Sliding window model — In many applications, there is a greater interest in considering only the “recently observed” items than the whole semi-infinite stream. This gives rise to the *sliding window* model (Datar et al. 2002): items arrive continuously and expire after exactly M steps. The relevant data is then the set of items that arrived in the last M steps, i.e., the *active window*. A step can either be defined as a sample arrival, then the active window would contain exactly M items, and the window is said to be count-based. Otherwise, the step is defined as a time tick, either logical or physical, and the window is said to be time-based. More formally, let us consider the count-based sliding window and recall that by definition, t_j is the item arriving at step j . In other words, the stream σ at step m is the sequence $\langle t_1, \dots, t_{m-M}, t_{m-M+1}, \dots, t_m \rangle$. Then, the desired function ϕ has to be evaluated over the stream $\sigma(M) = \langle t_{m-M+1}, \dots, t_m \rangle$. Notice that if $M = m$, the sliding window model boils down to the classical data streaming model. Two related models may be named as well: the landmark window and jumping window models. In the former, a step (landmark) is chosen, and the function is evaluated on the stream following the landmark. In the jumping window model, the sliding window is split into sub-windows and moves forward only when the most recent sub-window is full (i.e., it jumps forward). In general,

solving a problem in the sliding window model is harder than in the classical data streaming model: using little memory (low space complexity) implies some kind of data aggregation. The problem is then how to slide the window forward, i.e., how to remove the updates performed by the items that exited the window, and how to introduce new items. For instance, *basic counting*, i.e., count the number of 1 in the stream of bits, is a simple problem whose solution is a prerequisite for efficient maintenance of a variety of more complex statistical aggregates. While this problem is trivial for the data streaming model, it becomes a challenge in the sliding windowed model (Datar et al. 2002).

Distributed streaming model and functional monitoring — In large distributed systems, it is most likely critical to gather various aggregates over data spread across a large number of nodes. This can be modeled by a set of nodes, each observing a stream of items. These nodes collaborate to evaluate a given function over the global distributed stream. For instance, current network management tools analyze the input streams of a set of routers to detect malicious sources or to extract user behaviors (Anceaume and Busnel 2014; Ganguly et al. 2007).

The *distributed streaming* model (Gibbons and Tirthapura 2001) considers a set of nodes making observations and cooperating, through a *coordinator*, to compute a function over the union of their observations. More formally, let \mathcal{I} be a set of s nodes $S_1, \dots, S_i, \dots, S_s$ that do not communicate directly between them but only with a coordinator (i.e., a central node or base station). The communication channel can be either one way or bidirectional. The *distributed* stream σ is the union the sub-streams $\sigma_1, \dots, \sigma_i, \dots, \sigma_s$ locally read by the s nodes, i.e., $\sigma = \bigcup_{i=1}^s \sigma_i$, where $\sigma_i \cup \sigma_j$ is a stream containing all the items of σ_i and σ_j with any interleaving. The generic stream σ_i is the input to the generic node S_i . Then we have $m = \sum_{i=1}^s m_i$, where m_i is the size (or number of items) of the i -th sub-stream σ_i of the distributed stream σ . Each sub-stream σ_i implicitly defines a frequency vector

$\mathbf{f}_i = \langle f_{1,i}, \dots, f_{t,i}, \dots, f_{n,i} \rangle$ where $f_{t,i}$ is the frequency of item t in the sub-stream σ_i , i.e., the number of occurrences of item t in the sub-stream σ_i . Then, we also have $f_t = \sum_{i=1}^s f_{t,i}$. The empirical probability distribution is defined as $\mathbf{p}_i = \langle p_{1,i}, \dots, p_{t,i}, \dots, p_{n,i} \rangle$, where $p_{t,i} = f_{t,i}/m_i$ is the empirical probability of occurrence of item t in the stream σ_i .

With respect to the classical data streaming model, we want to compute the function $\phi(\sigma) = \phi(\sigma_1 \cup \dots \cup \sigma_s)$. This model introduces the additional challenge to minimize the communication complexity (in bits), i.e., the amount of data exchanged between the s nodes and the coordinator.

The *distributed functional monitoring* problem (Cormode et al. 2011; Cormode 2011) has risen only in the 2000s. With respect to the distributed streaming model, functional monitoring requires a continuous evaluation of $\phi(\sigma) = \phi(\sigma_1 \cup \dots \cup \sigma_s)$ at each time instant $j \in [m]$. Bounding ϕ to be monotonic, it is possible to distinguish two cases: *threshold* monitoring (i.e., raising an alert if $\phi(\sigma)$ exceed a threshold *heta*) and *value* monitoring (i.e., approximating $\phi(\sigma)$). It then can be shown (Cormode et al. 2011) that value monitoring can be reduced with a factor $O(1/\varepsilon \log R)$ (where R is the largest value reached by the monitored function) to threshold monitoring. However, this reduction does not hold any more in a more general setting with non-monotonic function (e.g., entropy). Notice that to minimize the communication complexity and maximize the accuracy, the algorithms designed in this model tend to minimize the communication when nothing relevant happens while reacting as fast as possible in response to outstanding occurrences or patterns.

Building Blocks

Approximation and randomization — To compute ϕ on σ in these models, most of the research relies on ε or (ε, δ) approximations. An algorithm A that evaluates the stream σ in a single pass (online) is said to be an (ε, δ) additive approximation of the function ϕ on a stream σ if, for any prefix of size m of the input stream σ , the

output $\hat{\phi}$ of A is such that $\mathbb{P}\{|\hat{\phi} - \phi| > \varepsilon\psi\} \leq \delta$, where $\varepsilon, \delta > 0$ are given as precision parameters and ψ is an arbitrary function (its parameter may be n and/or m). Similarly, an algorithm A that evaluates the stream σ in a single pass (online) is said to be an (ε, δ) approximation of the function ϕ on a stream σ if, for any prefix of size m of the input stream σ , the output $\hat{\phi}$ of A is such that $\mathbb{P}\{|\hat{\phi} - \phi| > \varepsilon\phi\} \leq \delta$, where $\varepsilon, \delta > 0$ are given as precision parameters. Finally, if $\delta = 0$, independently of the algorithm parametrization, then A is deterministic, and we drop the δ from the approximation notation.

Sampling — The sampling approach reads once all the items; however, only a few are kept for the computation. It is also current that some metadata are associated with the retained items. The aim is for a poly-logarithmic storage size with respect to size of the input stream. There are several methods, both deterministic and randomized, to choose which subset of items has to be kept (Muthukrishnan 2005; Alon et al. 1996; Misra and Gries 1982). This allows to exactly compute functions on these samples, which are expected to be representative. However, the accuracy of this computation, with respect to the stream in its entirety, fully depends on the volume of data that has been sampled and the location of the sampled data. Worse, an adversary may easily take advantage of the sampling policy to arbitrarily bias the sample itself.

Summaries, random projections, and sketches

— The summary approach consists in scanning on the fly each piece of data of the input stream and keep locally only compact synopses or sketches containing the most important information about data items. This approach enables to derive some data streams statistics with guaranteed error bounds. Random projections produce a storage size reduction, leveraging pseudorandom vectors and projections. The pseudorandom vector can be generated using space-efficient computation over limitedly independent random variables (Charikar et al.

2002; Cormode and Muthukrishnan 2005). A relevant class of projections are sketches. A data structure DS is a sketch if there is a space-efficient combining algorithm COMB such that, for every two streams σ_1 and σ_2 , we have $COMB(DS(\sigma_1), DS(\sigma_2)) = DS(\sigma_1 \cup \sigma_2)$, where $\sigma_1 \cup \sigma_2$ is a stream containing all the items of σ_1 and σ_2 in any order. In order to extend the sketch definition to the sliding window model, we limit the reordering of the items in σ_1 and σ_2 to the last M items (i.e., the active window).

Key Research Findings

There are several relevant results in the data streaming literature, including the computation of the number of distinct items (Bar-Yossef et al. 2002; Flajolet and Martin 1985; Kane et al. 2010), the frequency moments (Alon et al. 1996; Cormode et al. 2011), the most frequent data items (Cormode and Muthukrishnan 2005; Metwally et al. 2005; Misra and Gries 1982), similarity distance between two streams (Anceaume and Busnel 2014), and the entropy of the stream (Chakrabarti et al. 2007). For the sake of brevity, this section is limited to the classical problem of frequency estimation.

Estimating the frequency moments is one of the first problems to be dealt with in a streaming fashion, namely, in the seminal paper (Alon et al. 1996). The i -th frequency moment is defined as $F_i = \sum_{j=1}^n f_j^i = \|f\|_i$. F_0 is then the number of distinct items of the stream (assuming that $0^0 = 0$), and F_1 is the length m of the stream. The frequency moments for F_i where $i \geq 2$ indicate the skew of the data, which is a relevant information in many distributed applications.

The *frequency estimation* problem is closely related; however it does not provide a single aggregate value to represent the whole stream but a more detailed view. In particular, given a stream $\sigma = \langle t_1, \dots, t_m \rangle$, the frequency estimation problem is to provide an estimate \hat{f}_t of f_t for each item $t \in [n]$. In other words, the task is to build an approximation of the frequency distribution of the stream. Estimating the frequency of any piece of information in large-scale distributed

data streams became of utmost importance in the last decade (e.g., in the context of network monitoring, Big Data, *etc*). IP network management, among others, is a paramount field in which the ability to estimate the stream frequency distribution in a single pass (i.e., online) and quickly can bring huge benefits. For instance, it could rapidly detect the presence of anomalies or intrusions identifying sudden changes in the communication patterns.

Data streaming model — Considering the data streaming model, the Count-Sketch algorithm (Charikar et al. 2002) was an initial result satisfying the following accuracy bound: $\mathbb{P}[\|\hat{f}_t - f_t\| \geq \varepsilon \|f_{-t}\|_2] \leq \delta$, where f_{-t} represents the frequency vector f without the scalar f_t (i.e., $|f_{-t}| = n - 1$).

Few years later, a similar algorithm, Count-Min sketch (Cormode and Muthukrishnan 2005), has been presented. The bound on the estimation accuracy of the Count-Min is weaker than the one provided by the Count-Sketch, in particular, for skewed distribution. On the other hand, the Count-Min shaves a $1/\varepsilon$ factor from the space complexity and halves the hash functions. The Count-Min consists of a two-dimensional matrix \mathfrak{F} of size $r \times c$, where $r = \lceil \log 1/\delta \rceil$ and $c = \lceil e/\varepsilon \rceil$, where e is Euler's constant. Each row is associated with a different two-universal hash function $h_{i \in [r]} : [n] \rightarrow [c]$. For each item t_j , it updates each row: $\forall i \in [r], \mathfrak{F}[i, h_i(t)] \leftarrow \mathfrak{F}[i, h_i(t)] + 1$. That is, the entry value is the sum of the frequencies of all the items mapped to that entry. Since each row has a different collision pattern, upon request of \hat{f}_t , we want to return the entry associated with t minimizing the collisions impact. In other words, the algorithm returns, as f_t estimation, the entry associated with t with the lowest value: $\hat{f}_t = \min_{i \in [r]} \{\mathfrak{F}[i, h_i(t)]\}$. Listing 1 presents the global behavior of the Count-Min algorithm. The space complexity of this algorithm is $O(\frac{1}{\varepsilon} \log \frac{1}{\delta} (\log m + \log n))$ bits, while the update time complexity is $O(\log 1/\delta)$. Therefore, the following quality bounds hold: $\mathbb{P}[\|\hat{f}_t - f_t\| \geq \varepsilon \|f_{-t}\|_1] \leq \delta$, while $f_t \leq \hat{f}_t$ is always true.

