it has been applied within the Porsche approach (Saleem et al. 2008) to automatically merge many tree-structured XML schemas. The approach holistically clusters all matching elements in the nodes of the integrated schema. The placement of new source elements not found in the (intermediate) integrated schema is based on a simplistic heuristic only. A general problem of incremental merge approaches is that the final merge result typically depends on the order in which the input schemas are matched and merged.

A full pairwise matching has been applied in (Hu et al. 2011) to match the terms of more than 4000 web-extracted ontologies. The match process using a state-of-the-art match tool took about 1 year on six computers showing the insufficient scalability of unrestricted pairwise matching.

A holistic matching of concepts in linked sources of the so-called Data Web has been proposed in (Gruetze et al. 2012). The authors first cluster the concepts (based on keywords from their labels and descriptions) within different topical groups and then apply pairwise matching of concepts within groups to finally determine clusters of matching concepts. The approach is a good first step to automatic holistic schema matching but suffered from coverage and scalability limitations. So topical grouping was possible for less than 17% of the considered one million concepts, and matching for the largest group of 5 K concepts took more than 30 h.

The matching between many schemas/ontologies can be facilitated by the reuse of previously determined mappings (links) between such sources, especially if such mappings are available in the Data Web or in repositories such as Bio-Portal and LinkLion (Nentwig et al. 2014).

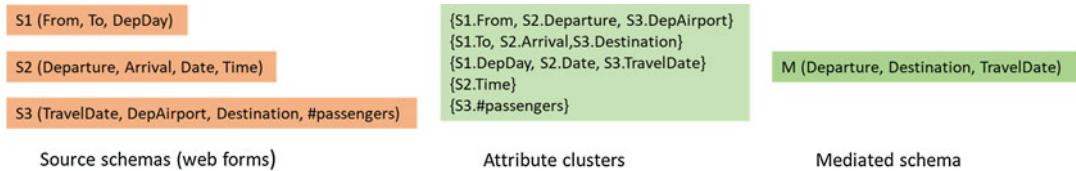

Such a reuse of mappings has already been proposed for pairwise schema and ontology matching based on a repository of schemas and mappings (Do and Rahm 2002; Madhavan et al. 2005; Rahm 2011). A simple and effective approach is based on the composition of existing mappings to quickly derive new mappings. In particular, one can derive a new mapping between schemas S_1 and S_2 by composing existing mappings, e.g., mappings between S_1 and S_i and between S_i and S_2 for any intermediate schema S_i . Such composition approaches have been investigated in (Gross et al. 2011) and were shown to be very fast and also effective. A promising strategy is to utilize a hub schema (ontology) per domain, such as UMLS in the biomedical domain, to which all other schemas are mapped. Then one can derive a mapping between any two schemas by composing their mappings with the hub schema.

Holistic Matching of Web Forms and Web Tables

The holistic integration of many schemas has mainly been studied for simple schemas such as web forms and web tables typically consisting of only a few attributes. Previous work for web forms concentrated on their integration within a mediated schema, while for web tables, the focus has been on the semantic annotation and matching of attributes.

The integration of *web forms* has been studied to support a meta-search across deep web sources, e.g., for comparing products from different online shops. Schema integration mainly entails grouping or clustering similar attributes from the web forms, which is simpler than matching and merging complex schemas. As a result, scalability to dozens of sources is typically feasible. Figure 1 illustrates the main idea for three simple web forms to book flights. The attributes in the forms are first clustered, and then the mediated schema is determined from the bigger clusters referring to attributes available in most sources. Queries on the mediated schema can then be answered on most sources.

Proposed approaches for the integration of web forms include WISE-Integrator and MetaQuerier (He et al. 2004; He and Chang

Holistic Schema Matching, Fig. 1 Integration of web forms (query interfaces) into a mediated schema for flight bookings

2003). Matching and clustering of attributes is mainly based on the linguistic similarity of the attribute names (labels). The approaches also observe that similarly named attributes co-occurring in the same schema (e.g., FirstName and LastName) do not match and should not be clustered together. Das Sarma et al. (2008) proposes the automatic generation of a so-called probabilistic mediated schema from N input schemas, which is in effect a ranked list of several mediated schemas.

A much larger number (thousands and millions) of sources have to be dealt with in the case of web-extracted datasets like *web tables* made available within open data repositories such as data.gov or datahub.io. The collected datasets are typically from diverse domains and initially not integrated at all. To enable their usability, e.g., for query processing or web search, it is useful to group the datasets into different domains and to semantically annotate attributes.

Several approaches have been proposed for such a semantic annotation and enrichment of attributes by linking them to concepts of knowledge graphs like YAGO, DBpedia, or Probbase (Limaye et al. 2010; Wang et al. 2012). In (Balakrishnan et al. 2015), attributes are mapped to concepts of the Google Knowledge Graph (which is based on Freebase) by mapping the attribute values of web tables to entities in the knowledge graph and thus to the concepts of these entities.

The enriched attribute information as well as the attribute instances can be used to match and cluster related web tables to facilitate the combined use of their information. This has only been studied to a limited degree so far. In particular, the Infogather system (Yakout et al. 2012) utilizes enriched attribute information to match web tables with each other. To limit the scope, they

determine topic-specific schema match graphs that only consider schemas similar to a specific query table. The match graphs help to determine matching tables upfront before query answering and to holistically utilize information from matching tables. Eberius et al. (2013) uses instance-based approaches to match the attributes of web tables considering the degree of overlap in the attribute values, but they do utilize the similarity of attribute names or their annotations.

The holistic integration of both web forms and web tables is generally only relevant for schemas of the same application domain. For a very large number of such schemas, it is thus important to first categorize schemas by domain. Several approaches have been proposed for the automatic domain categorization problem of web forms (Barbosa 2007; Mahmoud and Aboulnaga 2010) typically based on a clustering of attribute names and the use of further features such as explaining text in the web page where the form is placed. While some approaches (Barbosa 2007) considered the domain categorization for only few predefined domains, Mahmoud and Aboulnaga (2010) cluster schemas into a previously unknown number of domain-like groups that may overlap. This approach has also been used in Eberius et al. (2013) for a semantic grouping of related web tables. The categorization of web tables should be based on semantically enriched attribute information, the attribute instances, and possibly information from the table context in the web pages (Balakrishnan et al. 2015). The latter study observed that a large portion of web tables includes a so-called “subject” attribute (often the first attribute) indicating the kinds of entities represented in a table (companies, cities, etc.) which allows already a rough categorization of the tables.

Directions for Future Research

Compared to the huge amount of previous work on pairwise schema matching, research on holistic schema matching is still at an early stage. As a result, more research is needed in improving the current approaches for a largely automatic, effective, and efficient integration of many schemas and ontologies. In addition to approaches for determining an initial integrated schema/ontology, there is a need for incremental schema integration approaches that can add new schemas without having to completely reintegrate all source schemas. The use of very large sets of web-extracted datasets such as web tables also needs more research to categorize and semantically integrate these datasets.

To deal with a very large number of input schemas, it is important to avoid the quadratic complexity of a pairwise mapping between all input schemas. One approach, which is especially suitable for integrating complex schemas and ontologies, is to incrementally match and integrate the input schemas. More research is here needed to evaluate how known approaches for pairwise matching and integration could be used or extended for such a setting.

For simpler schemas, or if only a clustering of concepts/attributes is aimed at, grouping of the input schemas by domain or mutual similarity is able to reduce the overall complexity since matching can then be restricted to the schemas of the same group. To limit the effort for matching schema elements within such groups, performance techniques from entity resolution such as blocking (Koepcke and Rahm 2010) can further be utilized. More research is thus needed to investigate these ideas for a very large number of schemas/datasets.

HopsFS: Scaling Hierarchical File System Metadata Using NewSQL Databases

Salman Niazi, Mahmoud Ismail, Seif Haridi, and Jim Dowling
KTH – Royal Institute of Technology,
Stockholm, Sweden

Definitions

Modern NewSQL database systems can be used to store fully normalized metadata for distributed hierarchical file systems, and provide high throughput and low operational latencies for the file system operations.

Introduction

For many years, researchers have investigated the use of database technology to manage file system metadata, with the goal of providing extensible

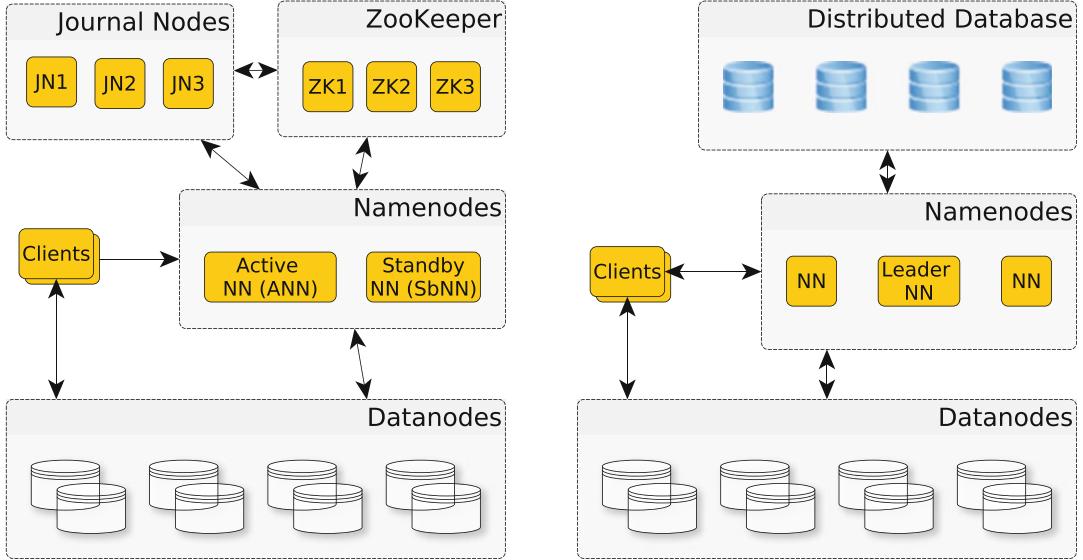

typed metadata and support for fast, rich metadata search. However, previous attempts failed mainly due to the reduced performance introduced by adding database operations to the file system's critical path. However, recent improvements in the performance of distributed in-memory online transaction processing databases (NewSQL databases) led us to reinvestigate the possibility of using a database to manage file system metadata, but this time for a distributed, hierarchical file system, the Hadoop file system (HDFS). The single-host metadata service of HDFS is a well-known bottleneck for both the size of HDFS clusters and their throughput. In this entry, we characterize the performance of different NewSQL database operations and design the metadata architecture of a new drop-in replacement for HDFS using, as far as possible, only those high-performance NewSQL database access patterns. Our approach enabled us to scale the throughput of all HDFS operations by an order of magnitude.

H

HopsFS vs. HDFS

In both systems, namenodes provide an API for metadata operations to the file system clients, see Fig. 1. In HDFS, an active namenode (ANN) handles client requests, manages the metadata in memory (on the heap of a single JVM), logs changes to the metadata to a quorum of journal servers, and coordinates repair actions in the event of failures or data corruption. A standby namenode asynchronously pull the metadata changes from the journal nodes and applies the changes to its in memory metadata. A ZooKeeper service is used to signal namenode failures, enabling both agreement on which namenode is active as well as failover from active to standby.

In HopsFS, namenodes are stateless servers that handle client requests and process the metadata that is stored in an external distributed database, NDB in our case. The internal management (housekeeping) operations must be coordinated among the namenodes. HopsFS solves this problem by electing a leader namenode that is responsible for the housekeeping.

HopsFS: Scaling Hierarchical File System Metadata Using NewSQL Databases, Fig. 1 In HDFS, a single namenode manages the namespace metadata. For high availability, a log of metadata changes is stored on a set of journal nodes using quorum-based replication. The log is subsequently replicated asynchronously to a standby

We use the database as a shared memory to implement a leader election and membership management service (Salman Niazi et al. 2015).

In both HDFS and HopsFS, datanodes are connected to all the namenodes. Datanodes periodically send a heartbeat message to all the namenodes to notify them that they are still alive. The heartbeat also contains information such as the datanode capacity, its available space, and its number of active connections. Heartbeats update the list of datanode descriptors stored at namenodes. The datanode descriptor list is used by namenodes for future block allocations, and it is not persisted in either HDFS or HopsFS, as it is rebuilt on system restart using heartbeats from datanodes.

HopsFS clients support random, round-robin, and sticky policies to distribute the file system operations among the namenodes. If a file system operation fails, due to namenode failure or overloading, the HopsFS client transparently retries the operation on another namenode (after backing off, if necessary). HopsFS clients refresh the namenode list every few seconds, enabling new

namenode. In contrast, HopsFS supports multiple stateless namenodes and a single leader namenode that all access metadata stored in transactional shared memory (NDB). In HopsFS, leader election is coordinated using NDB, while ZooKeeper coordinates leader election for HDFS

namenodes to join an operational cluster. HDFS v2.X clients are fully compatible with HopsFS, although they do not distribute operations over namenodes, as they assume there is a single active namenode.

MySQL's NDB Distributed Relational Database

HopsFS uses MySQL's Network Database (NDB) to store the file system metadata. NDB is an open-source, real-time, in-memory, shared nothing, distributed relational database management system.

NDB cluster consists of three types of nodes: NDB datanodes that store the tables, management nodes, and database clients; see Fig. 3.

The management nodes are only used to disseminate the configuration information and to detect network partitions. The client nodes access the database using the SQL interface via MySQL Server or using the native APIs implemented in C++, Java, JPA, and JavaScript/Node.js.

Figure 3 shows an NDB cluster setup consisting of four NDB datanodes. Each NDB datanode consists of multiple transaction coordinator (TC) threads, which are responsible for performing two-phase commit transactions; local data management threads (LDM), which are responsible for storing and replicating the data partitions assigned to the NDB datanode; send and receive threads, which are used to exchange the data between the NDB datanodes and the clients; and IO threads which are responsible for performing disk IO operations.

MySQL Cluster horizontally partitions the tables, that is, the rows of the tables are uniformly distributed among the database partitions stored on the NDB datanodes. The NDB datanodes are organized into node replication groups of equal sizes to manage and replicate the data partitions. The size of the node replication group is the replication degree of the database. In the example setup, the NDB replication degree is set to two (default value); therefore, each node replication group contains exactly two NDB datanodes. The first replication node group consists of NDB datanodes 1 and 2, and the second replication node group consists of NDB datanodes 3 and 4. Each node group is responsible for storing and replicating all the data partitions assigned to the NDB datanodes in the replication node group.

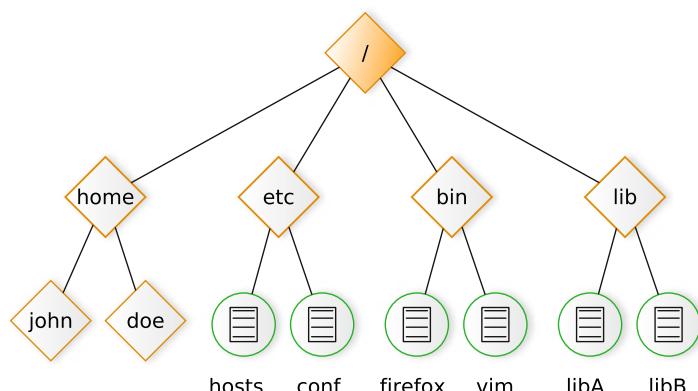

By default, NDB hashes the primary key column of the tables to distribute the table's rows among the different database partitions. Figure 3 shows how the inodes table for the namespace shown in Fig. 2 is partitioned and

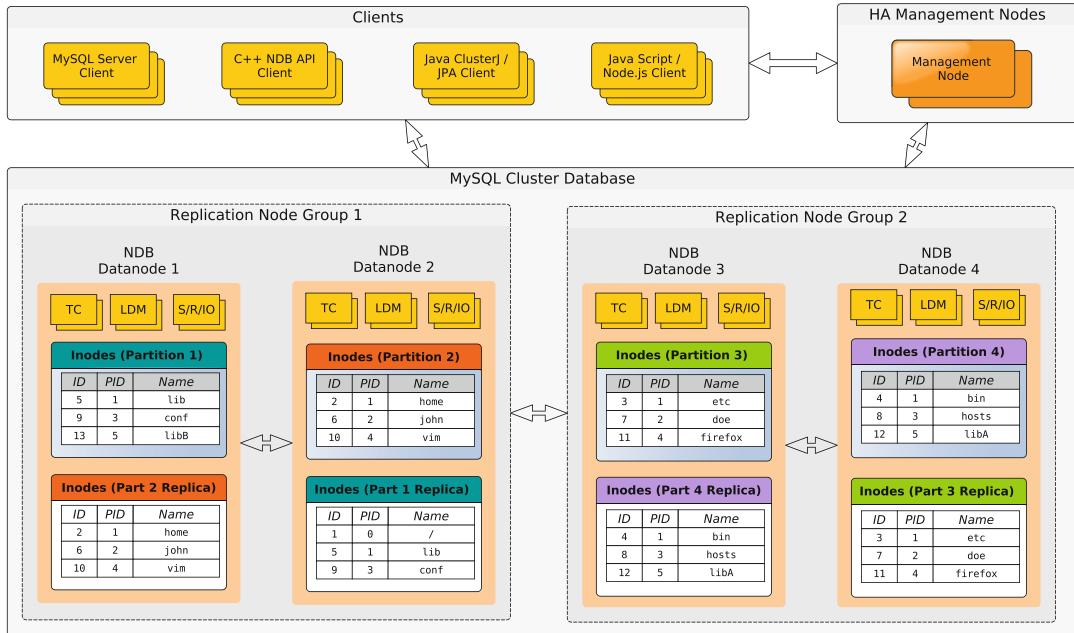

stored in the NDB cluster database. In production deployments each NDB datanode may store multiple data partitions, but, for simplicity, the datanodes shown in Fig. 3 store only one data partition. The replication node group 1 is responsible for storing and replicating partitions 1 and 2 of the inodes' table. The primary replicas of partition 1 is stored on the NDB datanode 1, and the replica of the partition 1 is stored on the other datanode of the same replication node group, that is, NDB datanode 2. NDB also supports user-defined partitioning of the stored tables, that is, it can partition the data based on a user-specified table column. User-defined partitioning provides greater control over how the data is distributed among different database partitions, which helps in implementing very efficient database operations.

NDB only supports *read-committed* transaction isolation level which is not sufficient for implementing practical applications. However, NDB supports row-level locking which can be used to isolate transactions operating on the same datasets. NDB supports *exclusive* (write) locks, *shared* (read) locks, and *read – committed* (read the last committed value) locks. Using these locking primitives, HopsFS isolates different file system operations trying to mutate the same subset of inodes.

and the circles represent
files

HopsFS: Scaling Hierarchical File System Metadata Using NewSQL Databases, Fig. 3 System architecture diagram of MySQL's Network Database (NDB) cluster.

The NDB cluster consists of three types of nodes, that is, database clients, NDB management nodes, and NDB database datanodes

Types of Database Operations

A transactional file system operation consists of three distinct phases. In the first phase, all the metadata that is required for the file system operation is read from the database; in the second phase, the operation is performed on the metadata; and in the last phase, all the modified metadata (if any) is stored back in the database. As the latency of the file system operation greatly depends on the time spent in reading and writing the data, therefore, it is imperative to understand the latency and computational cost of different types of database operations, used to read and update the stored data, in order to understand how HopsFS implements low-latency scalable file system operations. The data can be read using four different types of database operations, such as *primary key*, *partition-pruned index scan*, *distributed index scan*, and *distributed full table scan* operations. NDB also supports *user-defined data partitioning* and *data distribution-aware transactions* to reduce the latency of the distributed transactions. A brief description of these operations is as follows:

Application-Defined Partitioning (ADP)

NDB allows developers to override the default partitioning scheme for the tables, enabling a fine-grained control on how the tables' data is distributed across the data partitions. HopsFS leverage this feature, for example, the inodes table is partitioned by the parent inode ID, that is, all immediate children of a directory reside on the same database partition, enabling an efficient directory listing operation.

Distribution-Aware Transactions (DAT)

NDB supports *distribution-aware transactions* by specifying a *transaction hint* at the start of the transaction. This enlists the transaction with a transaction coordinator on the database node that holds the data required for the transaction, which reduces the latency of the database operation. The choice of the transaction hint is based on the *application-defined partitioning* scheme. Incorrect hints do not affect the correctness of the operation, since the transaction coordinator (TC) will route the requests to different NDB

datanode that holds the data; however, it will incur additional network traffic.

Primary Key (PK) Operation

PK operation is the most efficient operation in NDB that reads/writes/updates a single row stored in a database shard.

Batched Primary Key Operations

Batch operations use batching of PK operations to enable higher throughput while efficiently using the network bandwidth.

Partition-Pruned Index Scan (PPIS)

PPIS is a distribution-aware operation that exploits the *distribution-aware transactions* and *application-defined partitioning* features of NDB, to implement a scalable index scan operation such that the scan operation is performed on a single database partition.

Distributed Index Scan (DIS)

DIS is an index scan operation that executes on all database shards. It is not a distribution-aware operation, causing it to become increasingly slow for increasingly larger clusters.

Distributed Full Table Scan (DFTS)

DFTS operations are not distribution aware and do not use any index; thus, they read all the rows for a table stored in all database shards. *DFTS* operations incur high cpu and network costs; therefore, these operations should be avoided in implementing any database application.

Comparing Different Database Operations

Figure 4 shows the comparison of the throughput and latency of different database operations. These micro benchmarks were performed on a four-node NDB cluster setup running NDB version 7.5.6. All the experiments were run on premise using Dell PowerEdge R730xd servers (Intel(R) Xeon(R) CPU E5-2620 v3 @ 2.40 GHz, 256 GB RAM, 4 TB 7200 RPM HDD) connected using a single 10 GbE network adapter. We ran 400 concurrent database clients, which were uniformly distributed across 20 machines. The

experiments are repeated twice. The first set of experiments consist of read-only operations, and the second set of experiments consist of read-write operations where all the data that is read is updated and stored back in the database.

Distributed full table scan operations and distributed index scan operations do not scale, as these operations have the lowest throughput and highest end-to-end latency among all the database operations; therefore, these operations must be avoided in implementing file system operations. Primary key, batched primary key operations, and partition-pruned index scan operations are scalable database operations that can deliver very high throughput and have low end-to-end operational latency.

The design of the database schema, that is, how the data is laid out in different tables, the design of the primary keys of the tables, types/number of indexes for different columns of the tables, and data partitioning scheme for the tables, plays a significant role in choosing an appropriate (efficient) database operation to read/update the data, which is discussed in detail in the following sections.

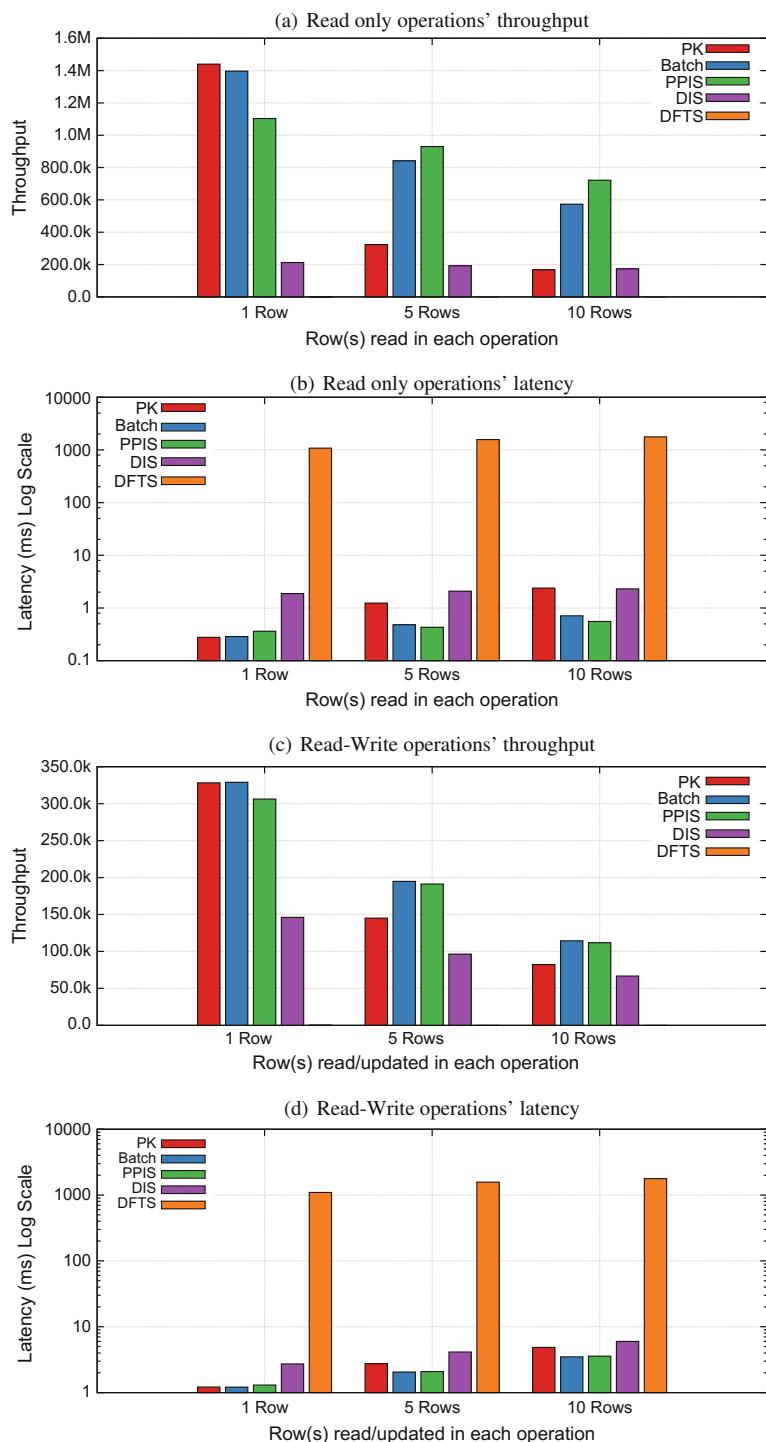

HopsFS Distributed Metadata

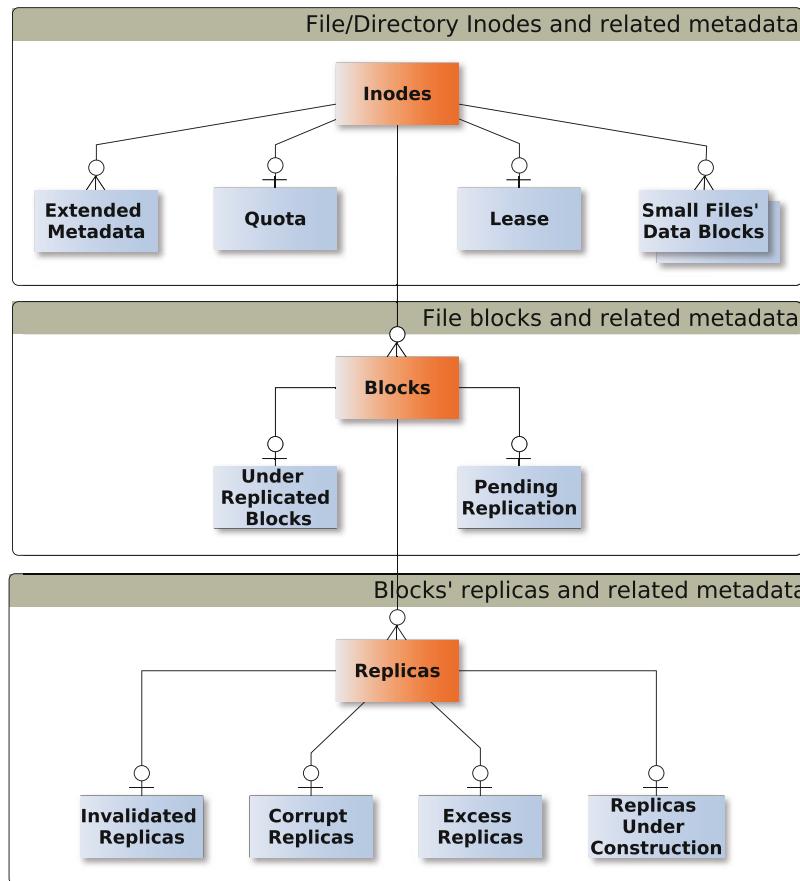

In HopsFS the metadata is stored in the database in normalized form, that is, instead of storing the full file paths with each inode as in Thomson and Abadi (2015), HopsFS stores individual file path components. Storing the normalized data in the database has many advantages, such as *rename* file system operation can be efficiently implemented by updating a single row in the database that represents the inode. If complete file paths are stored for each inode, then it would not only consume significant amount of precious database storage, but also, a simple directory rename operation would require updating the file paths for all the children of that directory subtree.