Sliding window model — There are two extensions of the Count-Min algorithm to the sliding window model. The ECM-Sketch replaces the entries of the Count-Min matrix with instances of the wave data structure (Gibbons and Tirthapura 2014) which provides an ($\varepsilon_{\text{wave}}$) approximation for the basic counting problem in the sliding window model. A more recent solution (Rivetti et al. 2015a) superseded the ECM-Sketch performances. It has a similar approach, replacing the entries with a novel data structure to keep track of the changes in the frequency distribution of the stream over time.

Applications

Distributed Denial of Service Detection

Network monitoring, as mentioned previously, is one of the classical fields of application given the natural fitting of the data streaming models to network traffics. The detection of distributed denial of service (DDoS) can be reduced to the *distributed heavy hitters* problem, having first been studied in Manjhi et al. (2005), by making the assumption that the attack is locally detectable by routers. Further solutions relaxed the model but relied on other assumptions such as the existence of a known gap between legit and attack traffic (Zhao et al. 2010), a priori knowledge of the IP addresses distribution (Zhao et al. 2006) (i.e., distributed bag model). Finally, Yi and Zhang (2013) propose a solution in the spirit of the distributed functional monitoring model to minimize the communication cost between the nodes and the coordinator. However each router maintains at any time the exact frequency of each IP address in its local network stream, i.e., their solution is extremely memory expensive. A recent solution (Anceaume et al. 2015), based on the Count-Min, detects distributed denial of service without relying on any assumption on the stream characteristics.

Stream Processing Optimization

Data streaming has also been extensively applied to databases, for instance, providing efficient estimation of the join size (Alon et al. 1996;

Listing 1: Count-Min Sketch Algorithm.

```

1: init ( $r, c$ ) do
2:    $\mathfrak{F}[1 \dots r, 1 \dots c] \leftarrow 0_{r,c}$ 
3:    $h_1, \dots, h_r : [n] \rightarrow [c]$ 
4: end init
5: function UPDATE( $tj$ )
6:   for  $i = 1$  to  $r$  do
7:      $\mathfrak{F}[i, h_i(t)] \leftarrow \mathfrak{F}[i, h_i(t)] + 1$ 
8: function GETFREQ( $t$ )
9:   return  $\min\{\mathfrak{F}[i, h_i(t)] \mid 1 \leq i \leq r\}$ 

```

▷ r hash functions from a 2-universal family.
 ▷ reads item tj from the stream σ
 ▷ returns \widehat{f}_t

Vengerov et al. 2015). There are many query plan optimizations performed in database systems that can leverage such estimations.

A more recent application field is stream processing (Hirzel et al. 2014) and complex event processing. Load balancing in distributed computing is a well-known problem that has been extensively studied since the 1980s (Cardellini et al. 2002). Two ways to perform load balancing can be identified in stream processing systems (Hirzel et al. 2014): either when placing the operators on the available machines (Carney et al. 2003; Cardellini et al. 2016) or when assigning load to the parallelized instances of operator O . If O is stateless, then tuples are randomly assigned to instances (*random* or *shuffle grouping*). Extending the Count-Min (Cormode and Muthukrishnan 2005), Rivetti et al. (2016a) presents an algorithm aimed at reducing the overall tuple completion time in shuffle-grouped stages. Key grouping is another grouping technique used by stream processing frameworks to simplify the development of parallel stateful operators. Through key grouping a stream of tuples is partitioned in several disjoint sub-streams depending on the values contained in the tuples themselves. Each operator instance target of one sub-stream is guaranteed to receive all the tuples containing a specific key value. A common solution to implement key grouping is through hash functions that, however, are known to cause load imbalances on the target operator instances when the input data stream is characterized by a skewed value distribution. Gedik (2014) proposes a solution to this problem leveraging consistent hashing and the lossy counting (Manku and Motwani 2002) algorithm. In Rivetti et al. (2015b) the authors propose an improvement over (Gedik 2014) using

the space-saving (Metwally et al. 2005) algorithm instead. The basic intuition is that heavy hitters induce most of the unbalance in the load distribution. Then, in both works the authors leverage solutions to the heavy hitter problem to isolate/carefully handle the keys that have a frequency larger than/close to $1/k$. On the other hand, Nasir et al. (2015) applied the power of two choices approach to this problem, i.e., relax the key grouping constraints by spreading each key on two instances, thus restricting the applicability of their solution but also achieving better balancing.

Caneill et al. (2016) present another work focusing on load balancing through a different angle. In topologies with sequences of stateful operators, and thus key-grouped stages, the likelihood that a tuple is sent to different operator instances located on different machines is high. Since network is a bottleneck for many stream applications, this behavior significantly degrades their performance. The authors use the space-saving (Metwally et al. 2005) algorithm to identify the heavy hitters and analyze the correlation between keys of subsequent key-grouped stages. This information is then leveraged to build a key-to-instance mapping that improves stream locality for stateful stream processing applications.

The *load-shedding* (or *admission control*) technique (Hirzel et al. 2014) goal is to drop some of the input in order to keep the input load under the maximum capacity of the system. Without load shedding, the load would pile up inducing buffer overflows and trashing. In Rivetti et al. (2016b) the authors provide a novel load-shedding algorithm based on an extension of the Count-Min (Cormode and Muthukrishnan 2005), targeted at stream processing systems.

Inverted Index Compression

Giulio Ermanno Pibiri and Rossano Venturini
Department of Computer Science, University of Pisa, Pisa, Italy

Definitions

The data structure at the core of nowadays large-scale search engines, social networks, and storage architectures is the *inverted index*. Given a collection of documents, consider for each distinct term t appearing in the collection the integer sequence ℓ_t , listing in sorted order all the identifiers of the documents (docIDs in the following) in which the term appears. The sequence ℓ_t is called the *inverted list* or *posting list* of the term t . The inverted index is the collection of all such lists.

The scope of the entry is the one of surveying the most important encoding algorithms developed for efficient inverted index compression and fast retrieval.

Overview

The inverted index owes its popularity to the efficient resolution of *queries*, expressed as a set of terms $\{t_1, \dots, t_k\}$ combined with a query operator. The simplest operators are Boolean AND and OR. For example, given an AND query, the index has to report *all* the docIDs of the documents containing the terms $\{t_1, \dots, t_k\}$. This operation ultimately boils down to *intersecting*

the inverted lists corresponding to the terms of the query set. Efficient list intersection relies on the operation $\text{NextGEQ}_t(x)$, which returns the integer $z \in \ell_t$ such that $z \geq x$. This primitive is used because it permits to *skip* over the lists to be intersected.

Because of the many documents indexed by search engines and stringent performance requirements dictated by the heavy load of user queries, the inverted lists often store several millions (even billion) of integers and must be searched efficiently. In this scenario, *compressing* the inverted lists of the index appears as a *mandatory* design phase since it can introduce a twofold advantage over a non-compressed representation: feed faster memory levels with more data in order to speed up the query processing algorithms and reduce the number of storage machines needed to host the whole index. This has the potential of letting a query algorithm work in internal memory, which is faster than the external memory system by several orders of magnitude.

Chapter Notation

All logarithms are binary, i.e., $\log x = \log_2 x$, $x > 0$. Let $B(x)$ represent the binary representation of the integer x and $U(x)$ its *unary* representation, that is, a run of x zeroes plus a final one: $0^x 1$. Given a binary string B , let $|B|$ represent its length in bits. Given two binary strings B_1 and B_2 , let $B_1 B_2$ be their concatenation. We indicate with $S(n, u)$ a sequence of n integers drawn from a universe of size u and with $S[i, j]$ the subsequence starting at position i and including endpoint $S[j]$.

Key Research Findings

Integer Compressors

The compressors we consider in this subsection are used to represent a single integer. The most classical solution is to assign each integer a *self-delimiting* (or *uniquely decodable*) variable-length code so that the whole integer sequence is the result of the juxtaposition of the codes of all its integers. Clearly, the aim of such encoders is to

assign the smallest code word as possible in order to minimize the number of bits used to represent the sequence.

In particular, since we are dealing with inverted lists that are monotonically increasing by construction, we can subtract from each element the previous one (the first integer is left as it is), making the sequence be formed by integers greater than zero known as *delta*-gaps (or just *d*-gaps). This popular *delta-encoding* strategy helps in reducing the number of bits for the codes. Most of the literature assumes this sequence form, and, as a result, compressing such sequences of *d*-gaps is a fundamental problem that has been studied for decades.

Elias' Gamma and Delta

The two codes we now describe have been introduced by Elias (1975) in the 1960s. Given an integer $x > 0$, $\gamma(x) = 0^{|B(x)|-1}B(x)$, where $|B(x)| = \lceil \log(x+1) \rceil$. Therefore, $|\gamma(x)| = 2\lceil \log(x+1) \rceil - 1$ bits. Decoding $\gamma(x)$ is simple: first count the number of zeroes up to the one, say there are n of these, then read the following $n+1$ bits, and interpret them as x .

The key inefficiency of γ lies in the use of the unary code for the representation of $|B(x)| - 1$, which may become very large for big integers. The δ code replaces the unary part $0^{|B(x)|-1}$ with $\gamma(|B(x)|)$, i.e., $\delta(x) = \gamma(|B(x)|)B(x)$. Notice that, since we are representing with γ the quantity $|B(x)| = \lceil \log(x+1) \rceil$ which is guaranteed to be greater than zero, δ can represent value zero too. The number of bits required by $\delta(x)$ is $|\gamma(|B(x)|)| + |B(x)|$, which is $2\lceil \log(\lceil |B(x)| + 1 \rceil) \rceil + \lceil \log(x+1) \rceil - 1$.

The decoding of δ codes follows automatically from the one of γ codes.

Golomb-Rice

Rice and Plaunt (1971) introduced a parameter code that can better compress the integers in a sequence if these are highly concentrated around some value. This code is actually a special case of the Golomb code (Golomb 1966), hence its name.

The Rice code of x with parameter k , $R_k(x)$, consists in two pieces: the quotient $q = \lfloor \frac{x-1}{2^k} \rfloor$

and the remainder $r = x - q \times 2^k - 1$. The quotient is encoded in unary, i.e., with $U(q)$, whereas the remainder is written in binary with k bits. Therefore, $|R_k(x)| = q+k+1$ bits. Clearly, the closer 2^k is to the value of x the smaller the value of q : this implies a better compression and faster decoding speed.

Given the parameter k and the constant 2^k that is computed ahead, decoding Rice codes is simple too: count the number of zeroes up to the one, say there are q of these, then multiply 2^k by q , and finally add the remainder, by reading the next k bits. Finally, add one to the computed result.

Variable-Byte

The codes described so far are also called *bit-aligned* as they do not represent an integer using a multiple of a fixed number of bits, e.g., a byte. The decoding speed can be slowed down by the many operations needed to decode a single integer. This is a reason for preferring *byte-aligned* or even word-aligned codes when decoding speed is the main concern.

Variable-Byte (VByte) (Salomon 2007) is the most popular and simplest byte-aligned code: the binary representation of a nonnegative integer is split into groups of 7 bits which are represented as a sequence of bytes. In particular, the 7 least significant bits of each byte are reserved for the data, whereas the most significant (the 8-th), called the *continuation bit*, is equal to 1 to signal continuation of the byte sequence. The last byte of the sequence has its 8-th bit set to 0 to signal, instead, the termination of the byte sequence. The main advantage of VByte codes is decoding speed: we just need to read one byte at a time until we find a value smaller than 128. Conversely, the number of bits to encode an integer cannot be less than 8; thus VByte is only suitable for large numbers, and its compression ratio may not be competitive with the one of bit-aligned codes for small integers.

Various enhancements have been proposed in the literature to improve the (sequential) decoding speed of VByte. This line of research focuses on finding a suitable format of control and data streams in order to reduce the prob-

ability of a branch misprediction that leads to higher instruction throughput and helps keeping the CPU pipeline fed with useful instructions (Dean 2009) and on exploiting the parallelism of SIMD instructions (single-instruction-multiple-data) of modern processors (Stepanov et al. 2011; Plaisance et al. 2015; Lemire et al. 2018).

List Compressors

Differently from the compressors introduced in the previous subsection, the compressors we now consider encode a whole integer list, instead of representing each single integer separately. Such compressors often outperform the ones described before for sufficiently long inverted lists because they take advantage of the fact that inverted lists often contain *clusters* of close docIDs, e.g., runs of consecutive integers, that are far more compressible with respect to highly scattered sequences. The reason for the presence of such clusters is that the indexed documents themselves tend to be clustered, i.e., there are subsets of documents sharing the very same set of terms. Therefore, not surprisingly, list compressors greatly benefit from reordering strategies that focus on reassigning the docIDs in order to form larger clusters of docIDs.

An amazingly simple strategy, but very effective for Web pages, is to assign identifiers to documents according to the lexicographical order of their URLs (Silvestri 2007). A recent approach has instead adopted a recursive graph bisection algorithm to find a suitable reordering of docIDs (Dhulipala et al. 2016). In this model, the input graph is a bipartite graph in which one set of vertices represents the terms of the index and the other set represents the docIDs. Since a graph bisection identifies a permutation of the docIDs, the goal is the one of finding, at each step of recursion, the bisection of the graph which minimizes the size of the graph compressed using delta-encoding.

Block-Based

A relatively simple approach to improve both compression ratio and decoding speed is to encode a *block* of contiguous integers. This line of

work finds its origin in the so-called frame of reference (FOR) (Goldstein et al. 1998).

Once the sequence has been partitioned into blocks (of fixed or variable length), then each block is encoded separately. An example of this approach is *binary packing* (Anh and Moffat 2010; Lemire and Boytsov 2013), where blocks of fixed length are used, e.g., 128 integers. Given a block $S[i, j]$, we can simply represent its integers using a universe of size $\lceil \log(S[j] - S[i] + 1) \rceil$ bits by subtracting the lower bound $S[i]$ from their values. Plenty of variants of this simple approach has been proposed (Silvestri and Venturini 2010; Delbru et al. 2012; Lemire and Boytsov 2013). Recently, it has also been shown (Ottaviano et al. 2015) that using more than one compressor to represent the blocks, rather than simply representing all blocks with the same compressor, can introduce significant improvements in query time within the same space constraints.

Among the simplest binary packing strategies, Simple-9 and Simple-16 (Anh and Moffat 2005, 2010) combine very good compression ratio and high decompression speed. The key idea is to try to pack as many integers as possible in a memory word (32 or 64 bits). As an example, Simple-9 uses 4 *header* bits and 28 *data* bits. The header bits provide information on how many elements are packed in the data segment using equally sized code words. The 4 header bits distinguish from 9 possible configurations. Similarly, Simple-16 has 16 possible configurations.

PForDelta

The biggest limitation of block-based strategies is their space inefficiency whenever a block contains at least one large value, because this forces the compressor to encode *all* values with the number of bits needed to represent this large value (universe of representation). This has been the main motivation for the introduction of PForDelta (PFD) (Zukowski et al. 2006). The idea is to choose a proper value k for the universe of representation of the block, such that a large fraction, e.g., 90%, of its integers can be written in k bits each. This strategy is called *patching*. All integers that do not fit in k bits are treated as

exceptions and encoded separately using another compressor.

More precisely, two configurable parameters are chosen: a base value b and a universe of representation k so that most of the values fall in the range $[b, b + 2^k - 1]$ and can be encoded with k bits each by shifting (delta-encoding) them in the range $[0, 2^k - 1]$. To mark the presence of an exception, we also need a special *escape* symbol; thus we have $[0, 2^k - 2]$ possible configurations for the integers in the block.

The variant OptPFD (Yan et al. 2009), which selects for each block the values of b and k that minimize its space occupancy, has been demonstrated to be more space-efficient and only slightly slower than the original PFD (Yan et al. 2009; Lemire and Boytsov 2013).

Elias-Fano

The encoding we are about to describe was independently proposed by Elias (1974) and Fano (1971), hence its name. Given a monotonically increasing sequence $S(n, u)$, i.e., $S[i-1] \leq S[i]$, for any $1 \leq i < n$, with $S[n-1] < u$, we write each $S[i]$ in binary using $\lceil \log u \rceil$ bits. The binary representation of each integer is then split into two parts: a *low* part consisting in the rightmost $\ell = \lceil \log \frac{u}{n} \rceil$ bits that we call *low bits* and a *high* part consisting in the remaining $\lceil \log u \rceil - \ell$ bits that we similarly call *high bits*. Let us call ℓ_i and h_i the values of low and high bits of $S[i]$, respectively. The Elias-Fano representation of S is given by the encoding of the high and low parts.

The array $L = [\ell_0, \dots, \ell_{n-1}]$ is written explicitly in $n \lceil \log \frac{u}{n} \rceil$ bits and represents the encoding of the low parts. Concerning the high bits, we represent them in *negated unary* using a bit vector of $n + 2^{\lfloor \log n \rfloor} \leq 2n$ bits as follows. We start from a 0-valued bit vector H , and set the bit in position $h_i + i$, for all $i \in [0, n)$. Finally the Elias-Fano representation of S is given by the concatenation of H and L and overall takes $\text{EF}(S(n, u)) \leq n \lceil \log \frac{u}{n} \rceil + 2n$ bits.

While we can opt for an arbitrary split into high and low parts, ranging from 0 to $\lceil \log u \rceil$, it can be shown that $\ell = \lceil \log \frac{u}{n} \rceil$ minimizes the overall space occupancy of the encod-

ing (Elias 1974). Figure 1 shows an example of encoding for the sequence $S(12, 62) = [3, 4, 7, 13, 14, 15, 21, 25, 36, 38, 54, 62]$.

Despite its simplicity, it is possible to randomly access an integer from a sequence encoded with Elias-Fano *without* decompressing the whole sequence. We refer to this operation as **Access**(i), which returns $S[i]$. The operation is supported using an auxiliary data structure that is built on bit vector H , able to efficiently answer **Select**₁(i) queries, that return the position in H of the i -th 1 bit. This auxiliary data structure is *succinct* in the sense that it is negligibly small in asymptotic terms, compared to **EF**($S(n, u)$), requiring only $o(n)$ additional bits (Navarro and Mäkinen 2007; Vigna 2013).

Using the **Select**₁ primitive, it is possible to implement **Access**(i) in $O(1)$ time. We basically have to relink together the high and low bits of an integer, previously split up during the encoding phase. The low bits ℓ_i are trivial to retrieve as we need to read the range of bits $L[i\ell, (i+1)\ell)$. The retrieval of the high bits deserves, instead, a bit more care. Since we write in negated unary how many integers share the same high part, we have a bit set for every integer of S and a zero for every distinct high part. Therefore, to retrieve the high bits of the i -th integer, we need to know how many zeros are present in $H[0, \text{Select}_1(i)]$. This quantity is evaluated on H in $O(1)$ as **Rank**₀(**Select**₁(i)) = **Select**₁(i) - i . Finally, linking the high and low bits is as simple as: **Access**(i) = ((**Select**₁(i) - i) \ll ℓ) | ℓ_i , where \ll is the left shift operator and $|$ is the bitwise OR.

The query **NextGEQ**(x) is supported in $O(1 + \log \frac{u}{n})$ time as follows. Let h_x be the high bits of x . Then for $h_x > 0$, $i = \text{Select}_0(h_x) - h_x + 1$ indicates that there are i integers in S whose high bits are less than h_x . On the other hand, $j = \text{Select}_0(h_x + 1) - h_x$ gives us the position at which the elements having high bits greater than h_x start. The corner case $h_x = 0$ is handled by setting $i = 0$. These two preliminary operations take $O(1)$. Now we have to conclude our search in the range $S[i, j]$, having *skipped* a potentially large range

Inverted Index

Compression, Fig. 1 An example of Elias-Fano encoding. We distinguish in light gray the *missing high bits*, i.e., the ones not belonging to the integers of the sequence among the possible $2^{\lfloor \log n \rfloor}$

	3	4	7	13	14	15	21	25	36	38	54	62
high	0	0	0	0	0	0	0	0	1	1	1	1
	0	0	0	0	0	0	1	1	0	0	0	1
	0	0	0	1	1	1	0	1	0	0	1	0
low	0	1	1	1	1	1	1	0	1	1	1	1
	1	0	1	0	1	1	0	0	0	1	1	1

	0	0	1	1	1	1	1	1	1	0	110	110
L	001100111	101110111	101	001	100110						110	110

of elements that, otherwise, would have required to be compared with x . We finally determine the successor of x by binary searching in this range which may contain up to u/n integers. The time bound follows.

Partitioned Elias-Fano

One of the most relevant characteristics of Elias-Fano is that it only depends on two parameters, i.e., the length and universe of the sequence. As inverted lists often present groups of close docIDs, Elias-Fano fails to exploit such natural clusters. Partitioning the sequence into chunks can better exploit such regions of close docIDs (Ottaviano and Venturini 2014).