Key tables in HopsFS metadata schema are shown in the entity relational (ER) diagram in Fig. 5. The inodes for files and directories are stored in the *inodes* table. Each inode is represented by a single row in the table, which also

HopsFS: Scaling Hierarchical File System Metadata Using NewSQL Databases

HopsFS: Scaling Hierarchical File System Metadata Using NewSQL Databases, Fig. 5 Entity relational diagram for HopsFS schema

stores information such as inode ID, name, parent inode ID, permission attributes, user ID, and size. As HopsFS does not store complete file paths with each inode, the inode's parent ID is used to traverse the inodes table to discover the complete path of the inode. The extended metadata for the inodes is stored in the *extended metadata* entity. The *quota* table stores information about disk space consumed by the directories with quota restrictions enabled. When a client wants to update a file, then it obtains a lease on the file, and the file lease information is stored in the *lease* table. Small files that are few kilobytes in size are stored in the database for low-latency access. Such files are stored in the *small files' data blocks* tables.

Non-empty files may contain multiple blocks stored in the *blocks* table. The location of each replica of the block is stored in the *replicas* table. During its life cycle a block goes through various phases. Blocks may be under-replicated if a datanode fails, and such blocks are stored in the *under-replicated blocks* table. HopsFS periodically checks the health of all the data blocks. HopsFS ensures that the number of replicas of each block does not fall below the threshold required to provide high availability of the data. The replication monitor sends commands to datanodes to create more replicas of the under-replicated blocks. The blocks undergoing replication are stored in the *pending replication blocks* table. Similarly, a

replica of a block has various states during its life cycle. When a replica gets corrupted due to disk errors, it is moved to the *corrupted replicas* table. The replication monitor will create additional copies of the corrupt replicas by copying healthy replicas of the corresponding blocks, and the corrupt replicas are moved to *invalidated replicas* table for deletion. Similarly, when a file is deleted, the replicas of the blocks belonging to the file are moved to the *invalidated replicas* table. Periodically the namenodes read the invalidated replicas tables and send commands to the datanodes to permanently remove the replicas from the datanodes' disk. Whenever a client writes to a new block's replica, this replica is moved to the *replica under construction* table. If too many replicas of a block exist (e.g., due to recovery of a datanode that contains blocks that were re-replicated), the extra copies are stored in the *excess replicas* table.

Metadata Partitioning

The choice of partitioning scheme for the hierarchical namespace is a key design decision for distributed metadata architectures. HopsFS uses user-defined partitioning for all the tables stored in NDB. We base our partitioning scheme on the expected relative frequency of HDFS operations in production deployments and the cost of different database operations that can be used to implement the file system operations. Read-only metadata operations, such as *list*, *stat*, and *file read* operations, alone account for $\approx 95\%$ of the operations in Spotify's HDFS cluster (Niazi et al. 2017). Based on the micro benchmarks of different database operations, we have designed the metadata partitioning scheme such that frequent file system operations are implemented using the scalable database operations such as primary key, batched primary key operations, and partition-pruned index scan operations. Index scans and full table scans are avoided, where possible, as they touch all database partitions and scale poorly.

HopsFS partitions *inodes* by their *parents' inode IDs*, resulting in inodes with the same parent inode being stored on the same database partitions. That enables efficient implementation

of the directory listing operation. When listing files in a directory, we use a hinting mechanism to start the transaction on a transaction coordinator located on the database partitions that holds the child inodes for that directory. We can then use a pruned index scan to retrieve the contents of the directory locally. File inode-related metadata, that is, blocks and replicas and their states, is partitioned using the file's *inode ID*. This results in metadata for a given file all being stored in a single database partition, again enabling efficient file operations. Note that the file inode-related entities also contain the inode's foreign key (not shown in the entity relational diagram Fig. 5) that is also the partition key, enabling HopsFS to read the file inode-related metadata using partition-pruned index scans.

It is important that the partitioning scheme distribute the metadata evenly across all the database partitions. Uneven distribution of the metadata across all the database partitions leads to poor performance of the database. It is not uncommon for big data applications to create tens of millions of files in a single directory (Ren et al. 2013; Patil et al. 2007). HopsFS metadata partitioning scheme does not lead to hot spots as the database partition that contains the immediate children (files and directories) of a parent directory only stores the names and access attributes, while the inode-related metadata (such as blocks, replicas, and associated states) that comprises the majority of the metadata is spread across all the database partitions because it is partitioned by the inode IDs of the files. For hot files/directories, that is, file/directories that are frequently accessed by many of concurrent clients, the performance of the file system will be limited by the performance of the database partitions that hold the required data for the hot files/directories.

HopsFS Transactional Operations

File system operations in HopsFS are divided into two main categories, that is, non-recursive file system operations that operate on a single file or directory, also called **inode operations**, and recursive file system operations that operate

on directory subtrees which may contain large number of descendants, also called **subtree operations**. The file system operations are divided into these two categories because databases, for practical reasons, put a limit on the number of read and write operations that can be performed in a single database transaction, that is, a large file system operation may take a long time to complete and the database may timeout the transaction before the operation successfully completes. For example, creating a file, mkdir, or deleting file are *inode operations* that read and update limited amount of metadata in each transactional file system operation. However, recursive file system operations such as delete, move, chmod on large directories may read and update millions of rows. As subtree operations cannot be performed in a single database operation, HopsFS breaks the large file system operation into small transactions. Using application-controlled locking for the subtree operations, HopsFS ensures that the semantics and consistency of the file system operation remain the same as in HDFS.

Inode Hint Cache

In HopsFS all file system operations are path based, that is, all file system operations operate on file/directory paths. When a namenode receives a file system operation, it traverses the file path to ensure that the file path is valid and the client is authorized to perform the given file system operation. In order to recursively resolve the file path, HopsFS uses primary key operations to read each constituent inode one after the other. HopsFS partitions the inodes' table using the parent ID column, that is, the constituent inodes of the file path may reside on different database partitions. In production deployments, such as in case of Spotify, the average file system path length is 7, that is, on average it would take 7 round trips to the database to resolve the file path, which would increase the end-to-end latency of the file system operation. However, if the primary keys of all the constituent inodes for the path are known to the namenode in advance, then all the inodes can be read from the database in a single-batched primary key operation. For reading multiple rows batched primary key operations scale better than

iterative primary key operations and have lower end-to-end latency. Recent studies have shown that in production deployments, such as in Yahoo, the file system access patterns follow a heavy-tailed distribution, that is, only 3% of the files account for 80% of file system operations (Abad 2014); therefore, it is feasible for the namenodes to cache the primary keys of the recently accessed inodes. The namenodes store the primary keys of the inodes table in a local least recently used (LRU) cache called the inodes hints cache. We use the inode hint cache to resolve the frequently used file paths using single-batch query. The inodes cache does not require cache coherency mechanisms to keep the inode cache consistent across the namenodes because if the inodes hints cache contains invalid primary keys, then the batch operation would fail and then the namenode will fall back to recursively resolving the file path using primary key operations. After recursively reading the path components from the database, the namenodes also update the inode cache. Additionally, only the move operation changes the primary key of an inode. Move operations are very tiny fraction of the production file system workloads, such as at Spotify less than 2% of the file system operations are file move operations.

Inode Operations

Inode operations go through the following phases.

Pre-transaction Phase

- The namenode receives a file system operation from the client.
- The namenode checks the local inode cache, and if the file path components are found in the cache, then it creates a batch operation to read all file components.

Transactional File System Operation

- The inodes cache is also used to set the partition key hint for the transactional file system operation. The inode ID of the last valid path component is used as partition key hint.
- The transaction is enlisted on the desired NDB datanode according to the partition hint. If the

namenode is unable to determine the partition key hint from the inode cache, then the transaction is enlisted on a random NDB datanode.

- The batched primary key operation is sent to the database to read all the file path inodes. If the batched primary key operation fail due to invalid primary key(s), then the file path is recursively resolved. After resolving the file path components, the namenode also updates the inode cache for future operations.
- The last inode in the file path is read using appropriate lock, that is, read-only file system operation takes shared lock on the inode, while file system operations that need to update the inode take exclusive lock on the inode.
- Depending on the file system operation, some or all of the secondary metadata for the inode is read using partition-pruned index scan operations. The secondary metadata for an inode includes quota, extended metadata, leases, small files data blocks, blocks, replicas, etc., as shown in the entity relational diagram of the file system; see Fig. 5.
- After all the data has been read from the database, the metadata is stored in a per-transaction cache. The file system operation is performed, which reads and updates the data stored in the per-transaction cache. All the changes to the metadata are also stored in the per-transaction cache.
- After the file system operations successfully finish, all the metadata updates are sent to the database to persist the changes for later operations.
- If there are no errors, then the transaction is committed; otherwise the transaction is rolled back.

Post Transaction

- After the transactional file system operation finishes, the results are sent back to the client.
- Additionally, the namenode also updates its matrices about different statistics of the file system operations, such as frequency of different types of file system operations and duration of the operations.

Subtree Operations

Recursive file system operations that operate on large directories are too large to fit in a single database transaction, for example, it is not possible to delete hundreds of millions of files in a single database transaction. HopsFS uses subtree operations protocol to perform such large file system operations. The subtree operations protocol uses application-level locking to mark and isolate inodes. HopsFS subtree operations are designed in such a way that the consistency and operational semantics of the file system operations remain compatible with HDFS. The subtree operations execute in three phases as described below.

Phase 1 – Locking the Subtree: In the first phase, the directory is isolated using application-level locks. Using an inode operation, an exclusive lock is obtained for the directory, and the subtree lock flag is set for the inode. The subtree lock flag also contains other information, such as the ID of the namenode that holds the lock, the type of the file system operation, and the full path of the directory. The flag is an indication that all the descendants of the subtree are locked with exclusive (write) lock. It is important to note that during path resolution, inode and subtree operations that encounter an inode with a subtree lock turned on voluntarily abort the transaction and wait until the subtree lock is removed.

Phase 2 – Quiescing the Subtree: Before the subtree operation updates the descendants of the subtree, it is imperative to ensure that none of the descendants are being locked by any other concurrent subtree or inode operation. Setting the subtree lock before checking if any other descendant directory is also locked for a subtree operation can result in multiple active subtree operations on the same inodes, which will compromise the consistency of the namespace. We store all active subtree operations in a table and query it to ensure that no subtree operations are executing at lower levels of the subtree. In a typical workload, this table does not grow too large as subtree operations are usually only a tiny fraction of all file system operations. Additionally, we wait for all ongoing inode operations to complete by taking and releasing database write

locks on all inodes in the subtree in the same total order used to lock inode. This is repeated down the subtree to the leaves, and a tree data structure containing the inodes in the subtree is built in memory at the namenode. The tree is later used by some subtree operations, such as *move* and *delete* operations, to process the inodes. If the subtree operations protocol fails to quiesce the subtree due to concurrent file system operations on the subtree, it is retried with exponential backoff.

Phase 3 – Executing the FS Operation: Finally, after locking the subtree and ensuring that no other file system operation is operating on the same subtree, it is safe to perform the requested file system operation. In the last phase, the subtree operation is broken into smaller operations, which are run in parallel to reduce the latency of the subtree operation. For example, when deleting a large directory, starting from the leaves of the directory subtree, the contents of the directory is deleted in batches of multiple files.

Handling Failed Subtree Operation

As the locks for subtree operations are controlled by the application (i.e., the namenodes), therefore, it is important that the subtree locks are cleared when a namenode holding the subtree lock fails. HopsFS uses lazy approach for cleaning the subtree locks left by the failed namenodes. The subtree lock flag also contains information about the namenode that holds the subtree lock. Using the group membership service, the namenode maintains a list of all the active namenodes in the system. During the execution of the file system operations, when a namenode encounters an inode with a subtree lock flag set that does not belong to any live namenode, then the subtree operation flag is reset.

It is imperative that the failed subtree operations do not leave the file system metadata in an inconsistent state. For example, the deletion of the subtree progresses from the leaves to the root of the subtree. If the recursive delete operation fails, then the inodes of the partially deleted subtree remain connected to the namespace. When a subtree operation fails due to namenode failure,

then the client resubmits the operation to another alive namenode to complete the file system operation.

Storing Small Files in the Database

HopsFS supports two file storage layers, in contrast to the single file storage service in HDFS, that is, HopsFS can store data blocks on HopsFS datanodes as well as in the distributed database. Large files blocks are stored on the HopsFS datanodes, while small files (≤ 64 KB) are stored in the distributed database. The technique of storing the data blocks with the metadata is also called inode stuffing. In HopsFS, an average file requires 1.5 KB of metadata. As a rule of thumb, if the size of a file is less than the size of the metadata (in our case 1 KB or less), then the data block is stored in memory with the metadata. Other small files are stored in on-disk data tables. The latest solid-state drives (SSDs) are recommended for storing small files data blocks as typical workloads produce large number of random reads/writes on disk for small amounts of data.

Inode stuffing has two main advantages. First, it simplifies the file system operations protocol for reading/writing small files, that is, many network round trips between the client and datanodes are avoided, significantly reducing the expected latency for operations on small files. Second, it reduces the number of blocks that are stored on the datanode and reduces the block reporting traffic on the namenode. For example, when a client sends a request to the namenode to read a file, the namenode retrieves the file's metadata from the database. In case of a small file, the namenode also fetches the data block from the database. The namenode then returns the file's metadata along with the data block to the client. Compared to HDFS, this removes the additional step of establishing a validated, secure communication channel with the datanodes (Kerberos, TLS/SSL sockets, and a block token are all required for secure client-datanode communication), resulting in lower latencies for file read operations (Salman Niazi et al. 2017).

Extended Metadata

File systems provide basic attributes for files/directories such as name, size, modification time, etc. However, in many cases, users and administrators require the ability to tag files/directories with extended attributes for later use. Moreover, rich metadata has become an invaluable feature especially with the continuous growth of data volumes stored in scale-out file systems, such as HopsFS. As discussed earlier HopsFS store all the file system metadata in a database, where each file/directory (inode) is identified by a primary key. Therefore, creating an extended metadata table with a foreign key to the inodes table should be sufficient to ensure consistency and integrity of the metadata and the extended metadata.

HopsFS offers two modes to store extended metadata, that is, *schema-based* and *schemaless* extended metadata. In the schema-based approach, users have to create a predefined schema for their extended metadata, similar to information schema in database systems, and then associate their data according to that schema. The predefined schema enables validation of the extended metadata before attaching them to the inodes. On the other hand, in the schemaless approach, users don't have to create a predefined schema beforehand; instead, they can attach any arbitrary extended metadata that is stored in a self-contained manner such as a JSON file.

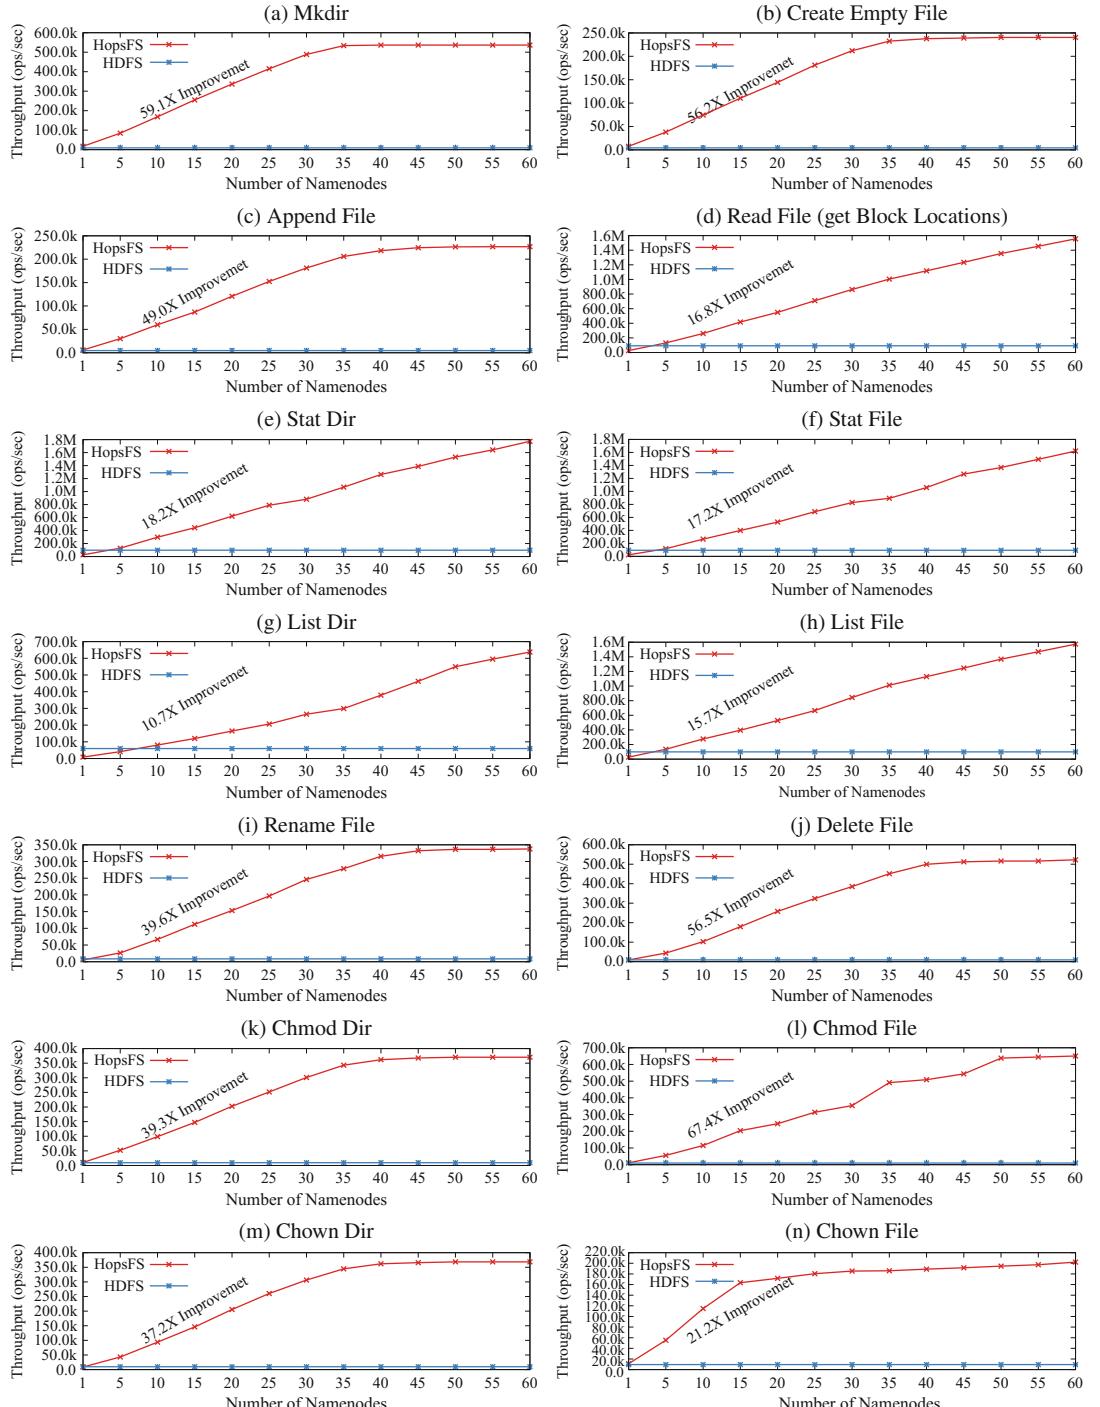

Using either approach schema-based or schemaless, users and administrators can tag their files/directories with extended metadata and then later query for the files/directories based on the tags provided. For example, users can tag files with a description field and later search for the files that match (or partially match) a given free-text query. Also, administrators could use the basic attributes, for example, file size to list all the big files in the cluster, or modification time to list all files that have not been modified within the last month. Depending on the queries pattern, it might be efficient for some queries to run directly on the metadata database, and for others especially the free-text queries, to run on a specialized free-text search engines. Also, the conventional wisdom in database community has been that

there is no-size-fits-all solution. This encourages the use of different storage engines according to the query pattern needed that is known as a polyglot persistence of the data. Therefore, the metadata of the namespace should be replicated into different engines to satisfy different query requirements such as free-text, point, range, and sophisticated join queries. We have developed a databus system, called *ePipe* (Ismail et al. 2017), that provides a strongly consistent replicated metadata service as an extension to HopsFS and that in real-time delivers file system metadata and extended metadata to different storage engines. Users and administrators can later query the different storage engines according to their query requirements.

Results

As HopsFS addresses how to scale out the metadata layer of HDFS, all our experiments are designed to comparatively test the performance and scalability of the namenode(s) in HDFS and HopsFS. Most of the available benchmarking utilities for Hadoop are MapReduce-based, primarily designed to determine the performance of a Hadoop cluster. These benchmarks are very sensitive to the MapReduce subsystem and therefore are not suitable for testing the performance and scalability of namenodes in isolation (Noll 2015). Inspired by the NNThroughputBenchmark for HDFS and the benchmark utility designed to test QFS (Ovsianikov et al. 2013), we developed a distributed benchmark that spawns tens of thousands of file system clients, distributed across many machines, which concurrently execute file system (metadata) operations on the namenode(s). The benchmark utility can test the performance of both individual file system operations and file system workloads based on industrial workload traces. The benchmark utility is open source (Hammer-Bench 2016) and the experiments described here can be fully reproduced on AWS using Karamel and the cluster definitions found in Hammer-Bench (2016).

We ran all the experiments on premise using Dell PowerEdge R730xd servers (Intel(R)

HopsFS: Scaling Hierarchical File System Metadata Using NewSQL Databases, Fig. 6 Throughput of different file system operations in HopsFS and HDFS. As HDFS only supports only one active namenode, the throughput for HDFS file system operations are represented by the

Xeon(R) CPU E5-2620 v3 @ 2.40 GHz, 256 GB RAM, 4 TB 7200 RPM HDDs) connected using a single 10 GbE network adapter. Unless stated otherwise, NDB, version 7.5.3, was deployed on 12 nodes configured to run using 22 threads each, and the data replication degree was 2. All other configuration parameters were set to default values. Moreover, in our experiments Apache HDFS, version 2.7.2, was deployed on 5 servers. We did not colocate the file system clients with the namenodes or with the database nodes. As we are only evaluating metadata performance, all the tests created files of zero length (similar to the NNThroughputBenchmark Shvachko 2010). Testing with non-empty files requires an order of magnitude more HDFS/HopsFS datanodes, and provides no further insight.

Figure 6 shows the throughput of different file system operations as a function of number of namenodes in the system. HDFS supports only one active namenode; therefore, the throughput of the file system is represented by (blue) horizontal line in the graphs. From the graphs it is quite clear that HopsFS outperforms HDFS for all file system operations and has significantly better performance than HDFS for the most common file system operations. For example, HopsFS improves the throughput of create file and read file operations by $56.2X$ and $16.8X$, respectively.

Additional experiments for industrial workloads, write intensive synthetic workloads, metadata scalability, and performance under failures are available in HopsFS papers (Niazi et al. 2017; Ismail et al. 2017).

Conclusions

In this entry, we introduced HopsFS, an open-source, highly available, drop-in alternative for HDFS that provides highly available metadata that scales out in both capacity and throughput by adding new namenodes and database nodes. We designed HopsFS file system operations to be deadlock-free by meeting the two preconditions for deadlock freedom: all operations follow the

same total order when taking locks, and locks are never upgraded. Our architecture supports a pluggable database storage engine, and other NewSQL databases could be used, providing they have good support for cross-partition transactions and techniques such as partition-pruned index scans. Most importantly, our architecture now opens up metadata in HDFS for tinkering: custom metadata only involves adding new tables and cleaner logic at the namenodes.

HTAP; Hybrid transactional and analytical processing; Operational analytics; Transactional analytics

Definitions

Hybrid transactional and analytical processing (HTAP) refers to system architectures and techniques that enable modern database management systems (DBMS) to perform real-time analytics on data that is ingested and modified in the transactional database engine. It is a term that was originally coined by Gartner where Pezzini et al. (2014) highlight the need of enterprises to close the gap between analytics and action for better business agility and trend awareness.

Overview

The goal of running transactions and analytics on the same data has been around for decades, but has not fully been realized due to technology limitations. Today, businesses can no longer afford to miss the real-time insights from data that is in their transactional system as they may lose competitive edge unless business decisions are made on *latest data* (Analytics on *latest data* implies allowing the query to run on any desired level of isolations including dirty read, committed read, snapshot read, repeatable read, or serializable.) or *fresh data* (Analytics on *fresh data* implies running queries on a recent snapshot of data that may not necessarily be the latest possible snapshot when the query execution began or a

consistent snapshot.). As a result, in recent years in both academia and industry, there has been an effort to address this problem by designing techniques that combine the transactional and analytical capabilities and integrate them in a single hybrid transactional and analytical processing (HTAP) system.

Online transaction processing (OLTP) systems are optimized for write-intensive workloads. OLTP systems employ data structures that are designed for high volume of point access queries with a goal to maximize throughput and minimize latency. Transactional DBMSs typically store data in a row format, relying on indexes and efficient mechanisms for concurrency control.

Online analytical processing (OLAP) systems are optimized for heavy read-only queries that touch large amounts of data. The data structures used are optimized for storing and accessing large volumes of data to be transferred between the storage layer (disk or memory) and the processing layer (e.g., CPUs, GPUs, FPGAs). Analytical DBMSs store data in column stores with fast scanning capability that is gradually eliminating the need for maintaining indexes. Furthermore to keep high performance and to avoid the overhead of concurrency, these systems only batch updates at predetermined intervals. This, however, limits the data freshness visible to analytical queries.