The core idea is as follows. The sequence $S(n, u)$ is partitioned into n/b chunks, each of b integers. First level L is made up of the last elements of each chunk, i.e., $L = [S[b - 1], S[2b - 1], \dots, S[n - 1]]$. This level is encoded with Elias-Fano. The second level is represented by the chunks themselves, which can be again encoded with Elias-Fano. The main reason for introducing this two-level representation is that now the elements of the i -th chunk are encoded with a smaller universe, i.e., $L[i] - L[i - 1] - 1, i > 0$. As the problem of choosing the best partition is posed, an algorithm based on dynamic programming can be used to find in $O(n \log_{1+\epsilon} 1/\epsilon)$ time partition whose cost (i.e., the space taken by the partitioned encoded sequence) is at most $(1 + \epsilon)$ away from the optimal one, for any $0 < \epsilon < 1$ (Ottaviano and Venturini 2014).

This inverted list organization introduces a level of indirection when resolving NextGEQ queries. However, this indirection only causes a very small time overhead compared to plain

Elias-Fano on most of the queries (Ottaviano and Venturini 2014). On the other hand, partitioning the sequence greatly improves the space efficiency of its Elias-Fano representation.

Binary Interpolative

Binary Interpolative coding (BIC) (Moffat and Stuiver 2000) is another approach that, like Elias-Fano, directly compresses a monotonically increasing integer sequence without a first delta-encoding step. In short, BIC is a recursive algorithm that first encodes the middle element of the current range and then applies this encoding step to both halves. At each step of recursion, the algorithm knows the reduced ranges that will be used to write the middle elements in fewer bits during the next recursive calls.

More precisely, consider the range $S[i, j]$. The encoding step writes the quantity $S[m] - low - m + i$ using $\lceil \log(hi - low - j + i) \rceil$ bits, where $S[m]$ is the range middle element, i.e., the integer at position $m = (i + j)/2$, and low and hi are, respectively, the lower bound and upper bound of the range $S[i, j]$, i.e., two quantities such that $low \leq S[i]$ and $hi \geq S[j]$. The algorithm proceeds recursively, by applying the same encoding step to both halves: $[i, m]$ and $[m + 1, j]$ by setting $hi = S[m] - 1$ for the left half and $low = S[m] + 1$ for the right half. At the beginning, the encoding algorithm starts with $i = 0$, $j = n - 1$, $low = S[0]$, and $hi = S[n - 1]$. These quantities must be also known at the beginning of the decoding phase. Apart from the initial lower and upper bound, all the other values of low and hi are computed on the fly by the algorithm.

Inverted Index Compression, Fig. 2 An example of Binary Interpolative coding. We highlight in bold font the middle element currently encoded: above each element we report a pair where the first value indicates the element *actually* encoded and the second value the universe of representation

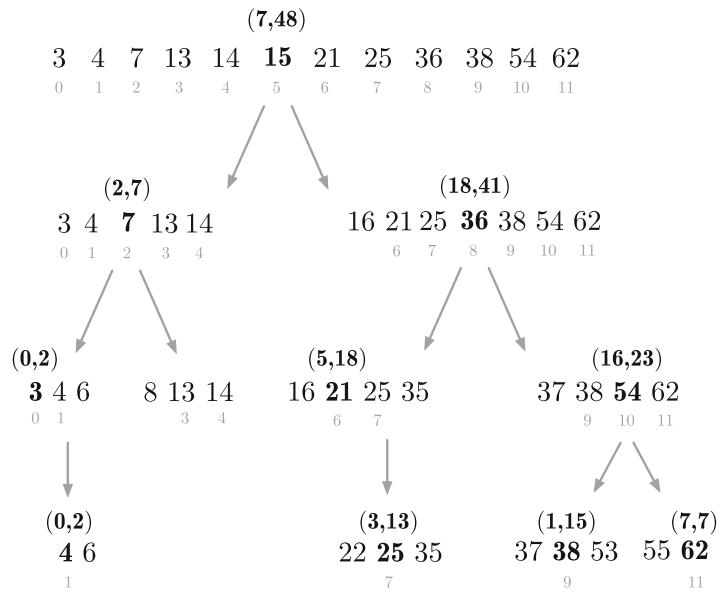

Figure 2 shows an encoding example for the same sequence of Fig. 1. We can interpret the encoding as a preorder visit of the binary tree formed by the recursive calls the algorithm performs. The encoded elements in the example are in order: [7, 2, 0, 0, 18, 5, 3, 16, 1, 7]. Moreover, notice that whenever the algorithm works on a range $S[i, j]$ of consecutive integers, such as the range $S[3, 4] = \{13, 14\}$ in the example, i.e., the ones for which the condition $S[j] - S[i] = j - i$ holds, it stops the recursion by emitting no bits at all. The condition is again detected at decoding time, and the algorithm implicitly decodes the run $S[i], S[i] + 1, S[i] + 2, \dots, S[j]$. This property makes BIC extremely space-efficient whenever the encoded sequences feature clusters of docIDs (Witten et al. 1999; Yan et al. 2009; Silvestri and Venturini 2010), which is the typical case for inverted lists. The key inefficiency of BIC is, however, the decoding speed which is highly affected by the recursive nature of the algorithm. This is even more evident considering random access to individual integers that cannot be performed in constant time as it is the case for Elias-Fano (see 1).

Future Directions for Research

This concluding section is devoted to recent approaches that encode many inverted lists together to obtain higher compression ratios. This is possible because the inverted index naturally presents some amount of redundancy, caused by the fact that many docIDs are shared between its lists. In fact, as already motivated at the beginning of section “List Compressors”, the identifiers of similar documents will be stored in the inverted lists of the terms they share.

Pibiri and Venturini (2017) proposed a clustered index representation. The inverted lists are divided into clusters of similar lists, i.e., the ones sharing as many docIDs as possible. Then for each cluster, a *reference list* is synthesized with respect to which all lists in the cluster are encoded. In particular, the *intersection* between the cluster reference list and a cluster list is encoded more efficiently: all the docIDs are implicitly represented as the *positions* they occupy within the reference list. This makes a big improvement for the cluster space, since each intersection can be rewritten in a much smaller universe. Although

any list compressor supporting NextGEQ can be used to represent the (rank-encoded) intersection and the residual segment of each list, the paper adopted partitioned Elias-Fano (see 1). With an extensive experimental analysis, the proposed clustered representation is shown to be superior to partitioned Elias-Fano and also Binary Interpolative coding for index space usage. By varying the size of the reference lists, different time/space trade-offs can be obtained.

Reducing the redundancy in highly repetitive collections has also been advocated in the work by Claude, Fariña, Martínez-Prieto, and Navarro (2016). The described approach first transforms the inverted lists into lists of d -gaps and then applies a general, i.e., *universal*, compression algorithm to the sequence formed by the concatenation of all the lists. The compressed representation is also enriched with pointers to mark where each individual list begins. The paper experiments with Re-Pair compression (Larsson and Moffat 1999), VByte, and LZMA (<http://www.7-zip.org/>) that is an improved version of the classic LZ77 (Ziv and Lempel 1977) and run-length encoding. The experimental analysis reveals that significant reduction in space is possible on highly repetitive collections, e.g., versions of Wikipedia, with respect to encoders tailored for inverted indexes while only introducing moderate slowdowns.

An approach based on generating a *context-free grammar* from the inverted index has been proposed by Zhang, Tong, Huang, Liang, Li, Stones, Wang, and Liu (2016). The core idea is to identify common patterns, i.e., repeated subsequences of docIDs, and substitute them with symbols belonging to the generated grammar. Although the reorganized inverted lists and grammar can be suitable for different encoding schemes, the authors adopted OptPFD (Yan et al. 2009). The experimental analysis indicates that good space reductions are possible compared to state-of-the-art encoding strategies with competitive query processing performance. By exploiting the fact that the identified common patterns can be placed directly in the final result

set, the query processing performance can also be improved.

Overview of the Julia Project and Historical Context

The inception of Julia was by Jeff Bezanson and his adviser, Prof. Alan Edelman, when the former was doing his PhD thesis at MIT. However, the project soon gathered momentum that went beyond that particular thesis encouraging more individuals to join it, contributing to it in various ways. Soon, Stefan Karpinski and Viral B. Shah undertook key roles in the project and turned this into a group effort.

The idea behind Julia was to have a programming language that is high-level (and therefore easy to prototype in), while at the same time exhibit high performance, comparable to that of low-level languages, such as C and Fortran.

Such a programming language would solve the two-language problem, which involves creating a script in a high-level language in order to prove a concept and then translating it into a low-level language to put that program in production. Even at its first stages, Julia managed to do that, though the lack of libraries (packages) made it more of a niche language that would appeal mainly to those dedicated enough to create a lot of processes from scratch.

By 2012, however, when Julia became accessible to the public, there were enough packages to allow for some basic processes to be implemented in the language. As more and more people became aware of its potential and as benchmarking experiments on various applications were conducted, the performance edge of Julia was beyond any reasonable doubt. Naturally, this encouraged many programmers to take it up and gradually build packages for it, most of which were made available through its website ([Official Julia Language 2017](#)).

Soon after that, Julia became an appealing tool both for businesses and universities alike. Apart from MIT, there were a few other universities around the world (including one in Europe) that taught Julia as part of a technical course. With the version 1.0 of the language still pending, this was a noteworthy accomplishment, especially considering that there were noticeable changes from one release to the next, rendering compatibility issues in many of the packages and scripts that were developed for earlier versions of the language.

Currently, Julia has packages for the vast majority of data science applications, including some niche ones, like T-SNE, a stochastic dimensionality reduction technique developed by Prof. Laurens van der Maaten in the Netherlands. Also, despite the common misconception that Julia is not data science ready yet, packages for all common data science applications exist in Julia right now, while anything that isn't there can be implemented without any compromise in performance. This is because a large part of the Julia code base is written in Julia itself (Official Julia Language 2017).

Key Characteristics of the Julia Language

There are various characteristics of the language that make it stand out from other programming languages and which are often used to promote it as a data science technology. These include (but are not limited to) the following (Voulgaris 2017):

- **Prototyping speed.** It is very easy to create a proof-of-concept script in Julia, implementing a data analytics algorithm or an ETL process.
- **Performance speed.** Scripts written in Julia are very fast to execute, be it on a single CPU or in parallel. This renders Julia ideal for production code, particularly for computationally expensive applications.
- **Easy to learn.** Although many programming languages require a certain familiarity with programming, Julia is fairly straightforward right off the shelf. Also, if someone has coded in Python, R, or MATLAB, it will seem even easier to learn.
- **Versatile in terms of hardware.** Julia works well in all major OSes, across various hardware configurations (including tiny computers).
- **Compatibility with other programming languages.** Julia scripts can be called from other languages, like Python and R, while

you can call scripts from other languages (including C), via the Julia kernel.

- **Growing user community.** Although the number of users of Julia is not as large as that of the users of other languages, there are communities all over the world through meetup, as well as some strictly online ones. Also, there are conferences on Julia taking place regularly.
- **Built-in package manager.** As the use of packages is commonplace in all high-level languages, Julia was designed with this in mind. As a result, it is possible to add, remove, and update packages (libraries) of the language within its kernel, using some simple commands.
- **Unicode support (not limited to UTF-8 only).** Julia can handle a variety of characters, including letters from non-Latin alphabets and special mathematical and scientific symbols. This renders the processing of text much more efficient and with a broader scope.
- **Multiple dispatch.** This is a very useful feature of the language enabling the programmer to have functions with the same name but taking different inputs. The idea is that the user of these functions doesn't have to remember numerous names for specialized versions of the same function, as Julia itself decides which one to use, based on the inputs it is given. Multiple dispatch therefore allows for cleaner code and easier maintenance of scripts, enabling the user to leverage the functional programming paradigm, saving time and effort.