Therefore, given the distinct properties of transactional data and (stale) analytical data, most enterprises have opted for a solution that separates the management of transactional and analytical data. In such a setup, analytics is performed as part of a specialized decision support system (DSS) in isolated data warehouses. The DSS executes complex long running queries on data at rest and the updates from the transactional database are propagated via an expensive and slow extract-transform-load (ETL) process. The ETL process transforms data from transactional-friendly to analytics-friendly layout, indexes the data, and materializes selected pre-aggregations. Today's industry requirements are in conflict with such a design. Applications want to interface with fewer systems and try to avoid the burden of moving the transactional data with the expensive ETL process to the analytical

warehouse. Furthermore, systems try to reduce the amount of data replication and the cost that it brings. More importantly, enterprises want to improve data freshness and perform analytics on operational data. Ideally, systems should enable applications to immediately react on facts and trends learned by posing an analytical query within the same transactional request. In short, the choice of separating OLTP and OLAP is becoming obsolete in light of exponential increase in data volume and velocity and the necessity to enrich the enterprise to operate based on real-time insights.

In the rest of this entry, we discuss design decisions, key research findings, and open questions in the database community revolving around exciting and imminent HTAP challenges.

Key Research Findings

Among existing HTAP solutions, we differentiate between two main design paradigms: (1) operating on a single data representation (e.g., row or column store format) vs. multiple representations of data (e.g., both row and column store formats) and (2) operating on a single copy of data (i.e., single data replica) vs. maintaining multiple copies of data (through a variety of data replication techniques).

Examples of systems that operate on a single data representation are SAP HANA by Sikka et al. (2012), HyPer by Neumann et al. (2015), and L-Store by Sadoghi et al. (2016a,b, 2013, 2014). They provide a unified data representation and enable users to analyze the latest (not just fresh data) or any version of data. Here we must note that operating on a single data representation does not necessarily mean avoiding the need for data replication. For instance, the initial version of HyPer relied on a copy-on-write mechanism from the underlying operating system, while SAP HANA keeps the data in a main and a delta, which contains the most recent updates still not merged with the main. L-Store maintains the history of changes to the data (the delta) alongside the lazily maintained latest copy of data in a unified representation form.

Other systems follow the more classical approach of data warehousing, where multiple data representations are exploited, either within a single instance of the data or by dedicating a separate replica for different workloads. Example systems are SQL Server's column-store index proposed by Larson et al. (2015), Oracle's in-memory dual-format by Lahiri et al. (2015), SAP HANA SOE's architecture described by Goel et al. (2015), and the work on fractured mirrors by Ramamurthy et al. (2002), to name a few.

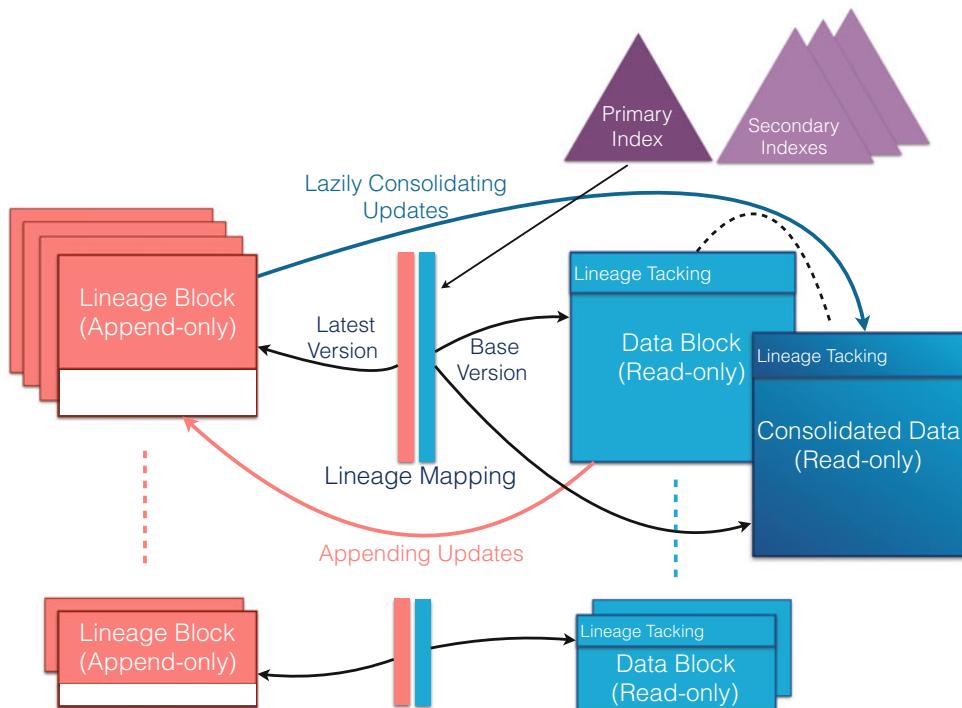

Unified Data Representation

The first main challenge for single data representation HTAP systems is choosing (or designing) a suitable data storage format for hybrid workloads. As noted earlier, there are many systems whose storage format was optimized to support efficient execution of a particular class of workloads. Two prominent example formats are row store (NSM) and column store (DSM), but researchers have also shown the benefit of alternative stores like *partition attribute across* (PAX) proposed by Ailamaki et al. (2001) that strike a balance between the two extremes. OLTP engines typically use a row-store format with highly tuned data structures (e.g., lock-free skip lists, latch-free BW trees), which provide low latencies and high throughput for operational workloads. OLAP engines have been repeatedly shown to perform better if data is stored in column stores. Column stores provide better support for data compression and are more optimized for in-memory processing of large volumes of data. Thus, the primary focus was on developing new storage layouts that can efficiently support both OLTP and OLAP workloads.

The main challenge is the conflict in the properties of data structures suitable to handle large volume of update-heavy requests on the one hand and fast data scans on the other hand. Researchers have explored where to put the updates (whether to apply them in-place, append them in a log-structured format, or store them in a delta and periodically merge them with the main), how to best arrange the records (row-store, column-store, or a PAX format), and how to handle multiple versions and when to do garbage collection.

Sadoghi et al. (2016a,b, 2013, 2014) proposed L-Store (lineage-based data store) that combines the real-time processing of transactional and analytical workloads within a single unified engine. L-Store bridges the gap between managing the data that is being updated at a high velocity and analyzing a large volume of data by introducing a novel update-friendly lineage-based storage architecture (LSA). This is achieved by developing a contention-free and lazy staging of data from write-optimized into read-optimized form in a transactionally consistent manner without the need to replicate data, to maintain multiple representation of data, or to develop multiple loosely integrated engines that limit real-time capabilities.

The basic design of LSA consists of two core ideas, as captured in Fig. 1. First, the base data is kept in read-only blocks, where a block is an ordered set of objects of any type. The modification to the *data blocks* (also referred to as *base pages*) is accumulated in the corresponding *lineage blocks* (also referred to as *tail pages*). Second, a lineage mapping links an object in the data blocks to its recent updates in a lineage block. This essentially decouples the updates from the physical location of objects. Therefore, via the lineage mapping, both the base and updated data are retrievable. A lazy, contention-free background process merges the recent updates with their corresponding read-only base data in order to construct new consolidated data blocks while data is continuously being updated in the foreground without any interruption. The merge is necessary to ensure optimal performance for the analytical queries. Furthermore, each data block internally maintains the lineage of the updates consolidated thus far. By exploiting the decoupling and lineage tracking, the merge process, which only creates a new set of read-only consolidated data blocks, is carried out completely independently from update queries, which only append changes to lineage blocks and update the lineage mapping. Hence, there is no contention in the write paths of update queries and the merge process. That is a fundamental property necessary to build a highly scalable distributed storage layer that is updatable.

Hybrid OLTP and OLAP, Fig. 1 Lineage-based storage architecture (LSA)

Neumann et al. (2015) proposed a novel MVCC implementation, which does update in place and store prior versions as before-image deltas, which enable both an efficient scan execution and fine-grained serializability validation needed for fast processing of point access transactions. From the NoSQL side, Pilman et al. (2017) demonstrated how scans can be efficiently implemented on a key-value store (KV store) enabling more complex analytics to be done on large and distributed KV stores. Wildfire from IBM by Barber et al. (2016, 2017) uses Apache Parquet to support both analytical and transactional requests. IBM Wildfire is a variant of IBM DB2 BLU that is integrated into Apache Spark to support fast ingest of updates. The authors adopt the relaxed last-writer-wins semantics and offer an efficient snapshot isolation on recent view of data (but stale) by relying on periodic shipment and writing of the logs onto a distributed file system.

Manifold of Data Representations

An alternative approach comes from systems that propose using hybrid stores to keep the data in two or more layouts, either by partitioning the data based on the workload properties or by doing partial replication. They exploit manifold specialization techniques that are aligned with the tenet “one size does not fit all” as explained by Stonebraker and Cetintemel (2005). Typically the hybrid mode consists of storing data in row and column formats by collocating attributes that are accessed together within a query. The main differentiators among the proposed solutions come by addressing the following challenges: How does a system determine which data to store in which layout – is it specified manually by the DB administrator, or is it derived by the system itself? Is the data layout format static or can it change over time? If the latter, which data is affected by the transformations – is it the hot or cold data? Does the system support update propagation or

is the data transformation only recommended for read-only data? If the former, when does the data transformation take place – is it incremental or immediate? Does it happen as part of query execution or is it done as part of a background process?

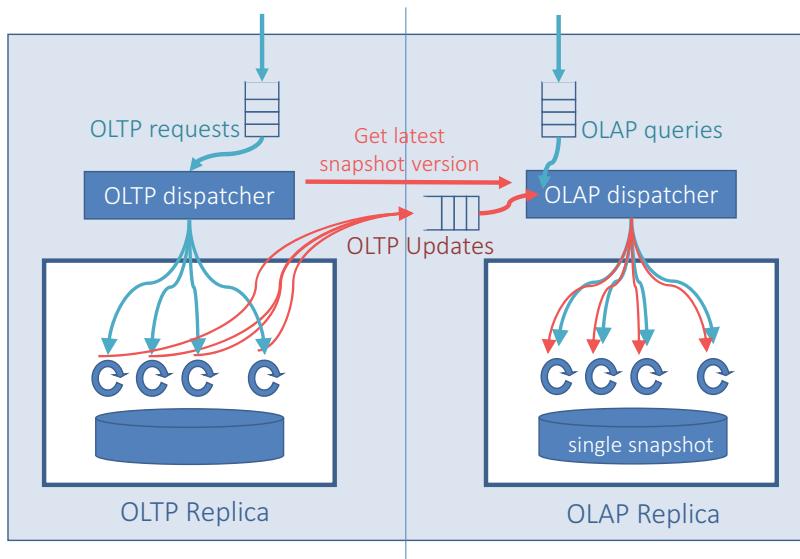

Grund et al. (2010) with their HYRISE system propose the use of the *partially decomposed* storage model and automatically partition tables into vertical partitions of varying depth, depending on how the columns are accessed. Unfortunately, the bandwidth savings achieved with this storage model come with an increased CPU cost. A follow-up work by Pirk et al. (2013) improves the performance by combining the partially decomposed storage model with just-in-time (JiT) compilation of queries, which eliminates the CPU-inefficient function calls. Based on the work in HYRISE, Plattner (2009) in SAP developed HANA, where tuples start out in a row-store and are then migrated to a compressed column-store storage manager. Similarly, also MemSQL, Microsoft's SQL Server, and Oracle support the two storage formats. One of the main differentiators among these systems is who decides on the partitioned layout: i.e., whether the administrator manually specifies which relations and attributes should be stored as a column store or the system derives it automatically. The latter can be achieved by monitoring and identifying hot vs. cold data or which attributes are accessed together in OLAP queries. There are a few research systems that have demonstrated the benefits of using adaptive data stores that can transform the data from one format to another with an evolving HTAP workload. Dittrich and Jindal (2011) show how to maintain multiple copies of the data in different layouts and use a logical log as a primary storage structure before creating a secondary physical representation from the log entries. In H2O, Alagiannis et al. (2014) maintain the same data in different storage formats and improve performance of the read-only workload by leveraging multiple processing engines. The work by Arulraj et al. (2016) performs data reorganization on cold data. The

reorganization is done as part of an incremental background process that does not impact the latency-sensitive transactions but improves the performance of the analytical queries.

Data Replication

Operating on a single data replica may come at a cost due to an identified trade-off between degree of data freshness, system performance, and predictability of throughput and response time for a hybrid workload mix. Thus, the challenges for handling HTAP go beyond the layout in which the data is stored. A recent study by Psaroudakis et al. (2014) shows that systems like SAP HANA and HyPer, which rely on partial replication, experience interference problems between the transactional and analytical workloads. The observed performance degradation is attributed to both resource sharing (physical cores and shared CPU caches) and synchronization overhead when querying and/or updating the latest data.

This observation motivated researchers to revisit the benefits of data replication and address the open challenge of efficient update propagation. One of the first approaches for addressing hybrid workloads was introduced by Ramamurthy et al. (2002), where the authors proposed replicating the data and storing it in two data formats (row and columnar). The key advantage is that the data layouts and the associated data structures as well as the data processing techniques can be tailored to the requirements of the particular workload. Additionally, the system can make efficient use of the available hardware resources and their specialization. This is often viewed as a loose-form of an HTAP system. The main challenge for this approach is maintaining the OLAP replica up to date and avoiding the expensive ETL process. BatchDB by Makreshanski et al. (2017) relies on primary-secondary form of replication with the primary replica handling the OLTP workload and the updates being propagated to a secondary replica that handles the OLAP workload (Fig. 2). BatchDB successfully addresses the problem of performance interference by spatially partitioning resources to the

Hybrid OLTP and OLAP, Fig. 2 Replication-based HTAP architecture

two data replicas and their execution engines (e.g., either by allocating a dedicated machine and connecting the replicas with RDMA over InfiniBand or by allocating separate NUMA nodes within a multi-socket server machine). The system supports high-performance analytical query processing on fresh data with snapshot isolation guarantees. It achieves that by queuing queries and updates on the OLAP side and scheduling them in batches, executing one batch at a time. BatchDB ensures that the OLAP queries see the latest snapshot of the data by using a lightweight propagation algorithm, which incurs a small overhead on the transactional engine to extract the updates and efficiently applies them on the analytical side at a faster rate than what has been recorded as a transactional throughput in literature so far. Such a system design solves the problem of high performance and isolation for hybrid workloads, and most importantly enables data analytics on fresh data. The main problem is that it limits the functionality of what an HTAP application may do with the data. For instance, it does not support interleaving of analytical queries within a transaction and does not allow analysts to go back in time and explore prior versions of the data to explain certain trends.

Oracle GoldenGate and SAP HANA SOE also leverage data replication and rely on specialized

data processing engines for the different replicas. In GoldenGate, Oracle uses a publish/subscribe mechanism and propagates the updates from the operational database to the other replicas if they have subscribed to receive the updates log.

Examples of Applications

There are many possible applications of HTAP for modern businesses. With today's dynamic data-driven world, real-time advanced analytics (e.g., planning, forecasting, and what-if analysis) becomes an integral part of many business processes rather than a separate activity after the events have happened. One example is online retail. The transactional engine keeps track of data including the inventory list and products and the registered customers and manages all the purchases. An analyst can use this online data to understand customer behavior and come up with better strategies for product placement, optimized pricing, discounts, and personalized recommendations as well as to identify products which are in high demand and do proactive inventory refill. Another business use for HTAP comes from the financial industry sector. The transactional engine already supports millions of banking transactions per second and real-time fraud detection and action which can save billions of dollars. Yet

another example of real-time detection and action is inspired by content delivery networks (CDNs), where businesses need to monitor the network of web servers that deliver and distribute the content at real time. An HTAP system can help identify distributed denial-of-service (DDoS) attacks, find locations with spikes to redistribute the traffic bandwidth, get the top- k customers in terms of traffic usage, and be able to act on it immediately.

Future Directions of Research

At the time of writing this manuscript, we argue that there is yet any system or technique that fulfill all HTAP promises to successfully interleave analytical processing within transactions. This is sometimes referred to as *true* or *in-process* HTAP, i.e., real-time analytics that is not limited to latest committed data and posed as a read-only request but incorporates the analytics as part of the same write-enabled transaction request. Supporting *in-process* HTAP is an ongoing effort in the research community and much sought-after feature for many enterprise systems.

Another open question is to investigate whether HTAP systems could and should support different types of analytical processing in addition to traditional OLAP analytics, e.g., the emergence of polystore by Duggan et al. (2015). Training and inferring from machine learning models that describe fraudulent user behavior could supplement the existing knowledge of OLAP analytics. Furthermore, with the support of graph processing, one can finally uncover fraudulent rings and other sophisticated scams that can be best identified using graph analytics queries. Therefore, it would be of great use if the graph analytical engine can process online data and be integrated in a richer and more expressive HTAP system (e.g., Hassan et al. 2017).

Finally, there is the question on how hardware heterogeneity could impact the design of HTAP systems. With the end of Moore's Law, the hardware landscape has been shifting towards specialization of computational units (e.g., GPUs, Xeon Phi, FPGAs, near-memory computing, TPUs) (Najafi et al. 2017, 2015; Teubner and Woods 2013). Hardware has always been

an important game changer for databases, and as in-memory processing enabled much of the technology for approaching true HTAP, there is discussion that the coming computing heterogeneity is going to significantly influence the design of future systems as highlighted by Appuswamy et al. (2017).

- ## Hybrid Systems Based on Traditional Database Extensions
- Yuanyuan Tian
IBM Research – Almaden, San Jose, CA, USA
- ### Synonyms
- Hadoop EDW Integration; Hybrid DBM-S-Hadoop Solution; Hybrid Data Warehouse; Hybrid Warehouse
- ### Definitions
- A hybrid system based on traditional database extensions refers to a federated system between Hadoop and an enterprise data warehouse (EDW). In such a system, a query may need to combine data stored in both Hadoop and an EDW.
- ### Overview
- The co-existence of Hadoop and enterprise data warehouses (EDWs), together with the new application requirement of correlating data stored in both systems, has created the need for a special federation between Hadoop-like big data platforms and EDWs. This entry presents the motivation behind such hybrid systems, highlights the unique challenges of building them, surveys existing hybrid solutions, and finally discusses potential future directions.

Introduction

More and more enterprises today start to embrace Hadoop-like big data technologies to process huge volumes of data and drive actionable insights. The Hadoop Distributed File System (HDFS) has become the core storage system for enterprise data, including enterprise application data, social media data, log data, click stream data, and other Internet data. Systems that support SQL queries over data stored on HDFS, dubbed as *SQL-on-Hadoop* systems, have emerged over the years, including Hive (Thusoo et al. 2009), Spark SQL (Armbrust et al. 2015), IBM Big SQL (Gray et al. 2015), and Impala (Kornacker et al. 2015).

At the same time, enterprise data warehouses (EDWs) continue to support critical business analytics. EDWs are usually massively parallel processing (MPP) databases that support complex SQL processing, updates, and transactions (EDW and database are used interchangeably in this entry). As a result, they manage up-to-date data and support various business analytics tools, such as reporting and dashboards.

Many new applications have emerged, requiring combining the large volumes of semi-structured and structured, somewhat raw big data, with the well ETLed warehouse data. An example scenario is presented below to illustrate the real application needs.

An Example Application Consider a retailer, such as Walmart or Target, who sells products in local stores as well as online. All the transactions, either offline or online, are managed and stored in a parallel database, whereas users' online click logs are captured and stored in a SQL-on-Hadoop system. The retailer wants to analyze the correlation of customers' online behaviors with sales data. This requires joining the transaction table T in the parallel database with the log table L in the Hadoop. One such analysis can be expressed as the following SQL query.

```
SELECT L.urlPrefix, COUNT(*)
FROM T, L
WHERE T.category = 'Canon Camera'
AND region(L.ip) = 'East Coast'
AND T.uid = L.uid
```

**AND T.tDate >= L.lDate AND T.tDate <= L.lDate + 1
GROUP BY L.urlPrefix**

This query tries to find out the number of views of the URLs visited by customers with IP addresses from the East Coast who bought Canon cameras within 1 day of their online visits.

Applications like the above example, together with the coexistence of Hadoop and EDWs, have created the need for a new generation of special federation between Hadoop and EDWs. The big data industry has used different terms to refer to this special federation, such as "Hadoop EDW integration" (Shankar 2015), "hybrid DBMS-Hadoop solution" (Portnoy 2013), "hybrid data warehouse" (Hortonworks 2015), or simply "hybrid warehouse" (Tian et al. 2015, 2016). This entry chooses to use the term "hybrid warehouse" to refer to this special federation.

The need for interacting with Hadoop has prompted many EDW vendors like Oracle, IBM, Teradata, and Microsoft to develop their hybrid warehouse solutions. Most of them start from their existing relational databases and augment them with the abilities to interoperate with Hadoop. This entry will focus on these hybrid warehouse solutions based on traditional database extensions.

H

Challenges

Before surveying the hybrid warehouse solutions, it is very important to highlight the unique challenges of the hybrid warehouse:

- Although SQL processing capability on Hadoop data has been provided by many SQL-on-Hadoop systems, a full-pledged relational database (EDW) and a SQL-on-Hadoop query processor have very different characteristics. First, the database owns its data, hence controls the partitioning and data organization. This is not true for a SQL-on-Hadoop query processor, which works with existing files on a HDFS. They do not dictate the physical layout of data, because it is simply prohibitive to convert petabytes of data on HDFS to a proprietary format before

processing. This is fundamentally different from databases. Second, a database can have indexes, but a SQL-on-Hadoop processor cannot exploit the same record-level indexes. Because they do not control the data; data can be inserted outside the query processor's control. In addition, HDFS does not provide the same level of performance for small reads as a local file system, as it was mainly designed for large scans. Finally, HDFS does not support update in place; as a result, SQL-on-Hadoop systems are mostly used for processing data that are not or infrequently updated. Although the latest version of Hive has added the transaction support, it is done through deltas, thus more appropriate for batch updates. These differences between the two systems make this problem both hybrid and asymmetric.

- There are also differences in terms of capacity and cluster setup. While EDWs are typically deployed on high-end hardware, Hadoop (or a SQL-on-Hadoop system) is deployed on commodity servers. A Hadoop cluster typically has a much larger scale (up to 10,000s machines), hence has more storage and computational capacity than an EDW. In fact, today more and more enterprise investment has shifted from EDWs to Hadoop.
- Finally, the hybrid warehouse is also not a typical federation between two databases. Existing federation solutions (Josifovski et al. 2002; Adali et al. 1996; Shan et al. 1995; Tomasic et al. 1998; Papakonstantinou et al. 1995) use a client-server model to access the remote databases and move the data. In par-

ticular, they use JDBC/ODBC interfaces for pushing down a maximal sub-query and retrieving its results. Such a solution ingests the result data serially through the single JDBC/ODBC connection and hence is only feasible for small amounts of data. In the hybrid warehouse case, a new solution that connects at a lower system layer is needed to exploit the massive parallelism on both the Hadoop side and the EDW side and move data between the two in parallel. This requires nontrivial coordination and communication between the two systems.

Table 1 summarizes the differences between an EDW and Hadoop, hence highlights the challenges of hybrid warehouse solutions.

Hybrid Warehouse Solutions Based on Database Extensions

As Hadoop ecosystem and related big-data technologies mature, the hybrid warehouse solutions have also evolved through several iterations.

Parallel Movement of Data in Bulk

The first iteration of hybrid warehouse solutions came right after EDW vendors realized that Hadoop is a major disruption to traditional EDWs. Both EDW and Hadoop vendors started to allow data to be moved between EDWs and Hadoop efficiently, and to improve performance most solutions leverage the massive parallelism in Hadoop and EDWs to transfer data in parallel. [Sqoop](#) is such a general tool from

Hybrid Systems Based on Traditional Database Extensions, Table 1 Differences between EDWs and Hadoop

	EDW	Hadoop
Data ownership	Own its data	Work with existing files on shared storage
	Control data organization and partitioning	Cannot dictate data layout
Index support	Build and exploit index	Scan-based only, no index support
Update	Efficient record-level updates	Good for batch updates
	High-end servers	Commodity machines
Capacity	Smaller cluster size	Larger cluster size (up to 10,000 s nodes)

the Hadoop camp that imports database tables onto HDFS in different formats and exports data in HDFS directories as database tables. Many EDW vendors have also provided their own version of “Hadoop connectors.” Özcan et al. (2011) introduced a utility to bulk-load HDFS data to IBM Db2. Teradata Connector for Hadoop (Teradata 2013) supports bi-directional bulk load between Teradata systems and Hadoop ecosystem components, such as HDFS and Hive. HP Vertica Connector for HDFS (Vertica 2016) allows bulk-loading HDFS data into HP Vertica. Oracle Loader for Hadoop (Oracle 2012) bulk-loads data from Hadoop to Oracle Database.

Batch movement of data between EDWs and Hadoop has several limitations. On one hand, with this approach, one data set resides in two places, thus maintaining it requires extra care. In particular, HDFS still does not have a good solution to do update in place, whereas warehouses always have up-to-date data. As a result, an application needs to reload EDW data to Hadoop frequently to keep the data fresh. On the other hand, HDFS tables are usually pretty big, so it is not always feasible to load them into the database. Such bulk reading of HDFS data into the database introduces an unnecessary burden on the carefully managed database resources.

EDWs Directly Reading HDFS Data

To avoid data replication, the second wave of hybrid warehouse solutions keep data where they are and allow EDWs to directly read HDFS data through external tables or table functions. For example, HP Vertica Connector for HDFS (Vertica 2016), besides the bulk-loading approach described in the previous subsection, also supports exposing the HDFS data as external tables to query from. Özcan et al. (2011) proposed a table function called HDFSRead to load HDFS data at runtime to IBM Db2 and a new DB2InputFormat to ingest data from Db2 to Hadoop. Oracle Direct Connector for HDFS (Oracle 2012) directly accesses data on HDFS as external tables from Oracle Database.

In this second iteration of hybrid solutions, the EDWs treat HDFS as an extended storage and pull data when needed from HDFS. However, the query processing is performed only inside the database. This is probably due to the fact that in the early days, people mostly viewed Hadoop as a good option for cheap storage and the processing support on Hadoop was still limited (MapReduce was not easy to program against). But as the first SQL-on-Hadoop system – Hive, as well as other systems exposing high-level language abstraction on top of MapReduce, such as Pig (Olston et al. 2008) and Jaql (Beyer et al. 2011), started to emerge, data processing on Hadoop became easier and more powerful.

H

Query Pushdown to Hadoop

Although the second wave of hybrid solutions do not require data replication, they still load an entire data set at runtime into the database for processing, even though only a small fraction of the data may be needed (e.g., through filter and projection). The processing burden on databases is still very high. Riding on the SQL-on-Hadoop boom, the third wave of hybrid warehouse solutions start to offload some data processing to the Hadoop side, by pushing mostly filters and projections down to Hadoop. Oracle Big Data SQL (McClary 2014) allows Oracle Exadata to query remote data on Hadoop via external tables. But, different from the external table approach in Oracle Direct Connector for HDFS, Oracle Big Data SQL is able to push down filter and projection to the Hadoop side by employing *smart scans* on Hadoop data. Teradata QueryGrid (Teradata 2016) provides a unified data architecture to query data in Teradata and Aster databases as well as other data sources. In particular, it enables a Teradata or Aster databases to call up Hive to query data on Hadoop and bring the results back to Teradata or Aster to join with other tables. Microsoft Polybase (DeWitt et al. 2013) also exposes HDFS data as external tables in SQL Server PDW and pushes filter and projection down to the Hadoop side. In addition, it also considers pushing down joins if both tables are stored in HDFS.

In all these systems, however, a join between an HDFS table and an EDW table is always executed inside the EDW. This is probably due to the assumption that SQL-on-Hadoop systems do not perform joins efficiently. Although this was true for the early SQL-on-Hadoop solutions, such as Hive (Thusoo et al. 2009) before version 0.13, it is not clear whether the same still holds for the current-generation solutions such as IBM Big SQL (Gray et al. 2015), Impala (Kornacker et al. 2015), and Presto (Traverso 2013). There has been a significant shift during the last few years in the SQL-on-Hadoop solution space, in which many new systems have moved away from MapReduce to have shared-nothing parallel database architectures. They run SQL queries using their own long-running daemons executing on every HDFS DataNode. Instead of materializing intermediate results, these systems pipeline them between computation stages. Many new SQL-on-Hadoop systems also employ columnar store technologies, vector-wise processing, and even runtime code generation for better query performance.

Moreover, HDFS tables are usually much bigger than database tables, so it is not always feasible to ingest HDFS data and perform joins in the database. Another important observation is that enterprises are investing more on big data systems such as Hadoop and less on expensive EDW systems. As a result, there is more capacity on the Hadoop side to leverage.

Collaborative Query Processing

Finally, with the advancement in the SQL-on-Hadoop land, it is possible to have EDWs and Hadoop to collaboratively process a query, even including executing a join together.

Tian et al. (2015) studied a number of distributed join algorithms for joining a HDFS table with an EDW table in the context of a hybrid warehouse. Besides algorithms that execute joins inside EDW, this work particularly explores algorithms that conduct the join on the Hadoop side, including a novel join algorithm called *zigzag* join, which heavily exploits the use of Bloom

filter (Bloom 1970) on both sides to minimize the data movement in join processing. Through extensive experimental study, Tian et al. (2015) concluded that with a sophisticated SQL execution engine on the Hadoop side, which most of the new-generation SQL-on-Hadoop systems qualify, it is better to move the smaller table to the side of the bigger table (after filter and projection are applied on the tables), whether it is in HDFS or in the EDW. Moreover, Bloom filter is very effective in reducing data movement in a hybrid warehouse setting, and it can even be applied on both sides in one join algorithm. In a follow-up work, Tian et al. (2016) proposed a cost model of various join algorithms for a future optimizer in the hybrid warehouse environment to choose the right algorithms.

Conclusion and Future Directions

Hadoop has become an important data repository in the enterprise as the center for all business analytics, from SQL queries to machine learning, to reporting. At the same time, EDWs continue to support critical business analytics. EDWs will coexist with Hadoop. That is why there is a strong need to have hybrid warehouse solutions. The hybrid warehouse is different from the traditional data federation. It requires exploiting massive parallelism between two sides for efficient data movement, and better collaborative query processing to minimize data that needs to be moved, especially given the powerful SQL processing capabilities on Hadoop in the recent years. With more and more enterprise investment on the Hadoop side, it is wise to better utilize the resource of the Hadoop side to do more of the processing.

In the future, EDWs and Hadoop will continue to coexist and evolve on their own, and the need for hybrid warehouse solutions will continue to grow. We need an even tighter integration between the two systems, in which an automated optimizer can decide where to store data and where the data processing is carried out, without the users even knowing (Portnoy 2013).

Overview

Apache Impala is a modern MPP SQL engine architected specifically for the Hadoop data processing environment. Impala provides low latency and high concurrency for business intelligence/analytic workloads, which are not served well by batch-oriented processing frameworks such as MapReduce or Spark. Unlike traditional commercial analytic DBMSs, Impala is not a monolithic system but instead relies on the functionality of common, shared components of the Hadoop ecosystem to provide RDBMS-like functionality. In particular, Impala utilizes Hive's Metastore as a system catalog, which it shares with other processing frameworks such as Hive and Spark. In addition, Impala does not provide persistence functionality itself; instead, it relies on storage management components of the Hadoop ecosystem (e.g., HDFS, Kudu), which it drives via their public APIs. These storage management components in effect implement the record service layer of a traditional RDBMS and define the degree to which Impala can support traditional update capabilities and transactional semantics. As an example, HDFS

provides append-only file system functionality, which Impala can take advantage of to provide bulk insert functionality. However, single-row insertions have poor performance, and updates are not supported at all. In contrast, an online record-oriented storage manager such as Kudu supports both single-row inserts and updates (and deletes), which allows Impala to support the standard SQL functionality for inserts and updates.

This chapter presents Impala from a user's perspective and gives an overview and motivation of its architecture and main components.

Introduction

Impala is an open-source, state-of-the-art MPP SQL query engine designed specifically to leverage the flexibility and scalability of the Hadoop ecosystem. Impala's goal is to provide the familiar SQL support and multiuser performance of a traditional analytic DBMS, but to do so in an environment that also supports multiple, non-SQL data processing frameworks (e.g., MapReduce (Dean and Ghemawat 2004), Spark (Zahari et al. 2010)) and to that end utilizes standardized, open file formats and data access APIs. Impala's development started in 2011 and its initial version was released in May of 2013. Impala has been an open-source project since its beta release, and it became a top-level Apache project in November of 2017.

Unlike other popular MPP analytic DBMSs, several of which are forks of Postgres, Impala was written from scratch in C++ and Java. It maintains Hadoop's flexibility with regard to the choice of processing frameworks by utilizing standard components (HDFS <http://hadoop.apache.org/>, Kudu <https://kudu.apache.org/>, Hive Metastore <https://hive.apache.org/>, Sentry <https://sentry.apache.org/>, etc.) and is able to read the majority of the file formats that are popular with Hadoop users (e.g., text, Parquet <https://parquet.apache.org/>, Avro <https://avro.apache.org/>, etc.). Impala implements principles pioneered for traditional parallel DBMSs, such as data-partitioned parallelism and pipelining, and runs on a collection of daemon processes that are responsible for all aspects of query execution and that run on the same machines as the rest of the Hadoop infrastructure.

User View of Impala

Impala is a query engine which is integrated into the Hadoop environment and relies on a number of standard Hadoop infrastructure components to deliver an RDBMS-like experience. The standardized file formats and component APIs that are part of Hadoop allow Impala to offer very broad SQL analytic functionality against a wide variety of data formats as well as storage options. The latter include on-premises storage as well as cloud object storage such as AWS S3 and Azure Data Lake Store.

However, due to the looser coupling between the query engine and the storage managers, there are some notable differences in the areas of supported SQL update functionality and transactional semantics. In both cases, Impala surfaces the functionality made available by the storage managers themselves but does not try to augment it to bring it up to a uniform functional standard.

Another aspect in which Impala differs from a monolithic analytic DBMS is the approach to physical schema design. Physical schema design allows the user to optimize the physical layout of the table data to match the require-

ments of the analytic workload and is therefore an important aspect of performance optimization. Since Impala does not manage physical data itself, the functionality related to physical schema design that is surfaced in Impala also depends on what is supported by the storage managers.

Impala was targeted at standard business intelligence environments and to that end supports most relevant industry standards: clients connect via ODBC or JDBC, authentication is handled via Kerberos or LDAP, and authorization functionality (supplied via Sentry) follows the standard SQL roles and privileges.

In order to query data that resides in one of the supported Hadoop storage managers, the user creates tables via the familiar CREATE TABLE statement. This provides the logical schema of the data as well as the storage manager-specific parameters needed for Impala to access the underlying physical data. Subsequently the user can then reference that table in a SELECT statement, with the familiar relational semantics and operations (joins, grouping, etc.). In particular, a single SELECT statement can reference multiple tables, regardless of their underlying storage managers, making it possible to join on-premises HDFS data with S3-resident data, etc.

Complex Types Support

Data ingested into Hadoop often arrives in a non-relational form because the source system is not relational or because the data is hierarchical and more naturally produced in a de-normalized fashion. Preserving the original structure of the data eliminates the need to flatten and remodel the data before querying it and alleviates the cognitive burden for users who are used to the existing structure. To this end, Impala supports querying tables with the complex types *array*, *map*, and *struct*, which are familiar from Hive and supported in the shared Hive metastore. At present, this functionality is only available for the Parquet file format but in principle can be supported for any nested relational file format, including JSON, Avro, etc. Parquet stores nested data using a

Dremel-style shredding (Melnik et al. 2010) that enables the full benefits of a columnar format for arbitrarily nested data.

Impala enhances its SQL syntax to query complex types in a concise and user-friendly way. The new syntax was designed to be a natural extension of SQL and provide the full functionality of SQL on complex types. The main ideas are summarized as follows:

- Nested fields are accessed with a familiar “dot” notation, e.g., `tbl.col.nested1.nested2`.
- The collection types *map* and *array* must be referenced in the `FROM` clause just like conventional tables. This flattens the nested collection via an implicit parent-child join and exposes the nested fields as columns that are accessible as usual via dot-path expressions.
- Collections can be referenced through absolute paths (`FROM tbl.nested_collection`) or relative paths (`FROM tbl t, t.nested_collection`). The former exposes the fields in “`nested_collection`” but not those in the parent “`tbl`,” while the latter exposes both the parent and child. Subqueries (including inline views) may use correlated relative paths in the `FROM` clause that reference maps/arrays from enclosing blocks. This allows a SQL-in-SQL pattern where the data in nested collections can be filtered/joined/aggregated with the full expressiveness of SQL.

The following query from (Behm 2015) illustrates the syntax extensions. It lists all customers that have at least five orders that were placed on a date where the customer also had at least one support call and web interaction.

```
SELECT cid, name, cnt
FROM customers c,
     (SELECT COUNT(oid) cnt
      FROM c.orders o
     WHERE order_date IN (SELECT visit_date
                           FROM c.web_visits)
       AND order_date IN (SELECT call_date
                           FROM c.support_calls))
HAVING cnt >= 5) v
```

Impala + HDFS

HDFS is the most widely used system for storing data in Hadoop and offers the highest performance for read-oriented workloads. It provides a file system API with append-only semantics and gives the user a choice of multiple file formats. As a consequence, for HDFS-resident data, Impala supports the SQL `SELECT` and `INSERT` statements; the latter writes at least one new file per statement and is therefore only recommended for bulk data insertion. The SQL `UPDATE` and `DELETE` statements are not supported.

When creating a table in HDFS, the user specifies the root storage location of the physical data as well as the file format, and possibly a list of partition columns, as in:

```
CREATE TABLE T (...)
PARTITIONED BY (day int, month int)
LOCATION '<hdfs-path>' STORED AS
    PARQUET;
```

For an unpartitioned table, data files are stored by default directly in the named storage location. For a partitioned table, data files are placed in subdirectories which themselves are located in the named storage location and whose paths embed the partition columns’ values. As an example, for `day = 17, month = 2` of Table T, all data files would be located in `<hdfs-path>/day = 17/month = 2/`. This form of partitioning separates the table data physically and allows static and dynamic partition pruning at runtime; however, it does not physically cluster the data files belonging to an individual partition (the blocks of those data files are spread across all HDFS DataNodes).

The file format should be chosen with an eye toward the provenance of the data and target application. Impala supports most popular file formats, including Parquet, text, Avro, RC, and sequence files, in combination with a number of compression algorithms (snappy, gzip, bz2, etc.). As a rule of thumb, row-oriented formats (e.g., text, Avro) favor small incremental data loads, whereas column-oriented formats (e.g., Parquet) provide superior performance for analytic queries.

Impala + Kudu

Kudu has a record-oriented interface capable of single-record inserts, updates, and lookups. In addition to that, it also supports sophisticated options for physical data partitioning: whereas HDFS only supports value-based partitioning, Kudu supports hash and range partitioning, which gives the user more flexibility in matching the physical data layout to the requirements of the workload. Range partitions allow partition pruning against a broad class of predicates (much like value-based partitioning, except that the number of partitions can be controlled more easily), and hash partitions facilitate value-based insertions (but otherwise only allow partition pruning for equality predicates).

To continue the previous example:

```
CREATE TABLE T (... , PRIMARY KEY (id,
    date))
PARTITION BY HASH (id) PARTITIONS 4
RANGE (date) (PARTITION VALUES ...)
STORED AS KUDU;
```

In this example, the user creates a table with partitions that reflect the hash value of the id column as well as the declared value range of the date column.

Architecture

Impala is a massively parallel SQL execution engine which is designed to run on hundreds of machines in existing Hadoop clusters. Its approach to parallelization and the way this is implemented follow the techniques pioneered for parallel database systems. Figure 1 gives an overview.

An Impala deployment is comprised of the following components:

- **Statestored:** The statestore daemon is a generic publish/subscribe service that disseminates shared metadata throughout the cluster. There is a single statestored instance for the entire cluster.
- **Catalogd:** The catalog daemon collects and synchronizes table metadata with other

Hadoop ecosystem components (such as the Hive metastore, the HDFS NameNode, and the Sentry Service). The catalog daemon uses the statestore to distribute a unified view of table metadata to the Impala daemons. There is a single catalogd instance for the entire cluster.

- **Impalad:** Impala daemons accept client requests and are responsible for query planning, coordination, and execution. They cache metadata received from the catalogd and are the only components actively involved in query execution. There is typically one impalad running on each node in the cluster.

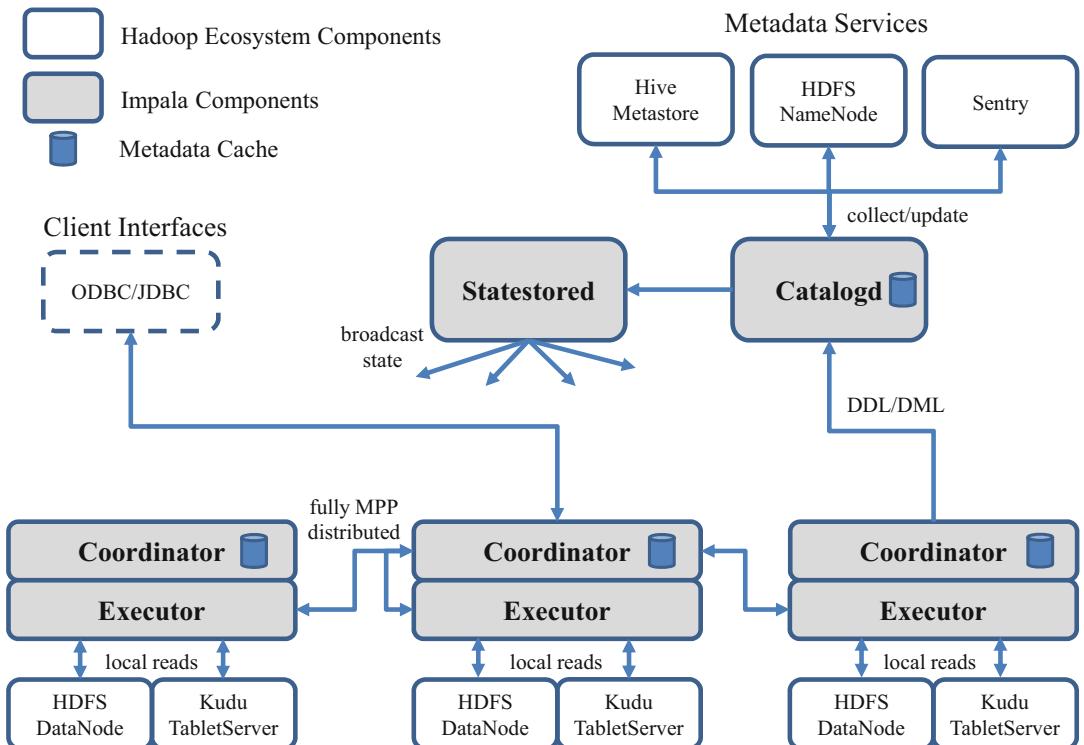

The following sections describe each daemon in more detail.

Statestore Daemon

The statestore is used to disseminate table metadata originating from the catalog daemon as well as membership and load information for the entire cluster. Its information is organized in topics which are versioned collections of topic items. Each impalad registers itself with the statestore at startup at which point it receives an initial bulk update to synchronize it with the current state of all topics. Subsequent updates utilize the topic version numbers to send deltas; thereby avoiding having to resend entire topics whenever a single piece of metadata changes.

The statestore also sends periodic keepalive messages to all registered impalads in order to detect node failures and update its membership information. Membership itself also has a topic, and changes are immediately disseminated using the generic topic update mechanism.

Given the asynchronous nature of how topic changes are broadcast, it is possible for two impalads to be caching different versions of any topic, e.g., the table metadata. This inconsistency is not a problem during query processing, because the query coordinator creates an execution plan that embeds all relevant metadata. An executing impalad then references that metadata rather than its local cache.

Impala, Fig. 1 Overview of Impala’s architecture and Hadoop ecosystem components. Executors can also read from cloud blob stores like S3 and ADLS (not shown)

Catalog Daemon

Impala’s catalogd has two purposes: (a) it collects and disseminates catalog data to impalads via the statestore broadcast mechanism, and (b) it serves as the liaison between the impalads and the external persistent metadata repository, the Hive metastore (HMS). The catalog daemon allows Impala daemons to execute DDL that is persisted in the HMS, and it synchronizes its view of the cluster’s metadata from the HMS, thereby allowing interoperability between Impala and other Hadoop processing frameworks that rely on the HMS for metadata storage.

The catalog service pulls metadata that is relevant for query planning and execution from the appropriate components of the Hadoop ecosystem: the Hive metastore for logical table definitions; the HDFS namenode for information about data files, blocks; and the Sentry Service for authorization metadata such as roles and privileges. That metadata is aggregated into a unified catalog structure. Any changes to that catalog (e.g., when

a new table is created) are disseminated via the statestore and cached by the Impala daemons.

Since catalogs are often very large, and access to tables is rarely uniform, the catalog service only loads a skeleton entry for each table it discovers at startup. The full table metadata can be loaded lazily in the background or on request, when it is first referenced. If an incoming query references a table before its full metadata has been loaded, the impalad acting as the query coordinator issues a synchronous prioritization request to the catalog service, which blocks the query until the query-relevant metadata has been loaded.

Impala Daemon

This process assumes one or both of these two roles:

- A query coordinator, which accepts client requests (submitted via Thrift), generates an ex-

ecution plan, and then coordinates the execution across the participating Impala executors in the cluster

- A query executor, which accepts execution plan fragments from a coordinator and executes them

There is no central “master” process that handles query coordination for all client requests, and the actual roles assumed by each deployed impalad process are configurable so that it is possible to independently scale up the number of coordinators and executors according to the throughput requirements of the workload.

In a typical on-premise deployment of Impala, one impalad process runs on every node that also runs a DataNode process (for HDFS) or tablet server process (for Kudu). This allows Impala to take advantage of data locality and do a maximal amount of local preprocessing before sending data across the network.

One design goal for Impala is to avoid synchronous RPCs to shared cluster components during query execution, which would severely limit throughput scalability for concurrent workloads. For that reason, each impalad coordinator caches all of the metadata relevant for query planning.

Query Planning

Impalads with the coordinator role are responsible for compiling SQL text into query plans executable by the Impala executors. Impala’s query compiler is written in Java and consists of a fully featured SQL parser and cost-based query optimizer. In addition to the basic SQL features (select, project, join, group by, order by, limit), Impala supports in-line views, uncorrelated and correlated subqueries (transformed into joins), and all variants of outer joins as well as explicit left/right semi- and anti-joins, analytic window functions, and extensions for nested data.

The query compilation process follows a traditional division into stages: query parsing, semantic analysis, and query planning/optimization. The latter stage constructs an executable

plan in two phases: (1) single-node planning and (2) plan parallelization and fragmentation.

In the first phase, the parse tree is translated into a single-node plan tree consisting of the following operators: scan (HDFS, Kudu, HBase), hash join, cross join, union, hash aggregation, sort, top-n, analytic evaluation, and subplan (for nested data evaluation). This phase is responsible for expression rewrites (e.g., constant folding), converting subqueries into joins, assigning predicates at the lowest possible operator in the tree, inferring predicates based on equivalence classes, pruning table partitions, setting limits/offsets, and applying column projections, as well as performing cost-based optimizations such as join ordering and coalescing analytic window functions to minimize total execution cost. Cost estimation is based on table and partition cardinalities plus distinct value counts for each column. Impala uses a quadratic algorithm to determine join order, instead of the more common dynamic programming approach, due to the absence of “interesting orders” (all operators are hash based).

The second planning phase takes the single-node plan as input and produces a distributed execution plan, consisting of a tree of plan fragments. A plan fragment is the basic unit of work sent to executors. It consumes data from any number of child fragments and sends data to at most one parent fragment. The general goal is to minimize data movement and maximize scan locality (in HDFS, local reads are considerably cheaper than remote ones). This is done by adding exchange operators to the plan where necessary and by adding extra operators to minimize data movement across the network (e.g., local pre-aggregation). This second optimization phase decides the join strategy (broadcast or partitioning) for every join operator (the join order is fixed at that point). A broadcast join replicates the entire build side of a join to all machines executing the hash join; a partitioning join repartitions both join inputs on the join expressions. Impala takes into account the existing data partitions of the join inputs and chooses the strategy that is estimated to minimize the amount of data transferred over the network.

Query Execution

An impalad with the executor role receives plan fragments from the coordinator and is responsible for their execution. It is written in C++ and was designed specifically to take advantage of modern hardware, among other things, by utilizing runtime code generation. The latter reduces the instruction count and memory overhead at runtime when compared to a more traditional, interpretive approach and to other engines implemented in Java.

Impala's execution model follows that of traditional parallel databases: it implements Volcano-style (Graefe 1990) distributed execution with Exchange operators and batch-at-a-time processing. With the exception of "stop-and-go" operators (e.g., sort), the execution is fully pipelined, which minimizes memory consumption for intermediate results. Impala employs a canonical row-oriented in-memory format which is separate from how data is represented on disk; this is necessary in order to allow Impala to support a range of file formats. Operators that may need to consume lots of memory are designed to be able to spill parts of their working set to external storage if needed. Spillable operators are hash join, hash aggregation, sort, and analytic function evaluation.

Runtime code generation using LLVM (Lattner and Adve 2004) is at the core of Impala's techniques for execution efficiency. LLVM allows applications like Impala to perform just-in-time compilation within a running process, with the full benefits of a modern optimizer and the ability to generate machine code for a number of architectures. Impala utilizes this to produce query-specific versions of functions that are critical to performance, namely, those "inner-loop" functions that are executed many times in a given query (e.g., for every tuple), and thus constitute the majority of the cycles executed on behalf of the query.

When running queries against HDFS-resident data, Impala takes advantage of two HDFS features to retrieve data at or near hardware speed: (a) short-circuit local reads (HDFS short-circuit local reads n.d.) allow the client to bypass

HDFS's DataNode protocol and read directly from local disk instead, in the case where the reader and the data are collocated and (b) in-memory caching (Centralized cache management n.d.) allows the client to map cached data directly into its address space, thereby avoiding extra data copies and checksums.

Further, Impala implements many of the advanced performance features pioneered by parallel RDBMS such as semi-join reductions with Bloom filters, dynamic partition pruning, and runtime data elimination by evaluating predicates against min/max column values and dictionaries inside data files.

Introduction

Stream analytics systems are an integral part of modern online services. These systems are extensively used for transforming raw data into useful information. Much of this raw data arrives as a continuous data stream and in huge volumes, requiring real-time stream processing based on parallel and distributed computing frameworks (Bhatotia et al. 2014; Murray et al. 2013; Zaharia et al. 2013).

Near real-time processing of data streams has two desirable, but contradictory, design requirements (Murray et al. 2013; Zaharia et al. 2013): (i) achieving low latency and (ii) efficient resource utilization. For instance, the low-latency requirement can be met by employing more computing resources and parallelizing the application logic over the distributed infrastructure. Since most data analytics frameworks are based on the data-parallel programming model (Dean and Ghemawat 2004), almost linear scalability can be achieved with increased computing resources (Quoc et al. 2013, 2014, 2015a,b). However, low latency comes at the cost of lower throughput and ineffective utilization of the computing resources. Moreover, in some cases, processing all data items of the input stream would require

more than the available computing resources to meet the desired SLAs or the latency guarantees.

To strike a balance between these two contradictory goals, there is a surge of new computing paradigms that prefer to compute over a subset of data items instead of the entire data stream. Since computing over a subset of the input requires less time and resources, these computing paradigms can achieve bounded latency and efficient resource utilization. In particular, two such paradigms are incremental and approximate computing.

Incremental computing. Incremental computation is based on the observation that many data analytics jobs operate incrementally by repeatedly invoking the same application logic or algorithm over an input data that differs slightly from that of the previous invocation (Bhatotia et al. 2015; Gunda et al. 2010; He et al. 2010). In such a workflow, small, localized changes to the input often require only small updates to the output, creating an opportunity to update the output incrementally instead of recomputing everything from scratch (Acar 2005; Bhatotia 2015). Since the work done is often proportional to the change size rather than the total input size, incremental computation can achieve significant performance gains (low latency) and efficient utilization of computing resources (Bhatotia et al. 2011b, 2012b; Popa et al. 2009).

The most common way for incremental computation is to rely on programmers to design and implement an application-specific incremental update mechanism (or a *dynamic algorithm*) for updating the output as the input changes (Brodal and Jacob 2002; Chiang and Tamassia 1992). While dynamic algorithms can be asymptotically more efficient than recomputing everything from scratch, research in the algorithms community shows that these algorithms can be difficult to design, implement, and maintain even for simple problems. Furthermore, these algorithms are studied mostly in the context of the uniprocessor computing model, making them ill-suited for parallel and distributed settings which are commonly used for large-scale data analytics.

Recent advancements in self-adjusting computation (Acar 2005; Acar et al. 2010; Ley-Wild et al. 2009) overcome the limitations of dynamic algorithms. Self-adjusting computation transparently benefits existing applications, without requiring the design and implementation of dynamic algorithms. At a high level, self-adjusting computation enables incremental updates by creating a dynamic dependence graph of the underlying computation, which records control and data dependencies between the sub-computations. Given a set of input changes, self-adjusting computation performs change propagation, where it reuses the *memoized* intermediate results for all sub-computations that are unaffected by the input changes, and recomputes only those parts of the computation that are transitively affected by the input change. As a result, self-adjusting computation computes only on a subset (*delta*) of the computation instead of recomputing everything from scratch.

Approximate computing. Approximate computation is based on the observation that many data analytics jobs are amenable to an approximate, rather than the exact, output (Krishnan et al. 2016; Quoc et al. 2017b,d). For such an approximate workflow, it is possible to trade accuracy by computing over a partial subset instead of the entire input data to achieve low latency and efficient utilization of resources.

Over the last two decades, researchers in the database community proposed many techniques for approximate computing including sampling (Al-Kateb and Lee 2010), sketches (Cor-mode et al. 2012), and online aggregation (Heller-stein et al. 1997). These techniques make different trade-offs with respect to the output quality, supported query interface, and workload. However, the early work in approximate computing was mainly targeted toward the centralized database architecture, and it was unclear whether these techniques could be extended in the context of big data analytics.