Key Julia Packages for Data Science

Beyond the base package of Julia, there are several packages out there which can be used for data science-related applications. The vast majority of these packages are available through the Julia package repository at the official Julia site. This repository contains all official Julia packages, which have undergone unit testing and have been tried on various benchmarks to ensure

they produce the expected results. However, reliable Julia packages can be found in other sites too, since there are various GitHub repositories containing nonofficial packages (e.g., the package for the T-SNE method, from its creator's repository).

The key packages that are most relevant for data science include the following:

1. **StatsBase** – a collection of various statistics functions, essential in most data science projects
2. **HypothesisTests** – a package containing several statistical methods for hypothesis testing (e.g., t-tests, chi-square tests, etc.)
3. **Gadfly** – one of the best plotting packages out there, written entirely in Julia
4. **PyPlot** – a great plotting package, borrowed from Python's Matplotlib; ideal for heat maps, among other plot types
5. **Clustering** – a package specializing in clustering methods
6. **DecisionTree** – decision trees and random forests package
7. **Graphs** – a graph analytics package (the most complete one out there)
8. **LightGraphs** – a package with relatively fast graph algorithms (not compatible with Graphs package)
9. **DataFrames** – the Julia equivalent of Python's pandas package
10. **Distances** – a very useful package for distance calculation, covering all major distance metrics
11. **GLM** – generalized linear model package for regression analysis
12. **T-SNE** – a package implementing the T-SNE algorithm by the creators of the algorithm
13. **ELM** – the go-to package for extreme learning machines, having a single hidden layer
14. **MultivariateStats** – a great place to obtain various useful statistics functions, including principal components analysis (PCA)
15. **MLBase** – an excellent resource for various support functions for machine learning applications
16. **MXNet** – the Julia API for Apache's MXNet, a great option for deep-learning applications

Even though this list is not exhaustive, it covers the majority of data science applications. Also, some applications may have more than one package out there. The packages here are the ones found to be better maintained, at the time of this writing. All of them, apart from T-SNE, can be found in the Julia package repository.

Implementing and Running Custom Algorithms in Julia

Let's take a look at how you can create a script in Julia, implementing a custom algorithm. For this example, we'll use the k nearest neighbor (kNN) algorithm for classification, which is one of the simplest machine learning systems out there. Although there is a package in Julia that provides a solid implementation of kNN, we'll examine how you can develop a similar script from scratch.

For starters, we'll need a distance function that calculates the Euclidean distance between two points, x and y . This is an auxiliary function, as it is not part of the actual kNN algorithm. Also, even though functions like this exist in the Distances package, it's useful to see how you can implement it here too, to see how you can use different functions in a script. A typical implementation of the Euclidean distance is the following:

```
function distance{T<:Number}(x::Array{T,1}, y::Array{T,1})
    dist = 0
    for i in 1:length(x)
        dist += (x[i] - y[i])^2
    end
    dist = sqrt(dist)
    return dist
end
```

An essential part of the kNN classification algorithm is the processing of a given element whose class is unknown, given the class information in the known elements. To accomplish this, it takes the k closest points (nearest neighbors) to that unknown point and performs a majority vote decision-making process, to figure out which class it should belong to. Despite its simplicity, this process is actually quite effective, given the

right selection of the k parameter. Below is a typical implementation of that part of the algorithm as an independent function.

```
function classify{T<:Any}
    (distances::Array{Float64, 1},
     labels::Array{T, 1, k::Int64})
        class = unique(labels)
        nc = length(class)
        indexes = Array(Int, 0)
        M = maxtype(typeof(distances[1]))
        class_count = Array(Int, nc)
        for i in 1:k
            indexes[i] = inmin(distances)
            distances[indexes[i]] = M
        end
        klables = labels[indexes]

        for i in 1:nc
            for j in 1:k
                if klables[j]
                    == class[i]
                    class_count[i]
                    += 1
                    break
                end
            end
        end
        index = inmax(class_count)
        return class[index]
    end
```

So, what would the actual kNN algorithm look like if it were implemented using the above functions as auxiliaries? The short function that follows is a typical implementation of the wrapper function of the algorithm, which makes use of `distance()` and `classify()` in order to make a series of predictions, for the classes of the data points in matrix Y . As expected, the number of neighbors k is passed as a parameter, just like in the `classify()` function.

```
function apply_kNN{T1<:Number, T2<:Any}
    (X::Array{T1,2}, x::Array{T2,1},
     Y::Array{T1,2}, k::Int)
    N = size(X,1)
    n = size(Y,1)
    D = Array(Float64, N)
    z = Array(typeof(x[1]), n)
    for i in 1:n
        for j in 1:N
            D[j] = distance(X[j,:], Y[i,:])
        end
        z[i] = classify(D, x, k)
    end
```

```
    end
    return z
end
```

This example was taken from Voulgaris (2016), where various aspects of the Julia language for data science applications are explored.

Structuring Code and Performance Measurement of Julia Scripts

Just like most programming languages, Julia has a set of built-in functions for measuring the performance of pieces of code written and executed in it. This is useful not only for gauging how much time it takes to run a script but also for figuring out how much memory the script requires, something particularly useful for scripts you wish to put to scale, for tackling more challenging data science problems.

First of all, let's start by defining what a chunk of code is for Julia. This is a set of commands in some kind of programming structure, such as a for loop or a script in a .jl file. However, for assessing individual parts of a program, you may want to use a block of code that is neither one of these forms. In this case, you can use a custom code block in the form of:

```
begin
    command 1
    command 2
    .
    .
    command n
end
```

Note that the indentation in the commands between “begin” and “end” is entirely optional. This is because Julia doesn't care about how you format the code, as long as it's clear where one command ends and another one begins. Instead of the line break, for example, you could always use the semi-colon (;) which is also used to suppress the output of a command when run. So, a block of code using the aforementioned structure could take the form:

```
begin; command 1; command 2; ...
    command n; end
```

This is quite useful if you wish to try something out to see if it works, while you are on the kernel window. Also, if you want to make your code obscure so that people will be more hesitant to copy it, though this tactic may not deter the more determined ones. Moreover, this compact way of writing code is useful when you want to measure its performance, particularly if you are on the kernel window.

Measuring the performance of a piece of code in Julia is fairly straightforward. The functions most commonly used are @time, @elapsed, and @allocated. Note the “@” is part of their name. This is a special character indicating that the function is a meta-command, something that applies not on regular data but on code instead. Meta-commands are part of meta-programming, which is a more advanced topic, beyond the scope of this article.

So, if we have a piece of code (e.g., begin; x = 0; for i = 1:2:1000000; x += i; end; println(x); end, which basically adds up all the odd integers between 1 and 1000000), we can gauge its performance by running the following code:

```
@time begin; x = 0;
for i = 1:2:1000000;
x += i; end; println(x); end
```

The output of this would be twofold. First, the actual result of the code will be given (from the println() command, which outputs something on the screen, adding a line break at the end of it). Following that, there will be three numbers in a single line. The first one will be the number of seconds it took Julia to run the script. Following that, there are a couple of numbers inside parentheses related to the memory usage of that code. The first of them has to do with the number of memory allocations performed, while the latter, with the actual memory usage in bytes, MiBs, etc. In some cases, there is a third number in the parenthesis, denoting the proportion of the time of that code that is used in the language’s built-in garbage collector (usually referred to as “gc”). Note that because of the gc and other reasons, when you first run the script, it always takes slightly longer than any consecutive runs, while the memory allocation is also higher then.

The @elapsed meta-command will just yield the number of seconds, and it is an actual number, of Float64 type to be exact (or Float32 if you are using a 32-bit processor). The use case of this function is storing and later on processing the times of a particular script (e.g., a data science model), for benchmarking purposes.

Similar to @elapsed is the @allocated meta-command. This basically returns an Int64 number reflecting the number of memory allocations of the given code. However, this may not include all of the memory allocations, so it is bound to differ from the number given in the output of the @time meta-command.

There are additional tools for evaluating the performance of a piece of code in Julia. Namely, if you are particularly interested in benchmarking, you will find the BenchmarkingTools package (benchmarkingtools.jl) by Jarrett Revels quite useful. In that package you can explore various options for more detailed benchmarking, such as the @benchmark meta-command, which performs a series of tests and provides some descriptive statistics of the results, so that you get a more in-depth understanding of the resources required in your code.

J

Firing Up Additional CPUs Through the Julia Kernel

It is often the case that we need additional CPUs (or GPUs) in order to carry out some tasks that are too computationally expensive for a single processor to handle. This is a usually advanced topic in data science, and it is usually used in deep-learning applications. However, in Julia it is fairly straightforward, and it can be done with a small set of commands that are in the base package of the language.

The process for performing parallelization is the following:

1. Add new processors to Julia (i.e., give Julia access to your computing resources, aka processors or threads).

2. Create one or more mapper functions that will be run on each processor, and make them available to all of the processors.
3. Create a wrapper function that will also act as a reducer or aggregator.
4. Test each mapper to make sure that it provides the desired result.
5. Run the wrapper function on two or so processors to ensure that it works as expected.
6. Make any changes if necessary.
7. Run the wrapper function on all of your processors.

For all of this, the following commands are essential:

- **nprocs()**: yields the number of processors available through Julia.
- **addprocs(n)**: adds n processors to Julia (n is an integer). The output of this function is an array containing the numbers of the added processors. Alternatively, you can give Julia access to n processors when firing it up by typing in the command line: `julia -p n`.
- **procs()**: yields an array of all the available processors (i.e., their code numbers).
- **@parallel**: performs a certain command, usually a loop, in parallel (note that indexing is not maintained in this case, so this command is useful for simulations mainly).
- **@everywhere**: makes the function that follows available in all the processors accessible to Julia. This is essential for parallelizing a custom function. If this meta-command is omitted, the functions you define will be accessible only to the active CPU.
- **pmap()**: this function is nonequivalent to `map()`, but instead of mapping a function to the various elements of an array, it does so across all available processors. The equivalent function in R is `sapply()`.

It is important to keep in mind that adding more CPUs (workers) has an inherent overhead. So, unless the process you want to parallelize is complex enough, the benefit may not be as meaningful. In other words, before adding more Julia

instances on the various CPUs/GPUs, first make sure that the process is framed in an efficient way and that it is computationally heavy enough to render this kind of approach.

Other Aspects of Working with Julia

Working with Julia is straightforward, considering that it is a fairly new language. For those who prefer an interactive prompt, similar to IPython, there is the Julia kernel, which comes with the installation of the language.

If you prefer a “cleaner” programming environment, there is also the option of Jupyter, a popular IDE among Python users. Jupyter is fully compatible with Julia, and it is the preferred option for many data scientists. One thing to keep in mind is that for Jupyter and Julia to work together, you need to have installed the IJulia package, as well as the anaconda package in Python.

However, even a basic text editor could work well with Julia, since there are editors like Notepad++ and Atom, which understand Julia code and enable useful coloring of certain keywords. Some Julia programmers also make use of Juno, which is a text editor that is linked to the Julia kernel, so you can execute specific parts of your code, without leaving the editor. Juno is based on the Atom editor, and it is distributed as part of a software bundle, from the official Julia site.

Julia Resources

Beyond the short introduction of the Julia language in this article, there are several other resources for the language that are recommended for more in-depth understanding of its functionality and usefulness, in a data science setting. Namely, the Julia wiki book ([2017](#)) is an excellent resource for the various technical aspects of the language, with many examples of how they are applied in practice. Also, the *Julia for Data Science* book (Technics Publications) (Voulgaris

2016) is a great place to start for learning not only how Julia can be applied in data science but also about the data science field itself.

Finally, as Julia is constantly evolving, it would be a good idea to follow its developments through the various blog articles written for it, through the Julia Bloggers meta-blog, an aggregate of the various blogs subscribed to this site. Not all of the entries are relevant for someone learning Julia, but all of them are useful for gaining a better understanding of the language's usefulness and applications.

Keyword privacy, Keyword-guessing attacks, Searchable encryption, Public key.

Overview

The notion of public key encryption with keyword search (PEKS) provides a flexible and

efficient approach to retrieve encrypted data stored in a remote server. A main threat in PEKS is the keyword guessing attack, where disclosed keywords leak the associated data and the user's interest. This gives rise to that the keyword privacy becomes a concern in searchable encryption. In this paper, we present a brief history of keyword privacy in searchable encryption. We make a systematic investigation of keyword privacy issue in public key-based searchable encryption. We describe keyword guessing attacks in a general PEKS scheme. According to different attackers, we refine inherent reasons and summarize enhancement achievements. This preserves the keyword privacy and provides guidance for the secure development of searchable encryption.

Introduction

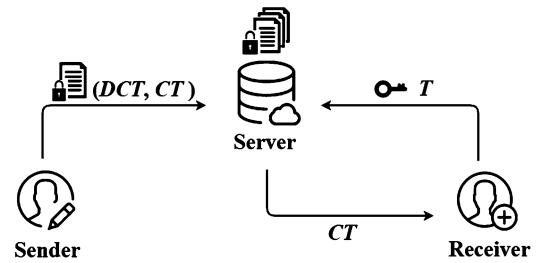

Driven by economic benefits, cloud-based database systems have been widely adopted in data storage. This, on the one hand, brings profits to the service provider and, on the other hand, reduces the local storage cost for users. In such an outsourcing storage, the data owner will lose control of his/her data, and the cloud server is not fully trusted, especially in the public cloud, which pose that several security and privacy issues arise. Encryption is a fundamental technique in order to protect outsourced data from disclosure. However, an inherent problem is how to efficiently search the intended data. The

traditional plaintext-based search is unavailable for encrypted data. There are two straightforward solutions. One is that users download and decrypt all the encrypted data to find the target locally, and the other is that the server with the key from the user decrypts all the data to find and return the target to the user. These two solutions are either impractical for extremely large bandwidth or insecure for compromising the data privacy. How to search over encrypted data efficiently and securely becomes an important and interesting problem.

Searchable encryption (SE) is a promising tool to retrieve encrypted data and gains growing interests. It follows a sender-receiver-server mode, and the function of each party is described as follows.

- *Sender* owns the data associated with some keyword. He/she encrypts both the data and the keyword to generate the data ciphertext DCT and the searchable ciphertext CT , respectively. Then the sender uploads (DCT, CT) to the server.
- *Receiver* generates the trapdoor T with the keyword and his/her secret key to search the data associated with this keyword. Then the receiver submits T to the server for searching.
- *Server* provides data storage and data searching service. When receiving a trapdoor T , the server checks whether T matches some searchable ciphertext CT by running a test algorithm. It returns the corresponding data ciphertext DCT to the receiver if and only if the matching succeeds. Note that the server is not fully trusted, which means that it honestly executes the searching operation but curiously learns the data as well as its associated information.

In SE, both the searchable ciphertext and the trapdoor include the encrypted keyword. If a searchable ciphertext matches with the given trapdoor, it means that the keywords are identical and the search succeeds. Figure 1 depicts an overview of the SE architecture.

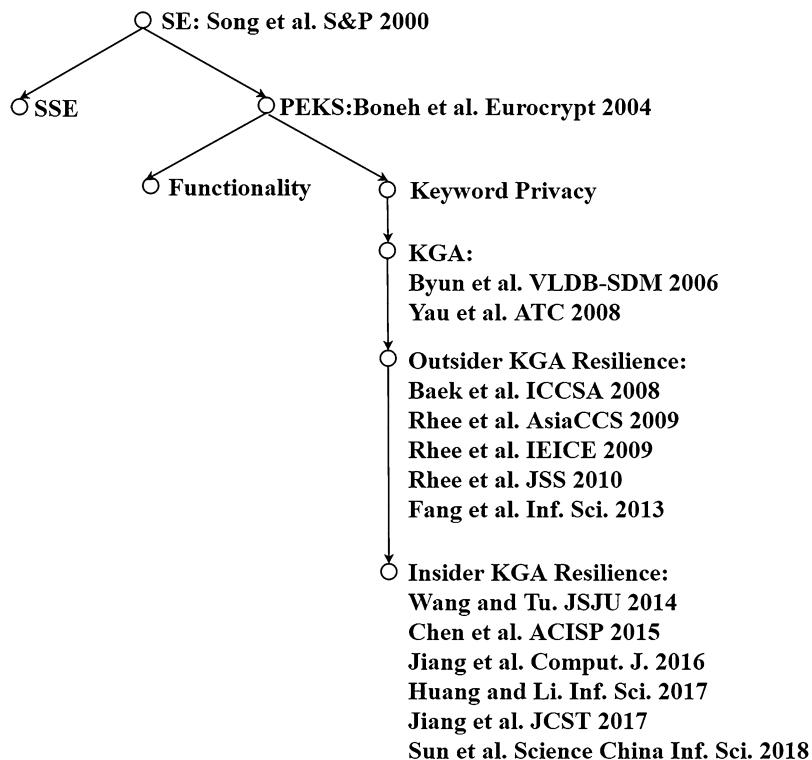

Keyword Attacks and Privacy Preserving in Public-Key-Based Searchable Encryption, Fig. 1 SE architecture

SE mainly consists of two types of techniques, namely, symmetric searchable encryption (SSE) using symmetric cryptography and public-key encryption with keyword search (PEKS) using public-key cryptography.

- SSE was first introduced by Song et al. (2000). In SSE, both the searchable ciphertext and the trapdoor are generated with the same secret key. SSE enjoys a high searching performance (Kim et al. 2017; Bost et al. 2017; Kamara and Moataz 2017). However, SSE is subjected to complicated key distribution problems when data can be uploaded and searched in multiuser setting.
- PEKS was first introduced by Boneh et al. (2004). In PEKS, any senders can upload the data to the receiver using his/her public key instead of a shared key, and the receiver who has the corresponding secret key can search. PEKS and its variants (e.g., Boneh and Waters 2007; Sun et al. 2016; Jiang et al. 2016b) provide a flexible way to share data for senders and search data for receivers. PEKS does not need the key distribution due to the public-key cryptography and thus overcomes the weaknesses of SSE.

Contribution. In this entry, we present a brief history of PEKS in Fig. 2. We conduct an in-depth study of the keyword privacy in PEKS and its variants. Our study spans both keyword-guessing attacks and the corresponding defenses in terms of different attackers. Finally, we list

Keyword Attacks and Privacy Preserving in Public-Key-Based Searchable Encryption, Fig. 2 Brief history of PEKS

several future directions to stir up efforts into searchable encryption.

(Boneh and Franklin 2001). In comparison with SSE, PEKS has the following advantages.

- PEKS allows any senders to generate the searchable ciphertext with the public key of the receiver, while SSE allows only the key holder to generate the ciphertext. PEKS benefits the data sharing from any sender without a shared key.
- PEKS does not need a complicated key distribution when multiple senders/receivers are involved, but directly specifying in searchable ciphertext. PEKS has cost efficiency in key management.

An application example of PEKS as mentioned in Boneh et al. (2004) is the email system. Bob sends an encrypted email to Alice under Alice's public key, and the email server can test whether the email contains some keyword so as to route the email accordingly. If SSE is applied, Bob must contact Alice to obtain the

Public-Key Encryption with Keyword Search

Table 1 summarizes the major notations used in this entry.

The general PEKS algorithm is shown in Fig. 3. A brief description is as follows. The sender generates the searchable ciphertext using the keyword and the public key of a receiver, and the receiver who has the corresponding secret key produces the trapdoor using the keyword and his/her secret key. The server returns the corresponding data ciphertext to the receiver when the received trapdoor matches the searchable ciphertext. The PEKS construction proposed in Boneh et al. (2004) was derived from the technique of identity-based encryption (IBE)

Keyword Attacks and Privacy Preserving in Public-Key-Based Searchable Encryption, Table 1 Major notations used in this entry

Notation	Description
λ	Security parameter
pk_R/sk_R	Public/secret key of the receiver
pk_S/sk_S	Public/secret key of the server
pk_{FS}/sk_{FS}	Public/secret key of the front server
pk_{BS}/sk_{BS}	Public/secret key of the back server
pk_E/sk_E	Public/private key of the sender
w	Keyword
W	Keyword space
CT	Searchable ciphertext
T	Trapdoor
C_{ITS}	Internal testing state

- 1: $\text{KeyGen}(\lambda) \rightarrow (pk_R, sk_R)$
- 2: $\text{PEKS}(pk_R, w) \rightarrow CT$
- 3: $\text{Trapdoor}(sk_R, w) \rightarrow T$
- 4: $\text{Test}(pk_R, CT, T) \rightarrow 1/0$

Keyword Attacks and Privacy Preserving in Public-Key-Based Searchable Encryption, Fig. 3 PEKS algorithms

shared key before sending an encrypted email to Alice. Therefore, SSE becomes impractical in this scenario.

To improve PEKS, kinds of variants have been proposed. For example, public-key encryption with conjunctive keyword search (PECKS) schemes (Park et al. 2004; Boneh and Waters 2007; Bethencourt et al. 2006; Yang and Ma 2016) were proposed to strengthen the query expressiveness and support combinable multi-keyword search. Authorized keyword search schemes (Zheng et al. 2014; Shi et al. 2014; Sun et al. 2016; Jiang et al. 2016b, 2017b) were proposed to control the search via the user's attributes or the assigned keyword class.