Recently, sampling-based approaches have been successfully adopted for distributed data analytics (Agarwal et al. 2013; Goiri et al. 2015). These systems show that it is possible to have a

trade-off between the output accuracy and performance gains (also efficient resource utilization) by employing sampling-based approaches for computing over a *subset* of data items. However, these “big data” systems target batch processing workflow and cannot provide required low-latency guarantees for stream analytics.

Combining incremental and approximate computing. This entry makes the observation that the two computing paradigms, incremental and approximate computing, are complementary. Both computing paradigms rely on computing over a subset of data items instead of the entire dataset to achieve low latency and efficient cluster utilization. Therefore, this entry proposes to combine these paradigms together in order to leverage the benefits of both. Furthermore, incremental updates can be achieved without requiring the design and implementation of application-specific dynamic algorithms and support approximate computing for stream analytics.

The high-level idea is to design a sampling algorithm that biases the sample selection to the memoized data items from previous runs. This idea is realized by designing an online sampling algorithm that selects a representative subset of data items from the input data stream. Thereafter, the sample is biased to include data items for which already there are memoized results from previous runs while preserving the proportional allocation of data items of different (strata) distributions. Next, the user-specified streaming query is performed on this biased sample by making use of self-adjusting computation, and the user is provided with an incrementally updated approximate output with error bounds.

INCAPPROX

System Overview

INCAPPROX is designed for real-time data analytics on online data streams. At the high level, the online data stream consists of data items from diverse sources of events or sub-streams. INCAPPROX uses a stream aggregator

(e.g., Apache Kafka ([Kafka – A high-throughput distributed messaging system](#))) that integrates data from these sub-streams, and thereafter, the system reads this integrated data stream as the input.

INCAPPROX facilitates user querying on this data stream and supports a user interface that consists of a streaming query and a query budget. The user submits the streaming query to the system as well as specifies a query budget. The query budget can either be in the form of latency guarantees/SLAs for data processing, desired result accuracy, or computing resources available for query processing. INCAPPROX makes sure that the computation done over the data remains within the specified budget. To achieve this, the system makes use of a mixture of incremental and approximate computing for real-time processing over the input data stream and emits the query result along with the confidence interval or error bounds.

System Model

In this section, the system model assumed in this work is presented.

Programming model. INCAPPROX supports a *batched stream processing* programming model. In batched stream processing, the online data stream is divided into small batches or sets of records; and for each batch, a distributed data-parallel job is launched to produce the output.

Computation model. The computation model of INCAPPROX for stream processing is *sliding window computations*. In this model the computation window slides over the input data stream, where new arriving input data items are added to the window, and the old data items are dropped from the window as they become less relevant to the analysis.

In sliding window computations, there is a substantial overlap of data items between the two successive computation windows, especially, when the size of the window is large relative to the slide interval. This overlap of unchanged data items provides an opportunity to update the output incrementally.

Assumptions. INCAPPROX makes the following assumptions. Possible methods to enforce them are discussed in section “[Discussion](#)” and in the entry Krishnan et al. (2016).

1. This work assumes that the input stream is stratified based on the source of event, i.e., the data items within each stratum follow the same distribution and are mutually independent. Here a *stratum* refers to one sub-stream. If multiple sub-streams have the same distribution, they are combined to form a stratum.
2. This work assumes the existence of a virtual function that takes the user-specified budget as the input and outputs the sample size for each window based on the budget.

Building Blocks

Techniques and the motivation behind INCAPPROX’s design choices are briefly described.

Stratified sampling. In a streaming environment, since the window size might be very large, for a realistic rate of execution, INCAPPROX performs approximation using samples taken within the window. But the data stream might consist of data from disparate events. As such, INCAPPROX needs to make sure that every sub-stream is considered fairly to have a representative sample from each sub-stream. For this the system uses stratified sampling (Al-Kateb and Lee 2010). Stratified sampling ensures that data from every stratum is selected and none of the minorities are excluded. For statistical precision, INCAPPROX uses proportional allocation of each sub-stream to the sample (Al-Kateb and Lee 2010). It ensures that the sample size of each sub-stream is in proportion to the size of sub-stream in the whole window.

Self-adjusting computation. For incremental sliding window computations, INCAPPROX uses self-adjusting computation (Acar 2005; Acar et al. 2010) to reuse the intermediate results of sub-computations across successive runs of jobs. In this technique the system maintains a dependence graph between sub-computations

of a job and reuses memoized results for sub-computations that are unaffected by the changed input in the computation window.

Algorithm

This section presents an overview algorithm of INCAPPROX. The algorithm computes a user-specified streaming *query* as a sliding window computation over the input data stream. The user also specifies a query *budget* for executing the query, which is used to derive the sample size (*sampleSize*) for the window using a cost function (see sections “Assumptions” and “Discussion”). The cost function ensures that processing remains within the query budget.

For each window, INCAPPROX first adjusts the computation window to the current start time t by removing all old data items from the *window* (*timestamp* $< t$). Similarly, the system also drops all old data items from the list of memoized items (*memo*) and the respective memoized results of all sub-computations that are dependent on those old data items.

Next, the system reads the new incoming data items in the *window*. Thereafter, it performs proportional stratified sampling (detailed in Krishnan et al. 2016) on the *window* to select a sample of size provided by the cost function. The stratified sampling algorithm ensures that samples from all strata are proportional and no stratum is neglected.

Next, INCAPPROX biases the stratified sample to include items from the memoized sample, in order to enable the reuse of memoized results from previous sub-computations. The biased sampling algorithm biases samples *specific to each stratum*, to ensure reuse and, at the same time, retain proportional allocation (Krishnan et al. 2016).

Thereafter, on this biased sample, the system runs the user-specified *query* as a data-parallel job *incrementally*, i.e., it reuses the memoized results for all data items that are unchanged in the window, and updates the output based on the changed (or new) data items. After the job finishes, the system memoizes all the items in the sample and their respective sub-computation

results for reuse for the subsequent windows (Krishnan et al. 2016).

The job provides an estimated output which is bound to a range of error due to approximation. INCAPPROX performs error estimation to estimate this error bound and define a confidence interval for the result as $output \pm error\ bound$ (Krishnan et al. 2016).

The entire process repeats for the next window, with updated windowing parameters and the sample size. (Note that the query budget can be updated across windows during the course of stream processing to adapt to the user’s requirements.)

Estimation of Error Bounds

In order to provide a confidence interval for the approximate output, the error bounds are computed due to approximation.

Approximation for aggregate functions. Aggregate functions require results based on all the data items or groups of data items in the population. But since the system computes only over a small sample from the population, an *estimated* result based on the weightage of the sample can be obtained.

Consider an input stream S , within a window, consisting of n disjoint strata $S_1, S_2 \dots, S_n$, i.e., $S = \sum_{i=1}^n S_i$. Suppose the i th stratum S_i has B_i items and each item j has an associated value v_{ij} . Consider an example of taking sum of these values across the whole window, represented as $\sum_{i=1}^n (\sum_{j=1}^{B_i} v_{ij})$. To find an approximate sum, INCAPPROX first selects a sample from the window based on stratified and biased sampling, i.e., from each i th stratum S_i in the window, the system samples b_i items. Then it estimates the sum from this sample as $\hat{\tau} = \sum_{i=1}^n (\frac{B_i}{b_i} \sum_{j=1}^{b_i} v_{ij}) \pm \epsilon$ where the error bound ϵ is defined as:

$$\epsilon = t_{f,1-\frac{\alpha}{2}} \sqrt{\widehat{Var}(\hat{\tau})} \quad (1)$$

Here, $t_{f,1-\frac{\alpha}{2}}$ is the value of the t-distribution (i.e., *t-score*) with f degrees of freedom and $\alpha = 1 - \text{confidence level}$. The degree of freedom f is expressed as:

$$f = \sum_{i=1}^n b_i - n \quad (2)$$

The estimated variance for sum, $\widehat{Var}(\hat{\tau})$ is represented as:

$$\widehat{Var}(\hat{\tau}) = \sum_{i=1}^n B_i * (B_i - b_i) \frac{s_i^2}{b_i} \quad (3)$$

where s_i^2 is the population variance in the i th stratum. Since the bias sampling is such that the statistics of stratified sampling is preserved, the statistical theories (Lohr 2009) for stratified sampling has been used to compute the error bound.

Currently, INCAPPROX supports error estimation only for aggregate queries. For supporting queries that compute extreme values, such as minimum and maximum, the system can make use of extreme value theory (Coles 2001; Liu and Meeker 2014) to compute the error bounds.

Error bound estimation. For error bound estimation, first the sample statistic used to estimate a population parameter is identified, e.g., *sum*, and a desired confidence level is selected, e.g., 95%. In order to compute the margin of error ϵ using t-score as given in Eq. 1, the sampling distribution must be nearly normal. The central limit theorem (CLT) states that when the size of sample is sufficiently large ($>= 30$), then the sampling distribution of a statistic approximates to *normal distribution*, regardless of the underlying distribution of values in the data (Lohr 2009). Hence, INCAPPROX computes t-score using a t-distribution calculator ([The Apache Commons Mathematics Library](#)), with the given degree of freedom f (see Eq. 2), and cumulative probability as $1 - \alpha/2$ where $\alpha = 1 - \text{confidence level}$ (Lohr 2009). Thereafter, the system estimates the variance using the corresponding equation for the sample statistic considered (for *sum*, the Equation is (3)). Finally, the system uses this t-score and estimated variance of the sample statistic and computes the margin of error using Eq. 1.

Discussion

The design of INCAPPROX is based on the assumptions in section “[Assumptions](#)”. Solving these assumptions is beyond the scope of this entry; however, this section discusses some of the approaches that could be used to meet the assumptions.

I: Stratification of sub-streams. Currently this work assumes that sub-streams are stratified, i.e., the data items of individual sub-streams have the same distribution. However, it may not be the case. Next, two alternative approaches are discussed, namely, bootstrap (Dziuda 2010) and a semi-supervised learning algorithm (Masud et al. 2012) to classify evolving data streams. Bootstrap (Dziuda 2010; Efron and Tibshirani 1986) is a nonparametric resampling technique used to estimate parameters of a population. It works by randomly selecting a large number of bootstrap samples with replacement and with the same size as in the original sample. Unknown parameters of a population can be estimated by averaging these bootstrap samples. Such a bootstrap-based classifier could be created from the initial reservoir of data, and the classifier could be used to classify sub-streams. Alternatively, a semi-supervised algorithm (Masud et al. 2012) can be employed to stratify a data stream. This algorithm manipulates both unlabeled and labeled data items to train a classification model.

II: Virtual cost function. Secondly, this work assumes that there exists a virtual function that computes the sample size based on the user-specified query budget. The query budget could be specified as either available computing resources or latency requirements. Two existing approaches – Pulsar (Angel et al. 2014) and resource prediction model (Wieder et al. 2010a,b, 2012; Ganapathi 2009) – can be used to design such a virtual function for the given computing resources and latency requirements, respectively (see details in Krishnan et al. 2016).

Related Work

INCAPPROX builds on two computing paradigms, namely, incremental and approximate computing. This section provides a survey of techniques proposed in these two paradigms.

Incremental computation. To apply incremental computing, the earlier big data systems (Google’s Percolator (Peng and Dabek 2010) and Yahoo’s CBP (Logothetis et al. 2010) proposed an alternative programming model where the programmer is asked to implement an efficient incremental-update mechanism. However, these systems depart from the existing programming model, and also require implementation of dynamic algorithms on per-application basis, which could be difficult to design and implement.

To overcome the limitations, researchers proposed transparent approaches for incremental computation. Examples of transparent systems include Incoop (Bhatotia et al. 2011a,b), DryadInc (Popa et al. 2009), Slider (Bhatotia et al. 2012a, 2014), and NOVA (Olston et al. 2011). These systems leverage the underlying data-parallel programming model such as MapReduce (Dean and Ghemawat 2004) or Dryad (Isard et al. 2007) for supporting incremental computation. INCAPPROX was built on transparent big data systems for incremental computation. In particular, the system leverages the advancements in self-adjusting computation (Acar 2005; Bhatotia 2015) to improve the efficiency of incremental computation. In contrast to the existing approaches, INCAPPROX extends incremental computation with the idea of approximation, thus further improving the performance.

Approximate computation. Approximation techniques such as sampling (Al-Kateb and Lee 2010), sketches (Cormode et al. 2012), and online aggregation (Hellerstein et al. 1997) have been well-studied over the decades in the context of traditional (centralized) database systems. In the last 5 years, sampling-based techniques have

been successfully employed in many distributed data analytics systems (Agarwal et al. 2013; Goiri et al. 2015; Quoc et al. 2017a,b). The systems such as ApproxHadoop (Goiri et al. 2015) and BlinkDB (Agarwal et al. 2013) showed that it is possible to achieve the benefits of approximate computing also in the context of distributed big data analytics. However, these systems target batch processing and are not able to support low-latency stream analytics.

Recently, StreamApprox (Quoc et al. 2017c,d) proposed an online sampling algorithm to “on-the-fly” take samples of input data streams in a distributed manner. Interestingly, the sampling algorithm is generalizable to two prominent types of stream processing models: batched and pipelined stream processing models. Lastly, PrivApprox (Quoc et al. 2017a,b) employed a combination of randomized response and approximate computation to support privacy-preserving stream analytics.

INCAPPROX builds on the advancements in approximate computing for big data analytics. However, the system is different from the existing approximate computing systems in two crucial aspects. First, unlike the existing systems, ApproxHadoop and BlinkDB, which are designed for batch processing, INCAPPROX is targeted at stream processing. Second, the system benefits from both approximate and incremental computing.

Conclusion

This entry presents the combination of incremental and approximate computations. The proposed approach transparently benefits unmodified applications, i.e., programmers do not have to design and implement application-specific dynamic algorithms or sampling techniques. The approach is based on the observation that both computing paradigms rely on computing over a subset of data items instead of computing over the entire dataset. These two paradigms are combined by designing a sampling algorithm that biases the

sample selection to the memoized data items from previous runs.

Introduction

There is a growing need to analyze large feeds of data that are continuously collected. Either due to the nature of the analysis or in order to bound the computational complexity of analyzing

a monotonically growing data set, this processing often resorts to a *sliding window* analysis. In this type of processing, the scope of the analysis is limited to a recent interval over the entire collected data, and, periodically, newly produced inputs are appended to the window and older inputs are discarded from it as they become less relevant to the analysis.

The basic approach to sliding window data processing is to recompute the analysis over the entire window whenever the window slides. Consequently, even old, unchanged data items that remain in the window are reprocessed, thus consuming unnecessary computational resources and limiting the timeliness of results.

We can improve on this using an incremental approach, which normally relies on the programmers of the data analysis to devise an incremental update mechanism (He et al. 2010; Logothetis et al. 2010; Peng and Dabek 2010), i.e., an *incremental algorithm* (or *dynamic algorithm*) containing the logic for incrementally updating the output as the input changes. Research in the algorithms and programming languages communities shows that while such incremental algorithms can be very efficient, they can be difficult to design, analyze, and implement even for otherwise simple problems (Chiang and Tamassia 1992; Ramalingam and Reps 1993; Demetrescu et al. 2004; Acar 2005). Moreover, such incremental algorithms often assume a uniprocessor computing model and due to their natural complexity do not lend themselves well to parallelization, making them ill suited for parallel and distributed data analysis frameworks (Dean and Ghemawat 2004; Isard et al. 2007).

Given the efficiency benefits of incremental computation, an interesting question is whether it would be possible to achieve these benefits without requiring the design and implementation of incremental algorithms on an ad hoc basis. Previous work on systems like Incoop (Bhatotia et al. 2011a,b), Nectar (Gunda et al. 2010), HaLoop (Bu et al. 2010), DryadInc (Isard et al. 2007), or Ciel (Murray et al. 2011) shows that such gains are possible to obtain in a transparent way, i.e., without changing the original (single-pass) data analysis code. However, these systems

resort to the memoization of sub-computations from previous runs, which still requires time proportional to the size of the whole data rather than the change itself. Furthermore, these systems are meant to support arbitrary changes to the input and as such do not take advantage of the predictability of changes in sliding window computations to improve the timeliness of the results.

In this paper, we propose SLIDER, a system for incremental sliding window computations where the work performed by incremental updates is proportional to the size of the changes in the window (the “*delta*”) rather than the whole data. In SLIDER, the programmer expresses the computation corresponding to the analysis using either MapReduce (Dean and Ghemawat 2004) or another dataflow language that can be translated to the MapReduce paradigm (e.g., Hive (Foundation 2017) or Pig (Olston et al. 2008)). This computation is expressed by assuming a static, unchanging input window. The system then guarantees the automatic and efficient update of the output as the window slides. The system makes no restrictions on how the window slides, allowing it to shrink on one end and to grow on the other end arbitrarily (though as we show more restricted changes lead to simpler algorithms and more efficient updates). SLIDER thus offers the benefits of incremental computation in a fully transparent way.

Our approach to automatic incrementalization is based on the principles of self-adjusting computation (Acar 2005; Acar et al. 2009), a technique from the programming-languages community that we apply to sliding window computations. In self-adjusting computation, a *dynamic dependency graph* records the control and data dependencies of the computation, so that a *change-propagation algorithm* can update the graph as well as the data whenever the data changes. One key contribution of this paper is a set of novel data structures to represent the dependency graph of sliding window computations that allow for performing work proportional primarily to the size of the slide, incurring only a logarithmic – rather than linear – dependency to the size of the window.

To the best of our knowledge, this is the first technique for updating distributed incremental computations that achieves efficiency of this kind.

We further improve the proposed approach by designing a *split processing model* that takes advantage of structural properties of sliding window computations to improve response times. Under this model, we split the application processing into two parts: a foreground and a background processing. The foreground processing takes place right after the update to the computation window and minimizes the processing time by combining new data with a precomputed intermediate result. The background processing takes place after the result is produced and returned, paving the way for an efficient foreground processing by precomputing the intermediate result that will be used in the next incremental update.

We implemented SLIDER by extending Hadoop and evaluate its effectiveness by applying it to a variety of micro-benchmarks and applications and consider three real-world cases (Bhatotia et al. 2012b, 2014). Our experiments show that SLIDER can deliver significant performance gains while incurring only modest overheads for the initial run (non-incremental preprocessing run).

Background and Overview

In this section, we present some background and an overview of the design of SLIDER.

Self-Adjusting Computation

Self-adjusting computation is a field that studies ways to incrementalize programs automatically, without requiring significant changes to the code base (Acar 2005; Bhatotia 2015). For automatic incrementalization, in self-adjusting computations, the system constructs and maintains a *dynamic dependency graph* that contains the input data to a program, all sub-computations, and the data and control dependencies in between, e.g., which outputs of sub-computations are used as inputs to other sub-computations, which sub-computations are created by another.

The dynamic dependency graph enables a *change propagation* algorithm to update the computation and the output by propagating changes through the dependency graph, re-executing all sub-computations transitively affected by the change, reusing unaffected computations, and deleting obsolete sub-computations which no longer take place. The change propagation algorithm has been shown to be effective for a broad class of computations called *stable* and has even helped solve algorithmically sophisticated problems in a more efficient way than more ad hoc approaches (e.g., Acar 2010 and Sümer et al. 2011.)

Design Overview

Our primary goal is to design techniques for automatically incrementalizing sliding window computation to efficiently update their outputs when the window slides. We wish to achieve this without requiring the programmer to change any of the code, which is written assuming that the windows do not slide, i.e., the data remains static. To this end, we apply the principles of self-adjusting computation to develop a way of processing data that leads to stable computation, i.e., one whose overall dependency structure does not change dramatically when the window slides. In this paper, we apply this methodology to the MapReduce model (Dean and Ghemawat 2004), which enables expressive, fault-tolerant computations on large-scale data, thereby showing that the approach can be practical in modern data analysis systems. Nonetheless, the techniques we propose can be applied more generally, since we only require that the computation can be divided in a parallel, recursive fashion. In fact, the techniques that we propose can be applied to other large-scale data analysis models such as Dryad (Isard et al. 2007), Spark (Zaharia et al. 2012), and Pregel (Malewicz et al. 2010), which allow for recursively breaking up a computation into sub-computations.

Assuming that the reader is familiar with the MapReduce model, we first outline a basic design and then identify the limitations of this basic approach and describe how we overcome them. For simplicity, we assume that each job includes a single Reduce task (i.e., all mappers output

tuples with the same key). By symmetry, this assumption causes no loss of generality; in fact our techniques and implementation apply to multiple keys and reducers.

The basic design. Our basic design corresponds roughly to the scheme proposed in prior work, Incoop (Bhatotia et al. 2011a,b), where new data items are appended at the end of the previous window and old data items are dropped from the beginning. To update the output incrementally, we launch a Map task for each new “split” (a partition of the input that is handled by a single Map task) that holds new data and reuse the results of Map tasks operating on old but live data. We then feed the newly computed results together with the reused results to the Reduce task to compute the final output.

Contraction trees and change propagation. The basic design suffers from an important limitation: it cannot reuse any work of the Reduce task. This is because the Reduce task takes to input all values for a given key ($< K_i >$, $< V_1, V_2, V_3, \dots, V_n >$), and therefore a single change triggers a recomputation of the entire Reduce task. We address this by organizing the Reduce tasks as a contraction tree and proposing a change propagation algorithm that can update the result by performing traversals on the contraction tree, while maintaining it balanced (low-depth) and thus guaranteeing efficiency.

Contraction trees (used in Incoop (Bhatotia et al. 2011b), Camdoop (Costa et al. 2012), iMR (Logothetis et al. 2011)) leverage *Combiner functions* of MapReduce to break a Reduce task into smaller sub-computations that can be performed in parallel. Combiner functions originally aim at saving bandwidth by offloading parts of the computation performed by the Reduce task to the Map task. To use Combiners, the programmer specifies a separate Combiner function, which is executed on the machine that runs the Map task, and performs part of the work done by the Reduce task in order to preprocess various $\langle \text{key}, \text{value} \rangle$ pairs, merging them into a smaller number of pairs. The Combiner function

takes both as an input and output types a sequence of $\langle \text{key}, \text{value} \rangle$ pairs. This new usage of Combiners is compatible with the original Combiner interface but requires associativity for grouping different Map outputs. To construct a contraction tree, we break up the work done by the (potentially large) Reduce task into many applications of the Combiner functions. More specifically, we split the Reduce input into small groups and apply the Combine to pairs of groups recursively in the form of a balanced tree until we have a single group left. We apply the Reduce function to the output of the last Combiner.

When the window slides, we employ a *change-propagation algorithm* to update the result. Change propagation runs the Map on the newly introduced data and propagates the results of the Map tasks through the contraction tree that replaced the Reduce task. One key design challenge is how to organize the contraction tree so that this propagation requires minimal amount of time. We overcome this challenge by designing contraction trees and the change propagation algorithm such that change propagation always guarantees that the contraction trees remain balanced, guaranteeing low depth. As a result, change propagation can perform efficient updates by traversing only through a short path of the contraction tree. In this approach, performing an update not only updates the data but also the structure of the contraction tree (so that it remains balanced), guaranteeing that updates remain efficient regardless of the past history of window slides.

In addition to contraction trees and change propagation, we also present a *split processing* technique that takes advantage of the structural properties of sliding window computation to improve response times. Split processing splits the total work into background tasks, which can be performed when no queries are executing, and foreground tasks which must be performed in order to respond to a query correctly. By preprocessing certain computation in the background, split processing can improve performance significantly (up to 40% in our experiments).

The techniques that we present here are fully general: they apply to sliding window computa-

tions where the window may be resized arbitrarily by adding as much new data at the end and removing as much new data from the beginning as desired. As we describe, however, more restricted updates where, for example, the window is only expanded by append operations (*append-only*) or where the size of the window remains the same (*fixed-size windows*) lead to a more efficient and simpler design, algorithms, and implementation.

Slider Architecture

In this section, we give an overview of our implementation. Its key components are described in the following.

Implementation of self-adjusting trees. We implemented our prototype of SLIDER based on Hadoop. We implemented the three variants of the self-adjusting contraction tree by inserting an additional stage between the shuffle stage (where the outputs of Map tasks are routed to the appropriate Reduce task) and the sort stage (where the inputs to the Reduce task are sorted). To prevent unnecessary data movement in the cluster, the new contraction phase runs on the same machine as the Reduce task that will subsequently process the data.

SLIDER maintains a distributed dependency graph from one run to the next and pushes the changes through the graph by recomputing subcomputations affected by the changed input. For this purpose, we rely on a memoization layer to remember the inputs and outputs of various tasks and the nodes of the self-adjusting contraction trees. A shim I/O layer provides access to the memoization layer. This layer stores data in an in-memory distributed data cache, which provides both low-latency access and fault tolerance.

Split processing knob. SLIDER implements the split processing capability as an optional step that is run offline on a best effort basis. This stage is scheduled during low cluster utilization periods as a background task. It runs as a distributed data processing job (similar to MapReduce) with only one offline preprocessing stage.

In-memory distributed data caching. To provide fast access to memoized results, we designed an in-memory distributed data caching layer. Our use of in-memory caching is motivated by two observations: First, the number of subcomputations that need to be memoized is limited by the size of the sliding window. Second, main memory is generally underutilized in data-centric computing (Ananthanarayanan 2012). The distributed in-memory cache is coordinated by a master node, which maintains an index to locate the memoized results. The master implements a simple cache replacement policy, which can be changed according to the workload characteristics. The default policy is the Least Recently Used (LRU).

Fault-tolerance. Storing memoized results in an in-memory cache is beneficial for performance but can lead to reduced cache effectiveness when machines fail, as it requires unnecessary recomputation (especially for long running jobs). We therefore conduct a background replication of memoized results to provide fault tolerance by creating two replicas of each memoized result (similar to RAMCloud (Ongaro et al. 2011)). This way fault tolerance is handled transparently: when a new task wants to fetch a memoized result, it reads that result from one of the replicas. To ensure that the storage requirements remain bounded, we developed a garbage collection algorithm that frees the storage used by results that fall out of the current window.

Scheduler modifications. The implementation of SLIDER modifies Hadoop’s scheduler to become aware of the location of memoized results. Hadoop’s scheduler chooses any available node to run a pending Reduce task, only taking locality into account when scheduling Map tasks by biasing toward the node holding the input. SLIDER’s scheduler adapts previous work in data locality scheduling (Bhatotia et al. 2011b; Wieder et al. 2010a,b, 2012), by attempting to run Reduce tasks on the machine that contains the memoized outputs of the combiner phase. When that target machine is overloaded, it migrates tasks from the overloaded node to another node, including

the relevant memoized results. Task migration is important to prevent a significant performance degradation due to straggler tasks (Zaharia et al. 2008).

Dataflow query processing. As SLIDER is based on Hadoop, computations can be implemented using the MapReduce programming model. While MapReduce is gaining in popularity, many programmers are more familiar with query interfaces, as provided by SQL or LINQ. To ease the adoption of SLIDER, we also provide a dataflow query interface that is based on Pig (Olston et al. 2008). Pig consists of a high-level language similar to SQL and a compiler, which translates Pig programs to sequences of MapReduce jobs. As such, the jobs resulting from this compilation can run in SLIDER without adjustment. This way, we transparently run Pig-based sliding window computations in an incremental way.

Related Work

Next, we present a survey of work in the areas of sliding window and incremental processing.

Dynamic and data-streaming algorithms. This class of algorithms is designed to efficiently handle changing input data. Several surveys discuss the vast literature on dynamic algorithms, e.g., (Chiang and Tamassia 1992; Ramalingam and Reps 1993; Demetrescu et al. 2004; Babcock 2002). Despite their efficiency, dynamic algorithms are difficult to develop and specific to a use case: their adaptation to other applications is either not simple or not feasible.

Programming language-based approaches. In programming languages, researchers developed incremental computation techniques to achieve automatic incrementalization (Ramalingam and Reps 1993; Acar 2005). The goal is to incrementalize programs automatically without sacrificing efficiency. Recent advances on self-adjusting computation made significant progress toward this goal by proposing general-purpose

techniques that can achieve optimal update times (Acar 2005). This work, however, primarily targets sequential computations. The recent work on iThreads (Bhatotia et al. 2015) supports parallel incremental computation. In contrast, we developed techniques that are specific to sliding window computations and operate on big data by adapting the principles of self-adjusting computation for a large-scale parallel and distributed execution environment.

Database systems. There is substantial work from the database community on incrementally updating a database view (i.e., a predetermined query on the database) as the database contents change (Ceri and Widom 1991). database view (Ceri and Widom 1991). In contrast, our focus on the MapReduce model, with a different level of expressiveness, and on sliding window computations over big data brings a series of different technical challenges.

Distributed systems. There is some work on incremental large-scale processing of unstructured data sets (Peng and Dabek 2010; Gunda et al. 2010; Logothetis et al. 2010; Bhatotia et al. 2011a,b, 2012a; Krishnan et al. 2016). SLIDER is designed to operate at the same scale and shares some characteristics with this work, such as including a simple programming model, transparent data parallelization, fault tolerance, and scheduling. Furthermore, it builds on some concepts from this prior work, namely, the idea of Incoop (Bhatotia et al. 2011b) to break up the work of Reduce task using Combiner functions organized in a tree. There are two important distinctions to these previous proposals. First, prior proposals such as Incoop use memoization instead of change propagation: when the data to a MapReduce computation changes, Incoop scans the whole input data again and performs all the steps of the computation except that it can reuse results from Map and Combine tasks stored via memoization. In contrast, each run in SLIDER knows only about the new data that was introduced to the window and the old data that was dropped and only has to examine and recompute the subset of the computation that is

transitively affected by those changes. Second, our design includes several novel techniques that are specific to sliding window computations which are important to improve the performance for this mode of operation. The follow-up work on IncApprox (Krishnan et al. 2016) extends the approach of Slider to support incremental approximate computing for sliding window analytics. In particular, IncApprox combines incremental computation and approximates computation (Quoc et al. 2017a,b,c,d).

Batched stream processing. Stream processing engines (He et al. 2010; Condie et al. 2010; Olston et al. 2011) model the input data as a stream, with data-analysis queries being triggered upon bulk appends to the stream. These systems are designed for append-only data processing, which is only one of the cases we support. Compared to Comet (He et al. 2010) and Nova (Olston et al. 2011), SLIDER avoids the need to design a dynamic algorithm, thus preserving the transparency relative to single-pass non-incremental data analysis. Hadoop online (Condie et al. 2010) is transparent but does not attempt to break up the work of the Reduce task, which is one of the key contributions and sources of performance gains of our work.

Conclusion

In this chapter, we present techniques for incrementally updating sliding window computations as the window slides. The idea behind our approach is to structure distributed data-parallel computations in the form of balanced trees that can perform updates in asymptotically sublinear time, thus much more efficiently than recomputing from scratch. We present several algorithms for common instances of sliding window computations; describe the design of a system, SLIDER (Bhatotia et al. 2012b, 2014), that uses these algorithms; and present an implementation along with an extensive evaluation. Our evaluation shows that (1) SLIDER is effective on a broad range of applications, (2) SLIDER drastically improves performance compared to

the recomputing from scratch, and (3) SLIDER significantly outperforms several related systems. These results show that some of the benefits of incremental computation can be realized automatically without requiring programmer-controlled hand incrementalization. The asymptotic efficiency analysis of self-adjusting contraction trees is available (Bhatotia 2016).

Definitions

Consider a set of n data objects $O = \{o_1, o_2, \dots, o_n\}$. Each object is associated with a d -dimensional vector representing its coordinate in a d -dimensional space ($d \in \mathbb{N}_+$). *Indexing* such a set of data is to organize the data in a way that provides fast access to the data, for processing spatial queries such as *point queries*, *range queries*, *kNN queries*, *spatial join queries*, etc.

Overview

The rapid growth of *location-based services* (LBS) has accumulated a massive amount of spatial data such as user GPS coordinates, which calls for efficient indexing structures to provide fast access to such data. Typical applications of spatial data include digital mapping services and location-based social networks, where spatial queries are issued by users such as *finding restaurants within 3 kilometers around*

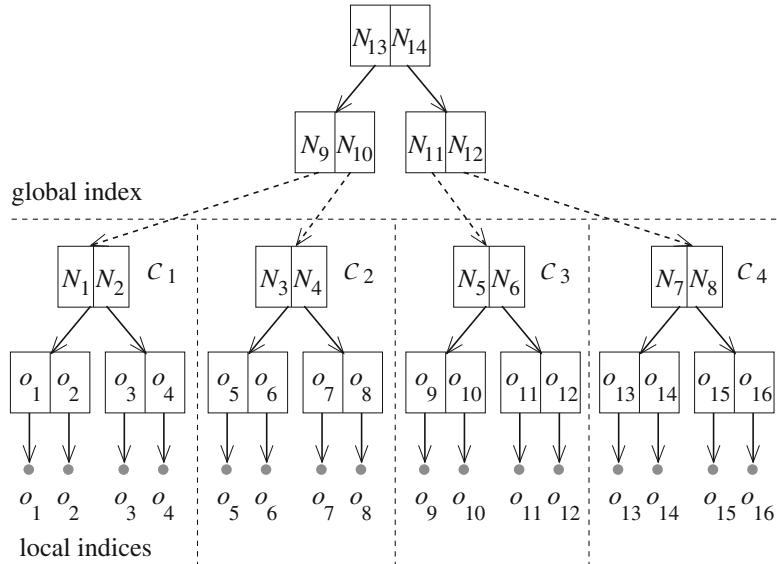

Alice or finding other users within 300 meters around Alice. Spatial indices have been studied extensively to support such queries. In the big data era, there may be millions of spatial queries and places of interests to be processed at the same time. This poses new challenges in both scalability and efficiency of spatial indexing techniques. Parallel spatial index structures are developed to address these challenges, which are summarized in the following section.

Key Research Findings

Traditional spatial indexing techniques can be classified into *space partitioning* techniques and *data partitioning* techniques. Space partitioning techniques such as *quad trees* (Finkel and Bentley 1974) partition the data space into nonoverlapping partitions where data objects in the same partition are indexed together. Data partitioning techniques such as *R-trees* (Guttman 1984) partition the data set directly where data objects nearby are grouped into the same partition and indexed together. We focus on recent developments of the indexing techniques. Readers interested in the traditional spatial indices are referred to a detailed survey on this topic by Gaede and Günther (1998).

Spatial indices have been extended to parallel computing environments to cope with the scalability and efficiency issues. For example, the R-trees have been implemented over a shared-nothing (client-server) architecture. Koudas et al. (1996) store the inner nodes of an R-tree on a server and the leaf nodes on clients. In this architecture, the inner nodes stored on the server forms a *global index*. At query processing, the server uses this index to prune the search space and locate the clients that contain the data objects being queried. Schnitzer and Leutenegger (1999) further create local R-trees on clients. This forms a two-level index structure where the global index is hosted on the server while the *local indices* are hosted on the clients. This is illustrated in Fig. 1, where there is a global index stored on the server and four local indices stored on four client machines C_1, C_2, C_3 , and C_4 .

Indexing, Fig. 1
Two-level distributed indexing

More recent work on parallelizing spatial indices uses the *MapReduce* and the *Spark* frameworks which have become standard parallel computation frameworks in the past decade. These frameworks hide the parallelism details such as synchronization and simplify parallel computation into a few generic operations (e.g., *Map* and *Reduce*). The two-level index structure as described above is still commonly used, although some of the techniques proposed only use either the global index or the local indices. We describe a few representative index structures using these two frameworks next.

MapReduce-Based Indexing

Hadoop-GIS (Aji et al. 2013) is a *Hadoop* (an open-source implementation of the MapReduce framework)-based spatial data warehousing system. It builds a two-level (global and local) index structure over the data objects to support parallel processing of spatial queries. The global index is pre-built by first partitioning the data space with a regular grid and then further partitioning every grid cell containing more than a predefined number of data objects n_{\max} into two equi-sized cells at the middle recursively until each cell contains no more than n_{\max} objects. Data objects in the same cell are associated with the same unique id and stored in the same block. Multiple

cells are grouped into a block for storage to suit the block size in the *HDFS* (a distributed file system used by Hadoop). The *minimum bounding rectangles* (MBR) of the grid cells are stored in the global index. A local index is built at query time over the data objects assigned to the same machine for query processing.

SpatialHadoop (Eldawy and Mokbel 2013) extends Hadoop to provide built-in support for spatial queries. It also uses a global index and a local index. Grid-based and R-tree-based indices can both be used for the global index, where the grid cells and leaf nodes, respectively, correspond to partitions that are stored in HDFS blocks. A local index is built for each partition, which can also use grid or R-tree-based indices. *AQWA* (Aly et al. 2015) builds a global index only, which uses the k-d tree. This index also stores the number of data points of each partition to help query processing.

A few other studies (e.g., Nishimura et al. 2011; Hsu et al. 2012; Zhang et al. 2014) use *space-filling curves* such as the *Z-curve* (Orenstein and Merrett 1984) to map multidimensional coordinates to one-dimensional values. This enables storing the data objects into *NoSQL* databases such as *HBase*, where the mapped coordinate value and the id of a data object are stored as a *key-value* pair. Data update

and spatial queries can then be handled via the APIs of NoSQL databases.

When a hierarchical index such as the R-tree or the k-d tree is built with MapReduce, dynamic index building procedures that insert the data objects into the index individually lack efficiency. A common assumption is that the entire data set is available. In this case, the entire index structure over the data set can be *bulk-loaded* at once. A straightforward approach is to bulk-load the hierarchical index level by level, where each level incurs a round of MapReduce computation (Achakeev et al. 2012). Sampling has been used to reduce the number of MapReduce rounds needed. Papadopoulos and Manolopoulos (2003) propose a generic procedure for parallel spatial index bulk-loading. This procedure uses sampling to estimate the data distribution, which guides the partition of the data space. Data objects in the same partition are assigned to the same machine for index building. SpatialHadoop uses a similar idea for R-tree bulk-loading, where an R-tree is built on a sample data set and the MBR of the leaf nodes are used for data partitioning. Agarwal et al. (2016) also use a sampling-based technique but bulk-load k-d trees. This technique involves multiple rounds of sampling. Each round uses a sample data set small enough to be processed by a single machine. A k-d tree is built on the sample data set, and data objects are assigned to the partitions created by the k-d tree. For the partitions that contain too many data objects to be stored together, another round of sampling- and k-d tree-based partitioning is performed. Repeating the procedure above, it takes $O(\text{poly} \log_s n)$ MapReduce rounds to bulk-load a k-d tree, where s denotes the number of data points that can be processed by a single machine in the MapReduce cluster.

Spark-Based Indexing

Spark models a data set as a *resilient distributed dataset* (RDD) and stores it across machines in the cluster. Spatial indices on Spark focus on optimizing with the RDD storage architecture.

GeoSpark (Yu et al. 2015) builds a local index such as a quad-tree on-the-fly for the data objects in each RDD partition, while the partitions are

created by a uniform grid partitioning over the data space. *SpatialSpark* (You et al. 2015) also builds a local index for data objects in each RDD partition, which can be stored together with the data objects in the RDD partition. SpatialSpark supports binary space partitioning and tile partitioning in addition to uniform grid partitioning over the data space. *STARK* (Hagedorn et al. 2017) uses R-trees for the local indices while uniform grid partitioning and cost-based binary space partitioning for creating the partitions. *Simba* (Xie et al. 2016) uses global and local indices (e.g., R-trees). The global index is held in-memory in the master node, while the local indices are held in each RDD partition.

Examples of Application

Spatial indexing techniques are used in spatial databases to support applications in both business and daily scenarios such as targeted advertising, digital mapping, and location-based social networking. In these applications, the locations (coordinates) of large sets of places of interests as well as users are stored in a spatial database. Spatial indices are built on top of such data to provide fast data access, facilitating spatial queries such as *finding customers within 100 meters of a shopping mall* (to push shopping vouchers), *finding the nearest restaurants for Alice*, and *finding users living in nearby suburbs who share some common interests* (for friendship recommendations).

Future Directions for Research

The indexing techniques discussed above do not consider handling location data with frequent updates. Such data is becoming more and more common with the increasing popularity of positioning system-enabled devices such as smart phones, which enables tracking and querying the continuously changing locations of users or data objects of interest (Zhang et al. 2012; Ward et al. 2014; Li et al. 2015). How to update the spatial indices and to record multiple versions of the

data (Lomet et al. 2008) with a high frequency is nontrivial. While the parallel frameworks such as MapReduce scale well to massive data, the indices stored in the distributed data storage may not be updated as easily as indices stored in a standalone machine. A periodic rebuilt of the indices is an option, but may not keep the indices updated between rebuilds, and hence may provide inaccurate query answers. More efficiency index update techniques are in need. Another important direction to pursue is efficient indexing techniques to support spatial data mining. Many data mining algorithms are computational intensive, which require iterative accesses to (high-dimensional) data. Spatial indices designed to cope with high-dimensional data (Zhang et al. 2004; Jagadish et al. 2005) and the special accessing patterns of such algorithms would have a significant impact in improving the usability of such algorithms.

Indexing Big Spatial Data

► Indexing

Indexing for Graph Query Evaluation

George Fletcher¹ and Martin Theobald²

¹Technische Universiteit Eindhoven, Eindhoven, Netherlands

²Université du Luxembourg, Luxembourg, Luxembourg

Definitions

Given a graph, an index is a data structure supporting a map from a collection of keys to a collection of elements in the graph. For example, we may have an index on node labels, which, given a node label as search key, facilitates accelerated access to all nodes of the graph having the given label. The evaluation of queries on graph databases is often facilitated by index data structures. An index can be the primary representation of the graph or can be a secondary access path to elements of the graph.

Overview

In this article, we give a succinct overview of the main approaches to indexing graphs for efficient graph query evaluation. We focus our discussion on exact query processing and do not consider lossy graph representations. Rather than aiming for an exhaustive survey, we illustrate each approach with select exemplars which highlight the main ideas of the approach.

Key Research Findings

There is a wealth of work on graph indexing, which can be organized along three directions: value indexing, reachability indexing, and compression and structural indexing. After introducing graph data and graph queries in the next section, we survey each of these approaches. We conclude the article with a discussion of issues in distribution and partitioning.

Graph Data and Queries

Data Model. The general data model we consider for this article is that of a *directed, labeled multigraph* $G = (V, E, L, \phi_V, \phi_E)$, consisting of a set of *vertices* V , a set of *edges* E over V , a set of *labels* L , a *vertex-labeling function* $\phi_V : V \mapsto L$, and an *edge-labeling function* $\phi_E : E \mapsto L$. For most applications, we assume ϕ_V to be bijective, i.e., all vertices have a distinct label (then also called “vertex identifier”), while ϕ_E is not necessarily injective nor surjective, i.e., edge labels may occur multiple times among edges.

Query Model. In analogy to our data model, we also consider a *subgraph pattern matching query* $G_Q = (V_Q, E_Q, L, Vars, \phi_Q)$ to be a labeled, directed multigraph, consisting of a set of *query vertices* V_Q , a set of *query edges* E_Q over V_Q , two disjoint sets of *labels* L and *variables* $Vars$ with $L \cap Vars = \emptyset$, and a labeling function $\phi_Q : V_Q \cup E_Q \mapsto L \cup Vars$. Also here, by

assuming unique vertex labels, we impose that $E_Q \subseteq V_Q \times (L \cup \text{Vars}) \times V_Q$.

Given a data graph $G = (V, E, L)$ and a query graph $G_Q = (V_Q, E_Q, L, \text{Vars})$, the semantics of evaluating G_Q on G consists of identifying all isomorphic subgraphs $G' = (V', E', L)$ of G , with $V' \subseteq V$, $E' \subseteq E \cap (V' \times L \times V')$, i.e., a bijection $f : V' \cup L \mapsto V_Q \cup L \cup \text{Vars}$ such that $(v_1, l, v_2) \in E' \implies (f(v_1), f(l), f(v_2)) \in E_Q$. For query evaluation, we impose the additional condition that for vertex and edge labels $l \in L$, it must hold that $f(l) = l$, i.e., the given labels in the query graph must be matched also by the data subgraph, such that only variables in the query graph are replaced by labels in the data subgraph. Some applications relax the semantics of query evaluation such that all homomorphic embeddings are constructed, i.e., f is not necessarily injective. Under homomorphic semantics, subgraph pattern matching queries can also be seen as *conjunctive queries* over relations consisting of edge-labeled adjacency lists with schema $V \times L \times V$ and be solved by a fixed number of joins over these relations.

RDF and SPARQL Directed labeled multi-graphs without repeating vertex labels are particularly well suited for indexing RDF data (RDF 2014) and for processing basic-graph-pattern (BGP) queries expressible in SPARQL 1.1 (SPA 2013). Due to the *unique-name assumption* and the corresponding usage of *unique resource identifiers* (URIs), both prevalent in the RDF data model, edge-labeled adjacency lists of the form $V \times L \times V$ resolve to subject-predicate-object (SPO) triples over the underlying RDF data graph. Most database-oriented indexing and query processing frameworks consider a collection of SPO triples either as a single large relation, or they horizontally partition the collection into multiple SO relations, one for each distinct predicate P (or “property” in RDF terminology). Moreover, various value- and grammar-based synopses and corresponding indexing techniques for RDF data have been developed recently. To further scale-out the indexing strategies to a distributed setting, both horizontal and vertical partitioning,

summarization, and related strategies have been developed, which we will cover in more detail in the following subsections.

SPARQL also supports the usage of complex-graph-pattern (CGP) queries with *labeled property paths* allows a user to formulate transitive reachability constraints among the query variables. Very few works so far focused on the combined processing of relational joins with additional graph-reachability predicates, e.g., Gubichev et al. (2013) and Sarwat et al. (2013). Przyjaciel-Zablocki et al. (2011) investigates an initial approach to evaluate property paths via MapReduce. Currently, only very few commercial RDF engines, such as Virtuoso (Erling and Mikhailov 2009), are available for processing property paths in SPARQL 1.1.

Value-Based Indexing

Value-based indexes are the simplest form of graph data structure, typically used as the primary representation of the graph in the database. Such indexes map values in the graph (node identifiers, edge identifiers, node labels, edge labels) to the nodes or edges associated with the search key. Among the centralized approaches, native RDF stores like 4store (Harris et al. 2009), SW-Store (Abadi et al. 2009), MonetDB-RDF (Sidiropoulos et al. 2008), and RDF-3X (Neumann and Weikum 2010a) have been carefully designed to keep pace with the growing scale of RDF collections. Efficient centralized architectures either employ various forms of horizontal (Neumann and Weikum 2010a; Harris et al. 2009) and vertical (Abadi et al. 2009; Sidiropoulos et al. 2008) partitioning schemes or apply sophisticated encoding schemes over the subjects’ properties (Atre et al. 2010; Yuan et al. 2013). We refer the reader to Luo et al. (2012) for a comprehensive overview of recent approaches for value-based indexing and query processing techniques for labeled graphs in the form of RDF.

Relational Approaches. The majority of existing RDF stores, both centralized and distributed, follow a relational approach toward

storing and indexing RDF data. By treating RDF data as a collection of triples, early systems like 3Store (Harris and Gibbins 2003) use relational databases to store RDF triples in a single large three-column table. This approach lacks scalability, as the query processing (then using SQL) involves many self-joins over this single table. Later approaches follow more sophisticated approaches for storing RDF triples. More recent approaches, such as SW-Store by Abadi et al. (2009), vertically partition RDF triples into multiple property tables. State-of-the-art centralized approaches, such as HexaStore (Weiss et al. 2008) and RDF-3X (Neumann and Weikum 2010a), employ index-based solutions by storing triples directly in B^+ -trees over multiple, redundant SPO permutations. Including all permutations and projections of the SPO attributes, this may result in up to 15 such B^+ -trees (Neumann and Weikum 2010a). Coupled with sophisticated statistics and query-optimization techniques, these centralized, index-based approaches still are very competitive as recently shown in Tsialiamanis et al. (2012).

Join-Order Optimization. Determining the optimal join-order for a query plan is arguably the main factor that impacts query processing performance of a relational engine. RDF-3X (Neumann and Weikum 2010a) thus performs an exhaustive plan enumeration in combination with a bottom-up DP algorithm and aggressive pruning in order to identify the best join-order. TriAD (Gurajada et al. 2014) adopts the DP algorithm, as described in Neumann and Weikum (2010a) and further adapts it to finding both the best exploration-order for the summary graph and the best join-order for the subsequent processing against the SPO indexes. Moreover, by including detailed distribution information and the ability to run multiple joins in parallel into the underlying cost model of the optimizer, TriAD is able to generate query plans that are more specifically tuned toward parallel execution than with a pure selectivity-based cost model.

Join-Ahead Pruning. Join-ahead pruning is a second main factor that influences the perfor-

mance of a relational query processor. In join-ahead pruning, triples that might not qualify for a join are pruned even before the actual join operator is invoked. This pruning of triples ahead of the join operators may thus save a substantial amount of computation time for the actual joins. Instead of the sideways information passing (SIP) strategy used in RDF-3X (Neumann and Weikum 2010a,b), which is a runtime form of join-ahead pruning, TriAD (Gurajada et al. 2014) employs a similar kind of pruning via graph compression, discussed below.

Reachability and Regular-Path Indexing

The reachability problem in directed graphs is one of the most fundamental graph problems and thus has been tackled by a plethora of centralized approaches; see Su et al. (2017) for a recent overview. All methods aim to find tradeoffs among query time and indexing space which, for a directed graph $G(V, E)$, are in between $\mathcal{O}(|V| + |E|)$ for both query time and space consumption when no indexes are used and $\mathcal{O}(1)$ query time and $\mathcal{O}(|V|^2)$ space consumption when the transitive closure is fully materialized. Distributed reachability queries for single-source, single-target queries have so far been considered in Fan et al. (2012b). For multisource, multi-target reachability queries, only comparably few centralized approaches have been developed (Gao and Anyanwu 2013; Then et al. 2014) that provide suitable indexing and processing strategies. Both are based on a notion of *equivalence sets* among graph vertices which effectively resolves to a preprocessing and indexing step of the data graph to predetermine these sets. Efficient centralized approaches, however, are naturally limited to the main memory of a single machine and usually do not consider a parallel, i.e., multi-threaded, execution of a reachability query. Then et al. (2014), on the other hand, focused on the *query-time optimization* of multisource BFS searches. Gubichev et al. (2013) have studied the use of reachability indexes for evaluation of richer property-path queries.

Compression for Query Evaluation

We next highlight three approaches for graph compression to accelerate graph query evaluation.

Structural Indexing

The first approach to graph compression considers graph summaries specifically tailored for a given query language. In particular, these methodologies propose *structural* indexing strategies, which identify characterizations of query language expressivity in terms of the (language independent) structure of the database instance.

Given a query language L , the general strategy proceeds in four steps. (1) A structural equivalence notion \equiv on graphs is identified which corresponds precisely with indistinguishability in L . Here we mean, given an arbitrary graph G and objects o_1 and o_2 of G , it holds that $o_1 \equiv o_2$ if and only if for every query $Q \in L$, it holds that either both or neither of o_1 and o_2 are in the evaluation of Q on G . In other words, objects are structurally equivalent if and only if they are indistinguishable by queries in L . Depending on L , objects might be nodes, edges, paths, or even more complex structures in G . Further, \equiv is independent of L in the sense that it can be computed based on the structure of G alone. (2) G is compressed under \equiv (i.e., the set of objects is partitioned by \equiv equivalence), giving the reduced instance G_{\equiv} . This reduced instance is the “ideal” basis for index data structures for accelerating evaluation of L on G . Indeed, elements of each equivalence class are identical from the perspective of L and so can be treated together in bulk during query evaluation. (3) Given a query $Q \in L$, it is rewritten and evaluated in terms of (an index data structure on) G_{\equiv} , and, finally (4) if necessary, the output of the previous step is post-processed to extract and materialize the complete results of Q evaluated on G .

Structural indexing only makes practical sense if the structural equivalence characterization is efficiently computable on large graphs. Core graph query languages such as the pattern

matching queries typically have impractical structural characterizations. The key challenge then is to identify relaxations of the problem which support efficient index construction and use for acceleration of query processing. There are two strategies which have been employed in this direction.

The first strategy is to identify languages which, on one hand, are rich enough to capture interesting queries and, on the other hand, have a tractable structural equivalence notion. This approach has been followed for the pattern matching queries and path queries, where expressive fragments of these languages have been identified with tractable structural characterizations. In particular, structural characterizations of fragments of the pattern matching queries have been identified by Fletcher et al. (2015) and Picalausa et al. (2012, 2014) and for fragments of path queries by Fan et al. (2012a) and Fletcher et al. (2015). Given a query Q in a full language, e.g., a pattern matching query, and a structural index I built for a particular fragment F of the language on instance G , evaluation of Q proceeds by (1) decomposing the query into subqueries in F , (2) evaluating these subqueries directly with I , and (3) further processing of these intermediate results to obtain the final result of evaluating Q on G . This methodology was first developed for navigational pattern matching queries on semi-structured data (Fletcher et al. 2009, 2016; Milo and Suciu 1999). Typically, the structural characterizations are variations of the well-known tractable structural notion of graph bisimulation. Effective methods for constructing bisimulation reductions of large acyclic and cyclic graphs have been developed for both external memory and distributed settings (Hellings et al. 2012; Luo et al. 2013b,a).

Instead of identifying “weaker” fragments of a query language in order to obtain practical structural characterizations, the second strategy which has been studied is to weaken the semantics of the query language itself. This approach has been developed by Fan et al. (2012a) for the case of the pattern matching queries. Here, adopting a

relaxed simulation-based semantics for pattern matching, query expressivity is captured by a tractable structural equivalence based on graph bisimulation. Although this relaxed semantics diverges from the standard semantics of pattern matching queries, which is typically based on the stronger notions of homomorphism or isomorphism, simulation-based semantics finds important applications, e.g., in analytics on social networks.

In general, structural indexing for graph query evaluation remains a relatively unexplored topic with strong potential for practical application.

Grammar-Based Compression

A second major approach to compression for query evaluation is based on using context-free grammars (CFG) for lossless graph summarization (Maneth and Peternek 2016).

Given a graph G , the basic idea is to build a CFG Γ_G which generates G . The gRePair method of Maneth and Peternek (2016) constructs Γ_G by repeatedly replacing “digrams” (i.e., pairs of connected edges in the graph) by edges labeled by nonterminals in Γ_G . Depending on the instance structure, the grammar Γ_G can be significantly smaller than G . Compression of this method, in terms of bits used per edge, has been shown experimentally to be competitive with state-of-the-art graph compressors.