Keyword-Guessing Attacks

A main concern in PEKS is the keyword privacy. The keyword space is usually low-entropy, instead of super-polynomially large. Anyone can

Algorithm 1 KGA algorithms

-
- 1: Given T for some unknown $w \in W$
 - 2: **for** $w' \in W$ **do**
 - 3: $CT \leftarrow \text{PEKS}(pk_R, w')$
 - 4: **if** $\text{Test}(pk_R, CT, T) = 1$ **then**
 - 5: $w = w'$
 - 6: **if** $w \neq w'$ and change another keyword
 - 7: Find the correct w
-

choose a keyword from the keyword space and generate a searchable ciphertext. The attacker always attempts to recover the keyword from a given trapdoor by checking whether his/her generated searchable ciphertext matches this trapdoor. If they match, the attack succeeds and finds the correct keyword; otherwise, the attacker continues to guess another keyword. This is called the keyword-guessing attack (KGA). PEKS (Boneh et al. 2004) was pointed out to be not secure against KGA (Byun et al. 2008; Yau et al. 2008).

We assume that there is a keyword set W in the system, where the size of W is N . Usually, the public key of any party is fully public and available to the whole system. KGA works as shown in Algorithm 1, where three steps includes “given a trapdoor,” “generate a searchable ciphertext,” and “execute the test.” The reason is that anyone who knows the public key of the receiver can generate the searchable ciphertext CT of arbitrary keyword himself. He/she then tries to check whether the generated CT matches the given trapdoor. If yes, the keyword in the trapdoor is identical to the keyword selected by the CT generator.

As the keyword always indicates the privacy of the user and his/her own data, it is therefore of practical importance to circumvent this vulnerability for searchable encryption. If the attacker is neither the server nor the receiver (i.e., outsider), a secure channel between the server and the receiver is an alternative solution. However, this compromises practicality since the deployment cost is quite expensive and such a system cannot use a regular public channel, such as Wi-Fi or 4G. If the attacker is the server itself (i.e., insider), the secure channel does not work, and hence some feasible solutions are desirable.

Privacy Enhancements Against KGA

KGA from outsider and insider are called *outsider attacks* and *insider attacks*, respectively. Depending on these two types of attacks, we summarize enhancement achievements for PEKS, which improve the keyword privacy.

Outsider Attacks Resilience

The essential reason for outsider attacks is that any outsider can run the test. To resist outsider attacks, the designated-tester PEKS was proposed (Rhee et al. 2009a) to restrict only the designated server to run the test. Figure 4 describes a general designated-tester PEKS construction. Its core idea is to introduce the public/private key pair into PEKS. Both the ciphertext and the trapdoor are generated with the public key of the server, such that only the designated server who holds the corresponding private key can do the test. The security model for designated-tester PEKS and the notion of trapdoor indistinguishability were defined in Rhee et al. (2009a, 2010), respectively. Designated-tester PEKS schemes proposed in Rhee et al. (2009b) and Fang et al. (2013) were provably secure in the random oracle model and in the standard model, respectively.

Insider Attacks Resilience

The technique used in outsider attacks resilience cannot work against insider attacks since the server has the secret key and is still able to do the test as Algorithm 1. There are two main reasons. One is that the ciphertext generation is public and the other is that the test is stand-alone.

- 1: $\text{Setup}(\lambda) \rightarrow SP$
- 2: $\text{KeyGen}_{\text{Server}}(SP) \rightarrow (pk_S, sk_S)$
- 3: $\text{KeyGen}_{\text{Receiver}}(SP) \rightarrow (pk_R, sk_R)$
- 4: $\text{PEKS}(SP, pk_R, pk_S, w) \rightarrow CT$
- 5: $\text{Trapdoor}(sk_R, pk_S, w) \rightarrow T$
- 6: $\text{Test}(SP, CT, T, sk_S) \rightarrow 1/0$

Keyword Attacks and Privacy Preserving in Public-Key-Based Searchable Encryption, Fig. 4 General construction against outsider attacks

Starting from these two reasons, two kinds of new frameworks for PEKS have been accordingly proposed to solve insider attacks.

The first framework is to introduce an authentication of the sender (e.g., the private key of the sender) into the searchable ciphertext, such that the server cannot generate a valid searchable ciphertext. A general authentication-based construction against insider attacks is shown in Fig. 5. Several constructions under this framework (Jiang et al. 2016a, 2017a; Huang and Li 2017; Sun et al. 2018) have been proposed. The online/offline keyword search scheme (Jiang et al. 2016b) achieved the quick generation of the trapdoor. The public-key authenticated encryption with keyword search scheme (Huang and Li 2017) was proved to be secure based on static assumptions. The constant-size trapdoor scheme (Jiang et al. 2017a) allowed to search ciphertexts from multiple senders with one trapdoor. The indistinguishability obfuscator-based scheme (Sun et al. 2018) considered the security against both the honest-but-curious server and the malicious server.

The second framework is to prevent an independent test from only one server. This needs at least two servers, e.g., the front server and the back server, and these servers are not allowed to collude. The general two-server construction against insider attacks is illustrated in Fig. 6. Under this framework, two-server PEKS schemes (Wang and Tu 2014; Chen et al. 2015) were proposed by borrowing the property of the secret sharing and using smooth projective hash function, respectively.

- 1: $\text{Setup}(\lambda) \rightarrow SP$
- 2: $\text{KeyGen}_{\text{Sender}}(SP) \rightarrow (pk_E, sk_E)$
- 3: $\text{KeyGen}_{\text{Receiver}}(SP) \rightarrow (pk_R, sk_R)$
- 4: $\text{PEKS}(SP, pk_R, pk_E, w) \rightarrow CT$
- 5: $\text{Trapdoor}(sk_R, pk_E, w) \rightarrow T$
- 6: $\text{Test}(SP, CT, T, pk_R, pk_E) \rightarrow 1/0$, where pk_R, pk_E are optional.

Keyword Attacks and Privacy Preserving in Public-Key-Based Searchable Encryption, Fig. 5 General authentication-based construction against insider attacks

```

1:  $\text{Setup}(\lambda) \rightarrow SP$ 
2:  $\text{KeyGen}(SP) \rightarrow (pk_{FS}, sk_{FS}), (pk_{BS}, sk_{BS})$ 
3:  $\text{PEKS}(SP, pk_{FS}, pk_{BS}, w) \rightarrow CT$ 
4:  $\text{Trapdoor}(SP, pk_{FS}, pk_{BS}, w) \rightarrow T$ 
5:  $\text{FTest}(SP, CT, T, sk_{FS}) \rightarrow C_{ITS}$ 
6:  $\text{BTest}(SP, sk_{BS}, C_{ITS}) \rightarrow 1/0$ 

```

Keyword Attacks and Privacy Preserving in Public-Key-Based Searchable Encryption, Fig. 6 General two-server construction against insider attacks

Future Directions

Based on the above investigations of current PEKS and its variants, we list several future directions to advance the development of PEKS.

- KGA over the multi-keyword setting. The originally defined KGA is launched on a keyword. However, for the multi-keyword PEKS variants, such as PECKS, guessing multiple keywords via repeated attacks seems to be less efficient. The first problem is to explore whether it is possible to launch KGA once and guess all of the keywords. If yes, how to resist KGA in multi-keyword setting? The previous solutions will not work because they aim at only one keyword. Conducting research on such a KGA variant will make a significant contribution to public-key-based searchable encryption.
- Improving search efficiency. The time complexity of the search in current schemes is linear in the number of data, even if they can achieve KGA resilience. However, in the big data era, large-scale data need to be stored on the server, and the one-by-one test is impractical. How to reduce the complexity in searching large-scale data is an open problem in the future.
- Search over encrypted media. The current searchable encryption schemes are based on the keyword. This is more suitable for file-based systems. However, some data is presented with image or video. Search over encrypted media information and the privacy preserving become challenging since these media contents have different formats from

the keyword and cannot be guessed from a low-entropy space. Research on media-based will widen the scope of searchable encryption.

Conclusion

In this survey, we focused on the keyword privacy issues of public-key encryption with keyword search. We analyzed the keyword-guessing attacks as well as corresponding reasons. We summarized enhancement achievements in terms of different types of attackers. Finally, we discussed several future directions for a better development of searchable encryption.

Definitions

Knowledge graph embeddings: a vector representation of entities and relations in a knowledge graph that preserves the inherent structure of the knowledge graph as well as the reasoning ability over the graph.

Overview

With the growing popularity of multi-relational data on the Web, knowledge graphs (KGs) have become a key data source in various application domains, such as Web search, question answering, and natural language understanding. In a typical KG such as Freebase (Bollacker et al. 2008) or Google’s Knowledge Graph (Google 2014), entities are connected via relations. For example, *Bern* is capital of *Switzerland*. Formally, a popular approach to represent such relational data is to use the Resource Description Framework. It defines a fact as a triple (subject, predicate, and object), which is also known as head, relation, and tail or (h, r, t) for short. Following the above example, the head, relation, and tail are *Bern*, *capitalOf*, and *Switzerland*, respectively. With a considerable number of entities and relations (e.g., Google’s Knowledge Graph has more than 18 billion of triples with 570 million of entities and 35,000 of relations by the end of 2014), KGs now become a valuable information source that can empower many semantic Web applications.

Despite the importance of building large-scale KGs, their symbolic and logical frameworks are not flexible enough to be compatible with modern statistical and machine learning techniques which require often numerical inputs. In this context, knowledge graph embeddings that project entities and relations in a KG into a low-dimensional continuous vector space have attracted much attention. One of the key benefits of such numeric representation is that they can easily serve as input to classical statistical and machine-learning approaches. The learnt entity and relation embeddings can thus be used in different tasks, such as KG completion (Bordes et al. 2013),

relation extraction (Weston et al. 2013), entity classification, and entity resolution (Nickel et al. 2011).

In the following, we first discuss typical KG embedding models and then their extensions by integrating additional data sources. We then summarize the applications of KG embeddings.

Learning Knowledge Graph Embeddings

Learning KG embeddings consists in two key steps in general:

1. Defining a KG embedding model with a specific scoring function, which computes the probability that a given triple is true;
2. Initializing entity and relation embeddings (e.g., vectors) according to the KG embedding model and learning those embeddings by maximizing the sum of the scoring function over all triples in the KG. Triples appearing in the KG will have higher scores than the triples that do not exist in the KG.

KG Embedding Models

Depending on the type of scoring function, there are two categories of embedding models: translational distance models and semantic matching models. Translational distance models, such as *TransE* (Bordes et al. 2013), use a scoring function that measures the distance between two entities, while semantic matching models, such as *RESCAL*, use a scoring function that measures the similarity of the facts.