In addition to high compression rates, Maneth and Peternek (2016) demonstrate good theoretical properties for query evaluation. In particular, adjacency (i.e., neighborhood) queries can be losslessly answered on Γ_G , reachability queries can be answered in linear time (in the size of Γ_G), and a regular path query Q can be answered in $O(|Q||\Gamma_G|)$ time. Hence, the speedup of path queries is proportional to the compression obtained with Γ_G .

In-depth empirical investigation of query evaluation performance on grammar-compressed graphs remains open. As with structural indexing, the study of grammar-based graph compression is a very promising and relatively unexplored approach for accelerated query evaluation.

Graph Dedensification

A third approach to compression-based acceleration of query evaluation is to introduce graph compression by modifying the structure of the graph itself. This strategy is orthogonal to, and can be used in combination with, the approaches discussed above.

Motivated by the large skew in degree-distributions in real-world complex networks, Maccioni and Abadi (2016) propose the use of graph “dedensification” to offset the negative impact of high-degree nodes during graph pattern matching query processing. Given a graph G , the basic idea is to identify and transform complete bipartite subgraphs in G , i.e., subgraphs whose node sets can be partitioned into subsets S and T such that there is an edge from each node in S to each node in T . In particular, for such subgraphs, (1) a new “compressor” node c is introduced; (2) all edges of the subgraph are removed; (3) for each node $s \in S$, an edge is added from s to c ; and (4) for each node $t \in T$, an edge is added from c to t . Hence, the introduction of the compressor nodes dedensifies the subgraph, by replacing a quadratic number of edges with a linear number of edges.

Given a dedensified graph, Maccioni and Abadi (2016) propose exact query evaluation strategies which are experimentally demonstrated to boost query evaluation performance by up to an order of magnitude.

The benefits of dedensification were demonstrated both in the absence of indexes and in combination with exhaustive valued-based indexing. The study of dedensification in combination with the compression strategies discussed above remains an interesting open problem.

Concluding our discussion of compression for query evaluation, we reiterate that, to our knowledge, the compression-based query evaluation solutions presented here have only been demonstrated in research prototypes. A major research challenge is to further study the systems challenges toward realizing these promising methods in graph database systems in practice.

Distribution and Partitioning

MapReduce. Based on the MapReduce paradigm, distributed engines like H-RDF-3X (Huang et al. 2011) and SHARD (Rohloff and Schantz 2011) horizontally partition an RDF collection over a number of compute nodes and employ Hadoop as communication layer for queries that span multiple nodes. H-RDF-3X (Huang et al. 2011) partitions an RDF graph into as many partitions as there are compute nodes. Then, a one- or two-hop replication is applied to index each of the local graphs via RDF-3X (Neumann and Weikum 2010b). Query processing in both systems is performed using iterative Reduce-side joins, where the Map phase performs selections and the Reduce phase performs the actual joins (Lin and Dyer 2010). Although such a setting works well for queries that scan large portions of the data graph, for less data-intensive queries, the overhead of iteratively running MapReduce jobs and scanning all – or at least large amounts – of the tuples during the Map phase may be significant. Even recent approaches like EAGRE (Zhang et al. 2013) that focus on minimizing I/O costs by carefully scheduling Map tasks and utilizing extensive data replication cannot completely avoid Hadoop-based joins in the case of longer-diameter queries or unexpected workloads.

Native Graph Approaches. Recently, a number of distributed approaches were proposed to store RDF triples in native graph format. The main motivation behind these approaches is that relational approaches might generate large intermediate relations which may hamper performance. Native graph engines typically employ adjacency lists as a basic building block for storing and processing RDF data. Moreover, by using sophisticated indexes, like gStore (Zou et al. 2011), BitMat (Atre et al. 2010), and TripleBit (Yuan et al. 2013), or by using graph exploration, like in Trinity.RDF (Zeng et al. 2013), these approaches prune many triples before invoking relational joins to finally generate the row-oriented results of a SPARQL query. Trinity.RDF thus represents

a new generation of native graph engines that are based on earlier ideas from systems such as Pregel (Malewicz et al. 2010) or Neo4j (Webber 2012). Other kinds of graph queries, such as reachability, shortest-paths, or random walks, are partly already included in the SPARQL 1.1 standard. Such queries are targeted by various graph engines, such as FERRARI (Seufert et al. 2013) or Spark’s GraphX (Xin et al. 2013).

Graph Partitioning. Apart from centralized engines like gStore (Zou et al. 2011), BitMat (Atre et al. 2010), and TripleBit (Yuan et al. 2013), Huang et al. (2011) also follow a graph partitioning approach over a distributed setting, where triples are assigned to different machines using a graph partitioner. Graph partitioning allows triples that are close to each other in the graph to be stored at the same machine, thus overcoming the randomness issued by the purely hashing-based partitioning schemes used in systems like SHARD (Rohloff and Schantz 2011).

Graph Exploration vs. Join Processing. To avoid the overhead of Hadoop-based joins, Trinity.RDF (Zeng et al. 2013) is based on a custom protocol based on the message passing interface (MPI) (Message Passing Interface Forum 2015) for internode communication. In Trinity.RDF, intermediate variable bindings are computed among all slave nodes via graph exploration, while the final results need to be enumerated at the single master node using a single-threaded, left-deep join over the intermediate variable bindings.

Distributed Reachability Queries. Very few works so far have been developed for distributed reachability queries. Fan et al. (2012b) recently discussed distributed, but single-source, single-target reachability algorithms for partitioned graphs and also provide performance guarantees. For a directed graph and given cut, Fan et al. (2012b) uses a partially iterative and partially indexing-based evaluation to find the reachability for a given pair of vertices over a classical master-slave architecture. Distributed graph engines, such as Google’s Pregel (Malewicz et al. 2010),

Berkeley's GraphX (Xin et al. 2013) (based on Spark Zaharia et al. 2010), Apache Giraph (Ching et al. 2015) and IBM's very recent Giraph++ (Tian et al. 2013), on the other hand, allow for the scalable processing of graph algorithms over massive, distributed data graphs. All of these provide generic API's for implementing various kinds of algorithms, including multisource, multi-target reachability queries. Graph indexing and query optimization, however, break the *node-centric computing* paradigm of Pregel and Giraph, where major amounts of the graph are successively shuffled through the network in each of the underlying MapReduce iterations (the so-called supersteps). Giraph++ is a very recent approach to overcome this overly myopic form of node-centric computing, which led to a new type of distributed graph processing that is coined *graph-centric computing* in Tian et al. (2013). By exposing intra-node state information as well as the internode partition structure to the local compute nodes, Giraph++ is a great step toward making these graph computations more context-aware. Further distributed approaches include Gurajada and Theobald (2016), Harbi et al. (2015), Peng et al. (2016), and Potter et al. (2016).

Definitions

“Influence analytics in graphs” is the study of the dynamics of influence propagation over a network. Influence includes anything that can be transferred or shaped through network interactions, such as pieces of information, actions, behavior, or opinions. Influence analytics includes modeling of the process of influence propagation and addressing algorithmic challenges that arise in solving optimization problems related to the dynamic propagation process.

Overview

Diffusion process on networks is one of the most important dynamics studied in network analysis, which can represent social influence such as the

word-of-mouth effect of a rumor in a social network, the spread of an infectious disease, opinion formation through social interaction, and many other phenomena that could happen online or offline. Although diffusion process on networks has been studied from the 1960s, in various research areas including sociology and economy, its importance has grown considerably because of the rapid growth of the web graph and online social networks. Socially, it has become more important because more and more influence is exerted on people through those networks. Academically, it has become more important because the massive scale of the networks raises new algorithmic challenges.

Among the various problems defined on the network diffusion process, this article focuses on an optimization perspective, that is, finding a small seed set of nodes in a given network that maximizes the total spread of influence in the final or the convergent state of the diffusion process. In particular, as notable examples, influence maximization arising in viral marketing and opinion maximization arising in opinion formation are discussed.

Influence Propagation

A social network acts as a medium for the spread of information, ideas, and innovations among its members. The idea of the *influence maximization problem*, which arose in the context of viral marketing, is controlling the spread so that an idea or product is widely adopted through word-of-mouth effects. More specifically, by targeting a small number of influential individuals, say, giving them free samples of the product, the goal is to trigger a cascade of influence by which friends will recommend the product to other friends, and many individuals will ultimately try it. One can rephrase this problem using graph terminology, that is, the goal is to find a set of small number of nodes, called a *seed set*, in a given network that maximizes the number of influenced nodes in the end of an influence propagation process.

Models

Most influence propagation models studied in the influence maximization problem consider a propagation process over a directed network $G = (V, E)$ that unfolds in discrete time steps in which each node is active (i.e., adopts an idea or innovation) or inactive. As representative models, this article focuses on the independent cascade (IC) model and the linear threshold (LT) model.

For a node $v \in V$, let $N_v^- = \{u \in V : uv \in E\}$ and $N_v^+ = \{w \in V : vw \in E\}$, denote the set of in-neighbors and out-neighbors of v , respectively.

Independent Cascade Model

The *independent cascade model* was firstly studied by Goldenberg et al. (2001) in the context of marketing. In this model, each arc $e \in E$ has a propagation probability $p_e \in [0, 1]$. The propagation process unfolds in discrete steps according to the following randomized rule:

- In step 0, some nodes are activated.
- When a node $v \in V$ becomes active in step $t \geq 0$, it is given a single chance of activating each inactive out-neighbor $w \in N_v^+$, which succeeds with probability p_{vw} . If v succeeds, then w will become active in step $t + 1$.
- The process terminates when no more activation is possible.

Note that, whether or not v succeeds in activating w , it cannot make any further attempts to activate w in subsequent steps.

An example of a propagation process in the IC model is shown in Fig. 1.

Linear Threshold Model

The *linear threshold model* was introduced by Granovetter (1978) to model collective behavior such as the riot and residential segregation. The threshold denotes the proportion

of others who must make a particular decision before an individual does so.

In the LT model, each arc $e \in E$ has a nonnegative weight b_e such that $\sum_{uv \in E} b_{uv} \leq 1$ for every $v \in V$. In this model, a node $v \in V$ is influenced by each in-neighbor $u \in N_v^-$ according to the weight b_{uv} . If the total amount of influence exceeds a randomly chosen threshold $\theta_v \in [0, 1]$, then v is activated. More formally, the propagation process unfolds in discrete steps according to the following rule.

- In step 0, some nodes are activated and each node $v \in V$ chooses a threshold $\theta_v \in [0, 1]$ uniformly at random from the interval $[0, 1]$.
- In step $t \geq 1$, all nodes that were active in step $t - 1$ remain active, and a node $v \in V$ is activated if the total weight of its active in-neighbors is at least θ_v .
- The process terminates when no more activation is possible.

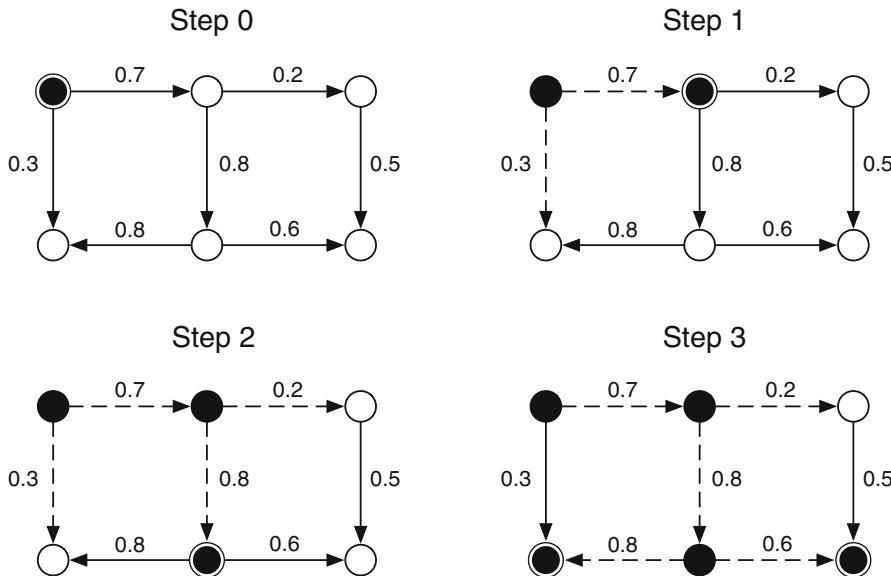

The fact that the thresholds are randomly selected is intended to model the lack of knowledge of their values. Note that, after the thresholds are fixed, the propagation process is deterministic.

An example of a propagation process in the LT model is shown in Fig. 2.

Influence Maximization

For the IC and LT models, one can formalize the influence maximization problem as follows: First, let $f : 2^V \rightarrow \mathbb{R}$ be a set function such that $f(S)$ is the expected number of activated nodes in the end of the propagation process when the propagation process starts with an initial seed set $S \subseteq V$. Then, given an additional integer parameter $1 \leq k \leq |V|$, the goal is to maximize $f(S)$ subject to $|S| \leq k$.

As computing the optimal solution is NP-hard, the following greedy algorithm is frequently used:

Influence Analytics in Graphs, Fig. 1 Example of a propagation process in the independent cascade model. Black nodes, black nodes with white boundary, and white nodes are active, activated in the current step, and inactive, respectively. Real numbers on arcs denote the success probability of activating the node in the head when the tail node is active. Step 0: The top-left vertex

is initially activated. Step 1: The top-middle vertex is activated, whereas the bottom-left vertex remains inactive. The arcs once used in the activation process will be no longer used (dashed arcs). Step 2: The bottom-middle vertex is activated. Step 3: The bottom-left and bottom-right vertices are activated

- Let S be an empty set.
- For k times:
 - Let $v \in V \setminus S$ be the vertex such that it maximizes $f(S \cup \{v\}) - f(S)$ and $f(S \cup \{v\}) - f(S) > 0$ (break ties arbitrarily).
 - Add v to S .
- Return S .

The greedy algorithm above is not merely a heuristic; it achieves $(1 - 1/e)$ -approximation to the optimal solution (Nemhauser and Wolsey 1978) for the IC and LT models due to the following key properties: (i) *monotonicity*, i.e.,

$$f(S) \leq f(T)$$

for every $S \subseteq T \subseteq V$, and (ii) *submodularity*, i.e.,

$$f(S) + f(T) \geq f(S \cap T) + f(S \cup T)$$

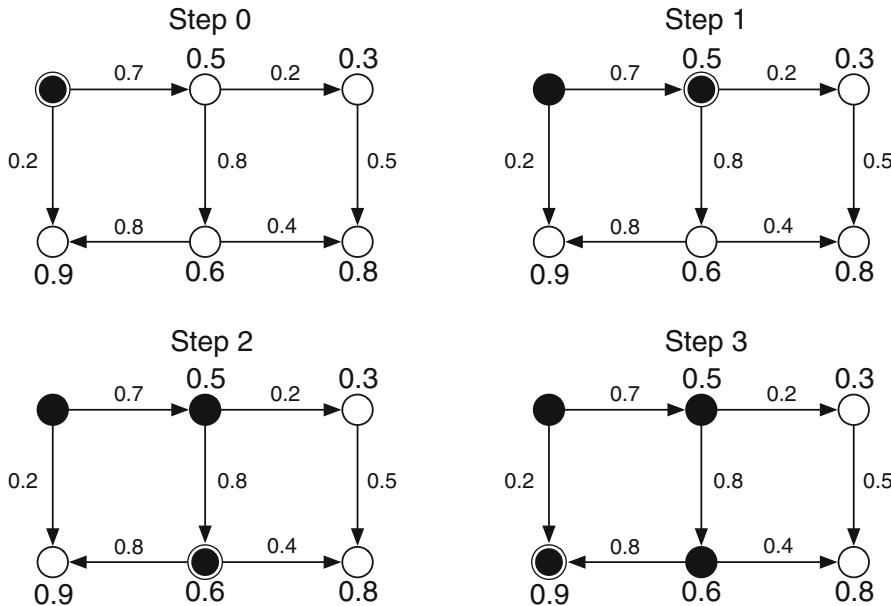

for every $S, T \subseteq V$. Monotonicity is equivalent to

$$f(S) \leq f(S \cup \{v\})$$

for every $S \subseteq V$ and $v \in V \setminus S$, meaning that the expected number of activated nodes is non-decreasing as a new node v is added into a seed set S . Submodularity is equivalent to

$$f(S \cup \{v\}) - f(S) \geq f(T \cup \{v\}) - f(T)$$

for every $S \subseteq T \subseteq V$ and $v \in V \setminus T$, meaning that the increase in the expected number of activated nodes from adding a new node v into a seed set S is no smaller than that into seed set

Influence Analytics in Graphs, Fig. 2 Example of a propagation process in the linear threshold model. Black nodes, black nodes with white boundary, and white nodes are active, activated in the current step, and inactive, respectively. Real numbers on arcs denote their weights, and

ones on nodes denote their thresholds. The top-left vertex is initially activated in Step 0 and then the top-middle, bottom-middle, and bottom-left vertices are activated in Steps 1, 2, and 3, respectively

$T \supseteq S$. Both properties are intuitively true and formally proved by Kempe et al. (2003).

An additional source of complexity in influence maximization is that evaluating the value of $f(S)$ is a $\#P$ -hard problem because $f(S)$ is defined as the expectation over exponentially many realizations of the propagation process. For details, Chen et al. (2013). Fortunately, the value of $f(S)$ can be well approximated by simulating the propagation process several times and taking the average of the number of activated nodes across the runs. Those approximated values are sufficient to obtain $(1 - 1/e - \varepsilon)$ -approximation in polynomial time for any constant $\varepsilon > 0$ (Kempe et al. 2003). This approach does not scale to large networks.

Borgs et al. (2014) achieved a scalable approximation algorithm for the influence maximization problem under the IC and LT models that runs in almost linear time in the network size. The current best time complexity for both models is $O(k(n + m) \log n / \varepsilon^2)$ and is due to Tang et al. (2014).

Learning the Model

An important question is where the edge probabilities (for the IC model) and edge weights (for the LT model) come from. These parameters are not readily available and thus must be learned. One approach that was pioneered by Saito et al. (2008) (for the IC model) and Goyal et al. (2010) (for the generalized threshold model) is to learn these parameters from action logs. An *action log* is a table $\text{Log}(\text{User}, \text{Action}, \text{Time})$ that records for every user and action performed by the user, the time at which it was performed.

Saito et al. (2008) assumed that the time stamps in an actual log of actions are partitioned into bins corresponding to discrete time steps. Given this, they develop an expectation maximization approach for learning the edge probabilities. The key idea is that based on the observed actions and the given network, one can formulate the likelihood of observing those actions given model parameters and learn the parameters as those that maximize the logarithm

of the said likelihood. A subtle point is that there may be many different ways to partition an actual action log into bins, and different partitions may lead to different values for the likelihood. The question of finding the “optimal” partitioning is not addressed by them. One inherent challenge with this approach is that the algorithm can take considerable time for learning model parameters on large networks and action logs.

Goyal et al. (2010) followed a simple frequentist approach and used a maximum likelihood estimator (MLE) for learning the edge weights under the generalized threshold model, which is a generalization of the LT model. In addition to a framework for learning model parameters, they show that their framework can handle the case where influence probabilities change (specifically, decay) over time (Indeed, in practice, one can expect influence to decay over time.). Using this, they show that in addition to predicting user activation, they can also predict the most likely time of activation of users. They also propose notions of user and action influenceability and ways of measuring them from an action log and show that for users with higher influenceability, both activation prediction and prediction of the most likely time of activation can be done more accurately. The learning algorithm proposed in Goyal et al. (2010) scales to large networks and action logs: the algorithm makes just one pass over the action log.

There has been significant subsequent work on learning influence models from given action propagation data, including improvements and extensions, which are omitted for lack of space.

Opinion Formation

Different from influence propagation models such as the IC and LT models, where nodes are in a binary state of being active or inactive, in opinion formation models, the state of a node $v \in V$ is a real value z_v which captures the *opinion* of the node. Typically, the opinion values range over the interval $[0, 1]$ (sometimes, $[-1, 1]$), where $z_v = 1$ signifies a strong positive opinion, while $z_v = 0$ signifies a strong negative opinion.

Similar to the influence propagation models, the underlying principle behind opinion formation models is that the state (opinion) of a node is determined by the states of the nodes in the neighborhood. Following the intuition that the opinions of individuals in real life are influenced from the opinions in their social circle, the opinion formation models assume a propagation of opinions in the network. However instead of activating the nodes, the opinion formation process adjusts the nodes’ opinions according to a specific model.

A variety of opinion formation processes have been proposed that aim to model different aspects of opinion dynamics (Degroot 1974; Hegselmann and Krause 2002; Castellano et al. 2009), such as, consensus (convergence to a single opinion), polarization (clustering of opinions around two extreme positions), or plurality (existence of multiple clusters of opinions). This article focuses on algorithmic challenges that arise in these processes. More specifically, it focuses on the problem of *opinion maximization*, where the goal is to maximize (say) the positive opinion in the network.

The Friedkin and Johnsen Model

A widely adopted opinion formation model is the model of Friedkin and Johnsen (1990). In this model, the network is undirected, and every node $v \in V$ has an *internal* opinion value $s_v \in [0, 1]$ and an *expressed* opinion value $z_v \in [0, 1]$. The internal opinion corresponds to the prior beliefs of the individual, and it is fixed and unchanged throughout the opinion formation process. The expressed opinion is malleable, and its value is the result of the influences exerted on the node by its neighbors in the graph.

Mathematically, the expressed opinion is defined as follows:

$$z_v = \frac{s_v + \sum_{u \in N_v} z_u}{1 + |N_v|}, \quad (1)$$

where $N_v = \{w \in V : vw \in E\}$ is the set of neighbors of v . Equation (1) intuitively means that the expressed opinion of a node is determined by taking average over its own internal opinion and the expressed opinions of its neighbors.

The expressed opinions can be computed by solving a system of linear equations. Let \mathbf{s} be the vector of internal opinions and \mathbf{z} the vector of expressed opinions. Then

$$\mathbf{z} = (\mathbf{I} + \mathbf{L})^{-1} \mathbf{s} \quad (2)$$

where \mathbf{L} is the Laplacian matrix of the adjacency matrix of the social graph.

The expressed opinions can also be viewed as the output of a dynamic system which iteratively updates the opinion values. The opinion formation model proceeds as follows:

- In step 0, initialize for each node $v \in V$, $z_v^0 = s_v$.
 - In step $t \geq 1$, all nodes update their expressed opinions as follows:
- $$z_v^t = \frac{s_v + \sum_{u \in N_v} z_u^{t-1}}{1 + |N_v|}$$
- Repeat the process until all expressed opinion values converge.

There are several interpretations of the Friedkin and Johnsen model. Bindel et al. (2015) showed that the opinion values are the result of the selfish behavior of nodes, where a node v tries to minimize their personal cost of adopting opinion value z_v , defined as

$$C(z_v) = (z_v - s_v)^2 + \sum_{u \in N_v} (z_v - z_u)^2$$

The first term in the cost function is the cost incurred to node v for compromising their own internal beliefs. The second term is the cost incurred to node v for nonconforming with the opinions of their social neighborhood.

A different interpretation is offered by Gionis et al. (2013), where they model the opinion formation process as a random walk on a graph with absorbing nodes. Intuitively, the social network

is viewed as an electrical network, where edges are resistances. Each node is connected to its own voltage source, with voltage equal to the internal opinion value of the node (in the absorbing random walk, these are absorbing nodes). The voltage value at each node is equal to the expressed opinion of the node.

Opinion Maximization

In the *opinion maximization* problem (Gionis et al. 2013), the goal is to maximize the sum of the opinion values in the network. This sum captures the average opinion in the network, which should be as favorable as possible. There are two ways to affect the average opinion in the network:

- I. Convince nodes to change their internal opinions to be as positive as possible (set $s_v = 1$). In the electrical network interpretation, this corresponds to setting the voltage of the power source of v to +1
- II. Convince nodes to adopt a positive expressed opinion (set $z_v = 1$). In this case the expressed opinion value remains fixed, and it is not iteratively updated. In the electrical network interpretation, this corresponds to turning node v into a voltage source with voltage +1.

The goal is to find a small set of nodes $S \subseteq V$ such that changing their opinions maximizes the sum of expressed opinion values. More formally, let G denote the social network. Let $g(\mathbf{z}; G, \mathbf{s}) = \sum_{v \in V} z_v$ be the sum of opinion values, and let $g(\mathbf{z}; S, G, \mathbf{s})$ be the sum of opinion values after changing the opinions of the nodes in S , by setting either their internal or expressed opinion to 1. The goal is to find a set S of k nodes so as to maximize $g(\mathbf{z}; S, G, \mathbf{s})$.

In Case I, the problem can be solved optimally in polynomial time by simply selecting S to be the nodes with the lowest internal opinion value. This follows from Eq.(2) and the fact that $g(\mathbf{z}; S, G, \mathbf{s}) = \sum_{v \in V} s_v$ (Gionis et al. 2013).

In Case II, the problem is NP-hard. Similar to influence maximization, the value of g as a

function of the set S is monotone and submodular, and thus, the greedy algorithm provides a $(1 - 1/e)$ -approximation to the optimal solution.

Future Directions

Although influence maximization and opinion maximization have been intensively studied, there are still many challenges that should be addressed.

The greedy method achieves $(1 - 1/e)$ -approximation to the optimal solution both for the influence maximization and opinion maximization problems. However, empirical performance seems to be much better than this theoretical guarantee and this gap should be filled.

The main focus of the influence maximization problem is to maximize the *expected* number of activated nodes. However, maximizing the number of activated nodes in less propagated scenarios is also important. To address this problem, Ohsaka and Yoshida (2017) exploited the notion of *conditional value at risk* (CVaR) from the field of financial risk measurement, which is the expected number of activated nodes in the worst α -fraction of the scenarios, where $\alpha \in (0, 1)$ is a parameter specified by a user. They proposed a polynomial-time algorithm that produces a portfolio over initial seed sets with a provable guarantee on its CVaR. Optimizing other measures on probability distributions such as variance will be interesting.

Information propagation models require some parameters on arcs (edge probabilities or edge weights), which are typically unknown for real networks. As previously discussed, approaches for learning these parameters have been developed. However, there may be noise in the learned parameters, on account of the action log being noisy or because of the inherent uncertainty of the learning problem. Hence, it is natural to introduce some intervals on those parameters and seek an initial seed set that has a good approximation guarantee no matter how parameters are chosen from the associated intervals. This problem is called the *robust influence maximization*, and

some positive and negative results are obtained by Chen et al. (2016) and He and Kempe (2016). Tightening the gap between them is an interesting problem.

Influence and opinion maximization can be considered together, in a model where nodes carry an opinion value, and the goal is to maximize the overall opinion of the activated nodes (e.g., see the work of Zhang et al. 2013). This formulation opens the possibility of combining techniques from both problems to design better models and algorithms.

The idea of selecting a few nodes to affect node opinions has also been applied to tasks other than opinion maximization. For example, Matakos et al. (2017) applied this idea for reducing polarization, while Golshan and Terzi (2017) applied it for minimizing tension in a related model. It would be interesting to consider other applications of this idea in different settings.

In-Memory Transactions

Spyros Blanas

Computer Science and Engineering, The Ohio State University, Columbus, OH, USA

Definitions

In-memory transactions are database transactions that operate on data that are stored in memory. Because the main memory is much faster than a disk, the processing throughput of in-memory transactions can be orders of magnitude higher than when transactions manipulate data on disk. To realize this potential, an in-memory transaction processing engine needs to avoid contention, blocking, and context switching when accessing memory for high performance while guaranteeing the atomicity, isolation, and durability of in-memory transactions for correctness.

Overview

Database management systems were designed assuming that the database resides on disk, which is orders of magnitude slower than memory. Many design decisions about data storage and transaction management focused on improving the concurrency and the performance of disk accesses. Less attention was devoted in making accesses to memory efficient. Through the decades, however, the memory capacity of each server grew substantially as memory modules became denser and cheaper. As a consequence, the actively-updated part of many transactional databases can now be stored entirely in memory. This has profound implications for the architecture of database management systems for transaction processing workloads.

Modern in-memory database engines strive to eliminate contention, blocking, and context switching when accessing memory-resident data. Through a combination of novel concurrency control algorithms, clever in-memory data storage methods, and efficient implementations, an in-memory transaction processing engine can process millions of transactions per second on a single server.

The impressive performance gains from in-memory transaction processing have attracted the interest of both established database vendors and disruptors to offer in-memory transaction processing capabilities in commercial products. Exemplars of established database management systems that are optimized for in-memory transactions include Microsoft SQL Server (Hekaton), SAP HANA, and Oracle 12c. Many start-ups, including VoltDB, Aerospike, and MemSQL, also offer products with in-memory transaction capabilities.

Key Research Findings

The intellectual underpinning of in-memory transaction processing is research on how to improve the concurrency of non-conflicting operations in memory. One research direction

focuses on in-memory data structures for highly concurrent accesses, frequently using lock-free techniques to eliminate blocking and context switching. Another research direction is fast concurrency control algorithms that enforce transactional atomicity and isolation by delaying or aborting transactions with conflicting logical operations. In addition, an in-memory transaction processing system needs to ameliorate contention at the tail of the transaction log and quickly recover the database after a crash. The research challenge is how to efficiently execute thousands of very short in-memory transactions concurrently.

Data Storage

Database systems that are optimized for in-memory transactions do not organize data in a traditional buffer pool. Prior work points to a number of disadvantages of using a buffer pool for in-memory data management. A buffer pool tracks pages, and updating pages requires costly coordination using locks (Harizopoulos et al. 2008). Lock-based synchronization blocks the thread that issues a conflicting request, which needs to either context switch or spin until the lock is granted. The overhead of context switching and spinning can be thousands of CPU cycles, which is comparable to the compute cost of completing an in-memory transaction. Therefore, conflicts on page locks of frequently accessed tuples would significantly underutilize a modern CPU for in-memory transaction processing. In addition, updating data in pages causes spurious conflicts: non-conflicting requests that access different tuples in the same page may spuriously conflict on the page lock.

Instead, database systems that are optimized for in-memory transactions avoid locking when reading data. Research has focused on two families of data structures: hash-based data structures use a hash function to determine the access location; tree-based data structures organize data hierarchically. In general, hash-based data structures are faster when looking up a single key as they do not need to traverse a hierarchy of objects. Tree-based structures out-

perform when subsequent accesses are sequential because they benefit from spatial and temporal locality.

Hash-Based Indexing

Hash-based indexing has been proposed for data storage in main memory transaction processing systems such as Hekaton (Diaconu et al. 2013). Multiple attributes can be indexed; each indexable attribute will have a separate in-memory hash table structure. An in-memory hash table is created by hashing the attribute of every tuple in a table. Every hash bucket is the root of a singly linked list that stores all the tuples that hash to the same value. By tracking individual tuples, this design avoids spurious conflicts during concurrent operations. In addition, using a singly linked list allows for lock-free operations on the hash table. Readers start their search at the hash table bucket and follow pointers to the next data item. Modifying the linked list uses atomic compare-and-swap (CAS) instructions.

Avoiding lock contention and blocking, however, requires lock-free memory allocation and reclamation. A lock-free memory allocator guarantees progress regardless of whether some threads are delayed or even killed and regardless of scheduling policies. Prior work has investigated how memory allocators can offer freedom from deadlocks, gracefully handle asynchronous signals, safely handle priority inversion, and tolerate thread preemption and thread termination (Michael 2004b). Another challenge is safe memory reclamation. In particular, the problem is how to allow memory to be freed in a lock-free manner that guarantees that no thread currently accesses this memory. One solution from prior work keeps the pointers that a thread accesses in a globally visible structure and carefully monitors when a reclamation is safe (Michael 2004a).

Bw-Tree

A tree-based in-memory data structure is the Bw-Tree (Levandoski et al. 2013). The Bw-Tree organizes data in pages and closely resembles the Blink-tree data structure (Lehman and Yao 1981). Nodes in the Bw-Tree contain key and

pointer pairs, sorted by key, to direct searches to lower levels of the Bw-Tree. In addition, all nodes contain a side link pointer that points to the immediate right sibling on the same level of the tree. The Bw-Tree thus offers logarithmic access time for key lookups and linear access time for queries on a one-dimensional key range. Range queries are particularly efficient as they access contiguous data items. Unlike disk-based structures that impose a pre-defined page size, pages in a Bw-tree are elastic: they can grow to arbitrarily large sizes until split by a system management operation.

The main distinction from disk-oriented tree structures is that all page references in the Bw-Tree are logical references to a page identifier. This level of indirection allows readers to access the data structure in a lock-free manner. An in-memory hash table, called the mapping table, maintains the current mapping of page identifiers to physical memory locations. The Bw-Tree never updates in place (i.e., it never modifies the contents of a page). Instead, updates in a Bw-Tree create delta records that are prepended to existing pages and describe the update. The memory address of the delta record is atomically installed in the mapping table using the atomic compare-and-swap (CAS) instruction. Hence, a concurrent read request that looks up the physical location of a logical page identifier in the mapping table will either see the new page address (that contains the delta record) or the old page address (that skips the delta record), but it will never see an inconsistent state.

Masstree

Another tree-based in-memory data structure is Masstree (Mao et al. 2012). Masstree combines properties of a trie and a B⁺-tree in one data structure. The Silo transaction processing engine uses a structure similar to Masstree for data storage (Tu et al. 2013). Masstree tracks individual tuples and carefully coordinates writes for high concurrency.

Masstree consists of multiple trees arranged in layers. Each layer is indexed by a different 8-byte slice of the key. Therefore, layer 0 has a single tree that is indexed by bytes 0–7 of the

key; trees in layer 1, the next deeper layer, are indexed by bytes 8–15; trees in layer 2 by bytes 16–23; and so forth. Each tree contains interior nodes and border (leaf) nodes. Interior nodes form the trie, whereas border nodes store values (akin to a B^+ -tree) or pointers to trees in deeper layers. Masstree creates additional layers as needed when an insertion cannot use an existing tree.

Masstree is designed for highly concurrent accesses. Instead of a lock, each node in the Masstree structure has a version counter. A writer increments the version counter of a node to denote an in-progress update and increments the version number again after the update has been installed. Readers coordinate with writers by checking the version of a node before a read and comparing this number to the version after the operation. If the two version numbers differ or a version number is an odd number, the reader may have observed an inconsistent state and will retry. Therefore, conflicting requests in Masstree may restart, but readers will never write globally accessible shared memory.

Concurrency Control Algorithms

In-memory concurrency control algorithms guarantee the atomicity and isolation of in-memory transactions. The goal is serializability, that is, to allow transactions to execute concurrently while appearing to the user that they run in isolation. If the concurrency control algorithm detects an operation that violates serializability, such as two transactions updating the same item at the same time, it can delay or abort a transaction. The challenge is detecting and resolving any conflicts efficiently.

A widely used concurrency control protocol is single-version two-phase locking (Bernstein et al. 1987). In this protocol, transactions acquire read or write locks on a tuple, perform the operation, and release the lock at the end of the transaction. Lower isolation levels than serializable permit a transaction to release read locks earlier.

Single-version two-phase locking poses three problems for in-memory transactions. First, writers block readers in single-version two-phase locking. It is counterintuitive to many users why a

transaction that only reads should wait for update transactions, especially if the query does not need to access the latest data. In addition, blocking introduces the possibility of deadlocks where two transactions wait on each other. This requires the system to either perform expensive deadlock detection to abort a transaction that participates in a wait-for cycle or burden the user to specify a timeout parameter after which the transaction will be restarted. Finally, single-version two-phase locking triggers additional memory writes to the locks: a transaction needs to perform twice as many writes to locks (one write to acquire, one write to release) as the number of the records that it will access.

For these reasons, in-memory transaction processing research has looked for alternatives to single-version two-phase locking for in-memory transactions. Concurrency control algorithms for in-memory transactions can be classified into partitionable and non-partitionable categories.

Concurrency Control for Partitionable Workloads

Many transaction processing workloads exhibit a fairly predictable access pattern that allows a transaction processing system to partition the database such that most transactions only access a single partition. This access predictability is often because of the hierarchical structure of database entities, such as bank branches and accounts, customers and orders, or suppliers and parts.

The H-Store prototype (Kallman et al. 2008) abandons complex concurrency control protocols and just executes transactions serially on different database partitions. Multi-partition transactions, however, become more expensive as they require coordination across partitions, even if these partitions are assigned to different threads in the same node.

The DORA prototype (Pandis et al. 2010) proposes a shared-everything design that assigns data to threads. Transactions are decomposed into subtransactions that form a transaction flow graph. DORA then carefully routes subtransactions to the appropriate partition for execution to maintain serializability.

Partition-based approaches work very well if one can devise a good partitioning strategy. This may be challenging even for domain experts, however, as the query workload may change unpredictably. Automated methods can create a partitioning scheme for a given database and query workload. Schism (Curino et al. 2010) is a workload-aware database partitioner that attempts to minimize the number of distributed transactions while producing balanced partitions. Schism models this as a graph problem, where graph nodes are tuples and graph edges are co-accesses by the same transaction. Obtaining n balanced partitions that minimize inter-partition traffic requires performing n min-cuts to the graph. Sampling can be used to reduce the size of these graphs for very large databases. Clay (Serafini et al. 2016) proposes to perform partitioning in an adaptive and online fashion by carefully migrating tuple groups across partitions.

Concurrency Control for Non-partitionable Workloads

Not all in-memory transaction processing workloads are partitionable. Hekaton (Diaconu et al. 2013) and Silo (Tu et al. 2013) are designed for non-partitionable workloads and use optimistic multi-version concurrency control for transaction isolation. This concurrency control algorithm is rooted in the observation is that the short duration of in-memory transactions makes conflicts rare in a massive in-memory database. Optimistic concurrency control executes transactions speculatively until the end. Before making the writes of the transaction visible, optimistic concurrency control then verifies that the transaction did not observe or produce any inconsistent state because of conflicts.

Optimistic concurrency control validates that a transaction is serializable by comparing the set of accessed records of the committing transaction with the set of accessed records of every other active transaction in the system (Kung and Robinson 1981). This check becomes proportionally more expensive as the number active transactions increase in the system. This validation mechanism becomes a bottleneck with the massive

concurrency of modern multi-socket, multi-core CPUs for in-memory transactions.

The Hekaton in-memory concurrency control protocol (Larson et al. 2011) directly installs tentative versions in the database and carefully controls the visibility of these pending records by active transactions. A transaction then only needs to check once with the database to verify that no conflicting versions appeared or disappeared from the view. This permits the validation to be done in parallel from multiple threads without additional coordination. Compared with two-phase locking, non-conflicting transactions in the Hekaton in-memory concurrency control protocol perform an additional read per accessed record during validation, instead of two additional writes to acquire and release locks.

Multi-versioning allows readers to bypass writers. By retaining multiple versions, an in-memory transaction processing system can redirect readers to earlier versions instead of waiting for the writer to complete its transaction. Logically, the read transaction appears as if it arrived “just before” a write transaction. However, storing multiple versions also has drawbacks. First, the memory footprint of the database increases proportionally to the number of versions kept. Second, a garbage collection mechanism needs to determine when old versions will no longer be visible by any transaction and remove them from in-memory data structures. Recent work systematically explores the trade-offs between concurrency control protocol, version storage, garbage collection, and index management (Wu et al. 2017).

Durability Mechanisms for In-Memory Transactions

In-memory transaction processing systems must guarantee transaction durability in the presence of failures. The absence of a buffer pool means that “dirty” pages will never be written to durable storage. Therefore, in a main memory setting, traditional redo/undo logging and recovery as developed by ARIES (Mohan et al. 1992) is commonly replaced by redo-only logging.

Two challenges are ameliorating contention for the tail of the log and controlling the fre-

quency of checkpointing. Early lock release, consolidated buffer allocation, and asynchronous I/O move the latency of hardening log frames out of the critical path (Johnson et al. 2010). The checkpointing frequency is a trade-off between steady-state performance and recovery time: frequent checkpointing takes CPU cycles away from transaction processing, while checkpointing infrequently means substantial recovery work on failure.

Other Research Directions

In-memory transaction processing is a very active and evolving research field. Other research efforts improve the performance of in-memory transaction processing in the presence of heterogeneous workloads (Kim et al. 2016) and hotspots (Ren et al. 2016; Wang and Kimura 2016) or take advantage of determinism in transaction execution (Thomson et al. 2012). Another research direction considers properties of the serialization graph to enforce serializability (Wang et al. 2017) and reduce false aborts (Yuan et al. 2016). Multi-versioning has been shown to ameliorate lock contention through an indirection table (Sadoghi et al. 2014). Finally, new logging and recovery protocols promise to leverage byte-addressable non-volatile memory for in-memory transaction durability (Arulraj et al. 2016; Kimura 2015).

[Ontology-based Data Access](#)

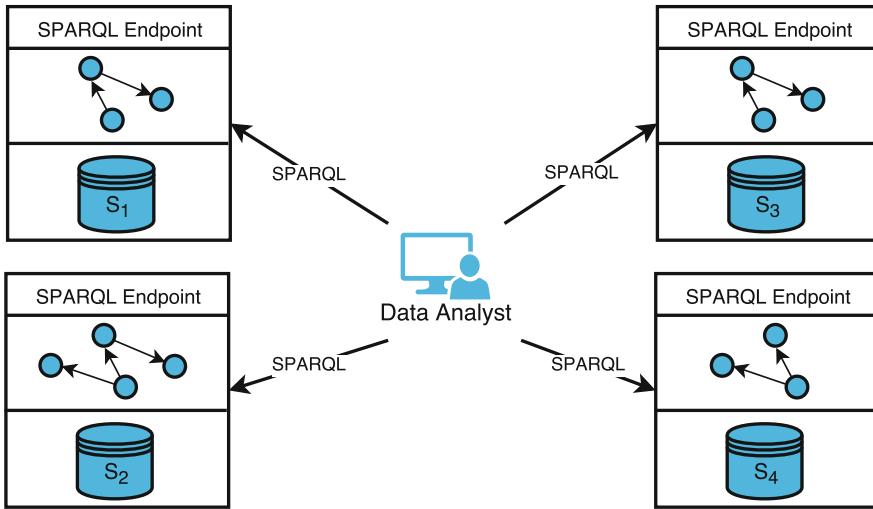

Definitions

The purpose of an integration-oriented ontology is to provide a conceptualization of a domain of interest for automating the data integration of an evolving and heterogeneous set of sources using Semantic Web technologies. It links domain concepts to each of the underlying data sources via schema mappings. Data analysts, who are domain experts but not necessarily have technical data management skills, pose ontology-mediated queries over the conceptualization, which are automatically translated to the appropriate query language for the sources at hand. Following well-established rules when designing schema mappings allows to automate the process of query rewriting and execution.

Overview

Information integration, or data integration, has been an active problem of study for decades. Shortly, it consists in giving a single query involving several data sources to get a single answer.

Semantic Web technologies are well-suited to implement such data integration settings, where given the simplicity and flexibility of ontologies, they constitute an ideal tool to define a unified interface (i.e., *global vocabulary* or *schema*) for such heterogeneous environments. Indeed, the goal of an ontology is precisely to conceptualize the knowledge of a domain; see Gruber (2009). Ontologies are structured into two levels, the TBox and the ABox, where the former represents general properties of concepts and roles (namely, terminology) and the latter represents instances of such concepts and roles (namely, assertions). Such knowledge is commonly represented in terms of the Resource Description Framework (RDF) in the form of triples *subject-predicate-object* (see Wood et al. 2014), which enables to automate its processing and thus opens the door to exchange such information on the Web as Linked Data; see Bizer et al. (2009). Therefore, a vast number of ontologies, or vocabularies, have been proposed to achieve com-

Integration-Oriented Ontology, Fig. 1 Example of query execution in the Semantic Web

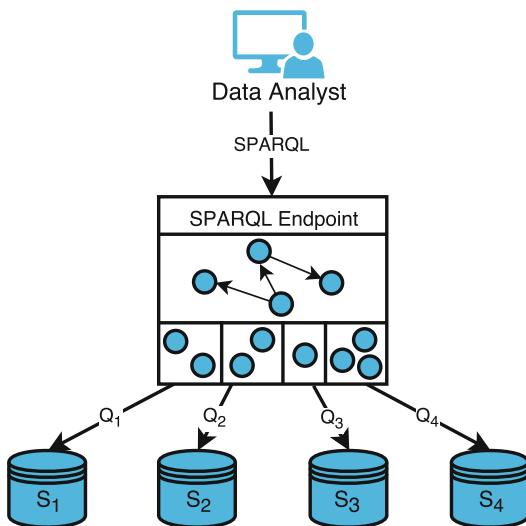

mon consensus when sharing data, such as the RDF Data Cube Vocabulary or the Data Catalog Vocabulary.

Data providers make available their datasets via SPARQL endpoints that implement a protocol where given a SPARQL query, a set of triples is obtained, properly annotated with respect to an ontology. Hence, the data analysts' queries must separately fetch the sets of triples of interest from each endpoint and integrate the results. Furthermore, such settings assume that both TBox and ABox are materialized in the ontology. Figure 1 depicts the Semantic Web architecture, where the data analyst is directly responsible of firstly decomposing the query and issuing the different pieces into several homogeneous SPARQL endpoints and afterward collecting all the results and composing the single required answer.

The alternative architecture for data integration is that of a federated schema that serves as a unique point of entry, which is responsible of mediating the queries to the respective sources. Such federated information systems are commonly formalized as a triple $(\mathcal{G}, \mathcal{S}, \mathcal{M})$, such that \mathcal{G} is the global schema, \mathcal{S} is the source schema, and \mathcal{M} are the schema mappings between \mathcal{G} and \mathcal{S} ; see Lenzerini (2002). With such definition two major problems arise, namely, how to design mappings capable of expressing complex rela-

tionships between \mathcal{G} and \mathcal{S} and how to translate and compose queries posed over \mathcal{G} into queries over \mathcal{S} . The former led to the two fundamental approaches for schema mappings, *global-as-view* (GAV) and *local-as-view* (LAV), while the latter has generically been formulated as the problem of rewriting queries using views; see Halevy (2001) for a survey.

Still, providing an integrated view over a heterogeneous set of data sources is a challenging problem, commonly referred to as the data variety challenge, that traditional data integration techniques fail to address in Big Data contexts given the heterogeneity of formats in data sources; see Horrocks et al. (2016). Current attempts, namely, *ontology-based data access* (OBDA), adopt ontologies to represent \mathcal{G} , as depicted in Fig. 2. In such case, unlike in the Semantic Web, the TBox resides in the ontology as sets of triples, but the ABox in the data sources, in its source format. The most prominent OBDA approaches are based on generic reasoning in description logics (DLs) for query rewriting (see Poggi et al. 2008). They present data analysts with a virtual knowledge graph (i.e., \mathcal{G}), corresponding to the TBox of the domain of interest, in an *OWL2 QL* ontology; see Grau et al. (2012). Such TBox is built upon the *DL-Lite* family of DLs, which allows to represent conceptual models with polynomial

Integration-Oriented Ontology, Fig. 2 Example of query execution in integration-oriented ontologies

cost for reasoning in the TBox; see Calvanese et al. (2007). These rewritings remain tractable as schema mappings follow a GAV approach that characterize concepts in \mathcal{G} in terms of queries over S , providing simplicity in the query answering methods, consisting just of unfolding the queries to express them in terms of the sources. More precisely, given a SPARQL query over \mathcal{G} , it is rewritten by generic reasoning mechanisms into a first-order logic expression and further translated into a union of conjunctive queries over S . Nevertheless, despite the flexibility on querying, the management of the sources is still a problem (magnified in Big Data settings), as the variability in their content and structure would potentially entail reconsidering all existing mappings (a well-known drawback in GAV).

Alternatively to generic reasoning-based approaches, we have vocabulary-based approaches, which are not necessarily limited by the expressiveness of a concrete DL, as they do not rely on generic reasoning algorithms. In such settings, tailored metadata models for specific integration tasks have been proposed, focusing on linking data sources by means of simple annotations with external vocabularies; see Varga et al. (2014). With such simplistic approach, it is possible to define LAV mappings that characterize elements of the source schemata in terms of a query over

the common ontology (facilitating the management of evolution in the sources). However, in the case of LAV, the trade-off comes at the expense of query answering, which now becomes a computationally complex task. Different proposals of specific algorithms exist in the literature for query rewriting under LAV mappings, such as the Bucket algorithm (see Levy et al. 1996) or MiniCon (see Pottinger and Halevy 2001). In the context of integration-oriented ontologies, new specific algorithms must be devised that leverage the information of the metamodel and the annotations to automatically rewrite queries over \mathcal{G} in terms of S .

Key Research Findings

In the line of OBDA, *DL-Lite* set the cornerstone for research, and many extensions have been proposed in order to increase the expressivity of the ontology while maintaining the cost of reasoning for query answering tractable. Some examples of such approaches are the families of description logics *ELH1* (see Pérez-Urbina et al. 2009), *Datalog*[±] (see Gottlob et al. 2011), or *ALC* (see Feier et al. 2017). Attention has also been paid to change management in this context and the definition of a logic able to represent temporal changes in the ontology; see Lutz et al. (2008). Relevant examples include *TQL* that provides a temporal extension of *OWL2 QL* and enables temporal conceptual modeling (see Artale et al. 2013) and a logic that delves on how to provide such temporal aspects for specific attributes (see Keet and Ongoma 2015).

Regarding vocabulary-based approaches purely in the context of data integration, R2RML has been proposed as a standard vocabulary to define mappings from relational databases to RDF (see Cyganiak et al. 2012), and different techniques ad hoc appeared to automatically extract such mappings; see Jiménez-Ruiz et al. (2015).

Examples of Application

Prominent results of generic reasoning OBDA systems are Ontop (see Calvanese et al. 2017),

Grind (see Hansen and Lutz 2017), or Clipper (see Eiter et al. 2012). Ontop provides an end-to-end solution for OBDA, which is integrated with existing Semantic Web tools such as Protégé or Sesame. It assumes a *DL-Lite* ontology for \mathcal{G} , and while processing an ontology-mediated query, it applies several optimization steps. Oppositely, Grind assumes that \mathcal{G} is formulated using the \mathcal{EL} DL, which has more expressivity than *DL-Lite*, but does not guarantee that a first-order logic rewriting exists for the queries. Clipper relies on Horn-SH \mathcal{IQ} ontologies, a DL that extends *DL-Lite* and \mathcal{EL} . All works assume relational sources and translate first-order logic expressions into SQL queries. Nonetheless, recent works present approaches to adopt NOSQL stores as underlying sources, such as MongoDB; see Botoeva et al. (2016).

Regarding vocabulary-based approaches, we can find an RDF metamodel to be instantiated into \mathcal{G} and S for the purpose of accommodating schema evolution in the sources and use RDF named graphs to implement LAV mappings; see Nadal et al. (2018). Such approach simplifies the definition of LAV mappings, for nontechnical users, which has been commonly characterized as a difficult task. Query answering, however, is restricted to only traversals over \mathcal{G} . Another proposal is GEMMS, a metadata management system for Data Lakes, that automatically extracts metadata from the sources to annotate them with respect to the proposed metamodel; see Quix et al. (2016).

Future Directions for Research

Despite that much work has been done in the foundations of OBDA and description logics, there are two factors that complicate the problem in the context of Big Data, namely, size and lack of control over the data sources. Given this lack of control and the heterogeneous nature of data sources, it is needed to further study the kind of mappings and query languages that can be devised for different data models. Nevertheless, this is not enough; new governance mechanisms must be put in place giving rise to Semantic Data Lakes, understood as huge repositories of

disparate files that require advanced techniques to annotate their content and efficiently facilitate querying. Related to this efficiency, more attention must be paid to query optimization and execution, specially when combining independent sources and data streams. Finally, from another point of view, given that the goal of integration-oriented ontologies is to enable access to non-technical users, it is necessary to empower them by providing clear and traceable query plans that, for example, trace provenance and data quality metrics throughout the process.

- Data streaming focuses on estimating functions over streams, which is an important task in data-intensive applications. It aims at approximating functions or statistical measures over (distributed) massive stream(s) in polylogarithmic space over the size and/or the domain

size (i.e., number of distinct items) of the stream(s).

Overview

Many different domains are concerned by the analysis of streams, including machine learning, data mining, databases, information retrieval, and network monitoring. In all these fields, it is necessary to quickly and precisely process a huge amount of data. This can also be applied to any other data issued from distributed applications such as social networks or sensor networks. Given these settings, the real-time analysis of large streams, relying on full-space algorithms, is often not feasible. Two main approaches exist to monitor massive data streams in real time with small amount of resources: sampling and summaries.

Computing information theoretic measures in the data stream model is challenging essentially because one needs to process a huge amount of data sequentially, on the fly, and by using very little storage with respect to the size of the stream. In addition, the analysis must be robust over time to detect any sudden change in the observed streams (which may be an indicator of some malicious behavior).

Data Streaming Models

Let (Muthukrishnan 2005) consider a stream $\sigma = \langle t_1, \dots, t_j, \dots, t_m \rangle$, where each item t is drawn from a universe of size n . More in details, t denotes the value of the item in the set $[n] = \{1, \dots, n\}$, while the subscript j denotes the position in the stream in the index sequence $[m] = \{1, \dots, m\}$. Then m is the size (or number of items) of the stream σ , and n is the number of distinct items. Notice that in general, both n and m are large (e.g., network traffic) and unknown.

The stream σ implicitly defines a frequency vector $\mathbf{f} = \langle f_1, \dots, f_t, \dots, f_n \rangle$ where f_t is the frequency of item t in the stream σ , i.e., the number of occurrences of item t in σ . The empirical probability distribution is defined as $\mathbf{p} = \langle p_1, \dots, p_t, \dots, p_n \rangle$, where $p_t = f_t/m$ is the empirical probability of occurrence of item

t in the stream σ . Our aim is to compute some function ϕ on σ . In this model we are allowed only to access the sequence in its given order (no random access), and the function must be computed in a single pass (online). The challenge is to achieve this computation in sublinear space and time with respect to m and n . In other words, the space and time complexities should be at most $smallO(\min\{m, n\})$, but the goal is $O(\log(m \cdot n))$. However, since reaching the latter bound is quite hard (if not impossible), one deals in general with complexities such as $polylog(m, n)$. In general, $\phi(x)$ is said to be $polylog(x)$ if $\exists C > 0$, $\phi(x) = O(\log^C x)$. By abusing the notation, we then define $polylog(m, n)$ as $\exists C, C' > 0$ such that $\phi(m, n) = O(\log^C m + \log^{C'} n)$.