Translational Distance Model: TransE and Its Extensions

TransE is a representative translational distance model that projects entities and relations onto a unique vector space. In this model, the head h and the tail t of a triplet are connected by their relation r , holding the fact that the embedding of t should be similar to the embedding of h plus the embedding of r (i.e., $h + r \approx t$). The proposed idea is based on the vector-offset method for identifying linguistic regularities in continuous

space word representations (Mikolov et al. 2013), for example, *USA – dollar ≈ Japan – yen*. In a KG, this analogy holds since through the *currencyOf* relation, we get *dollar + currencyOf ≈ USA* and *yen + currencyOf ≈ Japan*. In this way, the scoring function is defined as the negative distance between the sum of the head and the relation, subtracted by the tail:

$$f_r(h, t) = -\|\mathbf{h} + \mathbf{r} - \mathbf{t}\|_{1/2} \quad (1)$$

Following this initial idea, several techniques improved TransE by designing sophisticated scoring functions that are able to capture complex KG structures, in particular multi-mapping relations (one-to-many, many-to-one, or many-to-many). TransH (Wang et al. 2014b), for instance, suggests a new approach by projecting the relations on different hyperplanes in order to capture many-to-many mapping properties of some relations; TransR (Lin et al. 2015b) defines a mapping matrix and a vector for every relation; TransD (Ji et al. 2015) introduces dynamic matrices for each entity-relation pair by considering the diversity of entities and relations simultaneously. Sophisticated scoring functions can indeed improve the KG embeddings in some downstream learning tasks, though they also increase the complexity of the embedding models.

Semantic Matching Model: RESCAL and Its Extensions

RESCAL is a tensor factorization model for KG embeddings, which decomposes a three-way tensor consisting of head, relation, and tail dimensions. RESCAL generates for each entity a vector and for each relation a matrix capturing the interaction between the entities. The proposed model allows for discovering the correlation between multiple interconnected entities. The model represents facts via a tensor product with a corresponding scoring function defined as follows:

$$f_r(h, t) = \mathbf{h}^\top \mathbf{M}_r \mathbf{t} = \sum_{i=1}^d \sum_{j=1}^d [\mathbf{M}_r]_{ij} \cdot [\mathbf{h}]_i \cdot [\mathbf{t}]_j \quad (2)$$

where h and t are the vectors of the head and tail, respectively, and M_r is the matrix that represents the relations. d refers to the dimension of the embeddings.

Several pieces of work extend RESCAL by designing customized tensor factorization models. DistMult (Yang et al. 2014) simplifies the RESCAL model by using a bilinear formulation, showing similar performance with less parameters (more efficient in the learning process). However, the model works with symmetric relations only. Trouillon et al. (2016) propose a model called Complex Embeddings (ComplEx) that extends DistMult in order to model asymmetric relations. ComplEx introduces a complex space in which head, relation, and tail embeddings are represented. In this model, the scoring function generates different scores from facts with asymmetric relations. Neural tensor network (NTN) (Socher et al. 2013) is another model with a neural network architecture. For each fact, the embedding vectors of its head and tail are fed into the input layer of a neural network and then mapped onto its hidden layer combined with a relation-specific tensor. Finally, the output layer generates a score for each fact.

Learning Process

The goal of the learning process is to maximize the sum of the scoring function over all triples in the KG. Typical examples of optimization algorithms used in this context include stochastic gradient descent (SGD) (Robbins and Monroe 1951), Broyden-Fletcher-Goldfarb-Shanno (BFGS) (Battiti and Masulli 1990), and AdaGrad (Duchi et al. 2011). In order to accelerate the training process, negative sampling techniques can be applied by replacing the head, the relation, or the tail of a given fact. These generated triples are called negative samples. There are two main methods of generating negative samples, based on the *open-world assumption (OWA)* and on the *closed-world assumption (CWA)*.

Open-World Assumption

The open-world assumption assumes that the KG only contains true facts and the facts that do not appear can either be false or just missing

(Drumond et al. 2012). Under this assumption, a negative fact is probabilistically generated given a positive fact by randomly corrupting its head, relation, or tail. The entity and relation representations are learned by minimizing a loss function defined based on the scoring function, such as the logistic loss defined as follows:

$$\min_{h,r,t} \sum_{(h,r,t) \in D^+ \cup D^-} \log(1 + \exp(-y_{hrt} \cdot f_r(h, t))) \quad (3)$$

where D^+ and D^- are positive and negative training samples and y_{hrt} is equal to 1 if the label is positive, -1 otherwise. The logistic loss can be optimized using, for instance, stochastic gradient descent in mini-batch mode. In the training phase, a set of true facts are sampled and a set of negative facts get generated, and the embeddings can be iteratively updated with a fixed or adaptive learning rate.

Closed-World Assumption

The closed-world assumption assumes that all the facts that are not in the KG are negative samples (i.e., assuming the KG is complete). The entity and relation representations are learned by minimizing, for example, the squared loss:

$$\min_{h,r,t} \sum_{h,t \in \mathbb{E}, r \in \mathbb{R}} (y_{hrt} - f_r(h, t))^2 \quad (4)$$

where \mathbb{E} and \mathbb{R} are the set of entities and relations, respectively. y_{hrt} is equal to 1 if the triplet appears in the KG, 0 otherwise. In addition, Nickel and Tresp (2013) propose the logistic loss and (Miettinen 2011) the absolute loss as alternatives to the squared loss.

In summary, the closed-world assumption usually has more limitations than the open-world assumption, as it penalizes the missing true facts from a KG. In practice, despite their tremendous size, modern KGs all suffer from incompleteness issues (West et al. 2014). Consequently, the open-world assumption is more realistic for most settings and thus performs better on average than the closed-world assumption (Guo et al. 2017).

KG Embedding Extension by Integrating Additional Information

When learning KG embeddings, additional information, such as entity types, relation paths, textual descriptions, or logical rules, can be added to the embedding model to improve the quality of the embeddings on certain tasks.

Entity types represent semantic categories the entity belongs to. For example, the entity *PresidentObama* can be annotated as a *PERSON* entity type. This piece of information can be incorporated in different ways. Nickel et al. (2012) use the entity type as a relation and its corresponding facts (h, r, t) as training example. Guo et al. (2015) propose a method in which entities of the same type are close to each other in the vector space. The entity type can also be used to set constraints for different relations. For example, Xie et al. (2016) use this constraint to generate correct negative samples by filtering out triples with incorrect entity types.

Relation paths refer to a sequence of relations between two entities. The multi-hop relationships contain useful information that can be used for KG completion. For example, Lao and Cohen (2010) predict the relation between entities using a path ranking algorithm that connects two entities. More precisely, the relations can be represented as vectors or matrices, and their addition or multiplication can be used to compose a path as vector or matrix composition. Lin et al. (2015a) show a method to approximate the relation path via sampling and pruning. Along similar lines, Toutanova et al. (2016) propose an algorithm that incorporates paths with specific lengths and intermediate entities in the model.

Most of the KGs contain entity descriptions that can be used to enrich the semantic information of the entities. External information sources, such as Wikipedia articles (Wang et al. 2014a) or news releases (Socher et al. 2013), can be used to extend the entity description by providing richer textual information. A representative work by Wang et al. (2014a) introduces a model that combines text corpus and KG to align them in the same vector space and creates KG embeddings and text embeddings. The model includes

three main parts: a KG model, a text model, and an alignment model. Specifically, the KG model is used to generate embeddings of entities and relations in the KG, while the text model is used to generate embeddings from the text corpus. Finally, the alignment model is used to align the KG embedding and text embedding in the same vector space using different alignment mechanisms, such as entity name and Wikipedia anchors. In this way, the model is able to predict out-of-KG entities (phrases not stored in the KG but that appear in the text).

Logical rules are another type of information that could be integrated into embedding models. For instance, if two entities are connected by the relation *HasWife*, then they should also be connected by the relation *HasSpouse*. There exist systems, such as *WARMR* (Dehaspe and Toivonen 1999), *ALEPH* (Muggleton 1995), and *AMIE* (Galárraga et al. 2013), that can automatically extract such kinds of relations. Richardson and Domingos (2006) prove that the logical rules contain rich information and that they can be used to acquire and infer further knowledge. Following this idea, Wang et al. (2015) propose an approach seamlessly incorporating logic rules into KG embedding models by reducing the solution space and thus improving the inference accuracy for knowledge base completion tasks. Guo et al. (2016) propose a model that embeds KG and logical rules in a unified framework. Specifically, logical rules are first instantiated into ground rules, for example, $\text{HasWife}(x,y)$ implies $\text{HasSpouse}(x,y)$ and vector embeddings are introduced for entity pairs. For each fact of the logical rule, a score is computed in order to indicate whether the ground rule is satisfied or not. The embedding model is then learned based on the unified facts and rules. In this way, the model is more effective for knowledge acquisition and inference as the embeddings are compatible with both facts and rules.

In addition to the information described above, further types of information that can be added to the embedding models include entity attributes, temporal information, and graph structures. Nickel et al. (2012) highlight the fact that entity attributes and relations must be separated. The

authors propose a new algorithm to handle attributes efficiently. Jiang et al. (2016) show that the KG facts are often time-sensitive and that they develop a time-aware knowledge base embedding approach by taking advantage of the time at which facts have occurred. The proposed solution forces the embeddings to be temporally consistent by using temporal constraints to model the relations. Feng et al. (2016) show a graph-aware approach that learns entity and relation embeddings by leveraging the relation paths and edge context (i.e., all the relations that connect an entity). The intuition behind this approach is that all the relations linking to and from an entity are representative of that entity.

KG Embedding Applications

Typical applications of KG embedding include link prediction, triple classification, entity classification, and entity resolution.

- Link prediction (also called KG completion) attempts to discover missing facts based on the contents of the KG. Specifically, it predicts an entity given a relation and a second entity, i.e., given (r, t) , it predicts h , denoted also as $(?, r, t)$, or given (h, r) , it predicts t , denoted also as $(h, r, ?)$. Lin et al. (2015a) define this task as entity prediction, while Bordes et al. (2014b) define it as entity ranking. A similar approach predicts a relation given its head and tail entities, denoted also as $(h, ?, t)$, which is similar also to relation prediction (Xie et al. 2016). In order to evaluate the results generated by this task, a common practice is to store in a list all the answers and see the rank of the correct answer. Several evaluation metrics can be used in this context, such as *Hits@n* that considers only the ranks smaller than n , or the *mean rank*, that is, the average of the predicted ranks.
- Triple classification aims at determining whether a triple appears in a KG. More precisely, triple classification can be performed based on the score of a candidate triple

(h, r, t) that can be easily computed using the scoring function. In this way, an unseen fact can be either true if its score is higher than a threshold and false otherwise. Traditional evaluation metrics can be used in this task, for example, mean average precision (Guo et al. 2016) or micro- and macro-averaged accuracy (Guo et al. 2015).

- Entity classification classifies entities into different semantic categories. Concretely, the type of an entity is usually denoted using a *IsA* relation, and entity classification can thus be seen as a particular case of the link prediction task, in which only $(h, \text{IsA}, ?)$ triples are predicted.
- Entity resolution verifies whether two entities are actually referring to the same object or not. Bordes et al. (2014b) tackle this problem by considering a scenario in which the relation of two equivalent entities is explicitly denoted as *EqualTo*. By learning the embedding for this type of relation, the problem of entity resolution becomes a triple classification problem. Fundamentally, the triple classification problem judges whether the fact $(h, \text{EqualTo}, t)$ is true or not. Alternatively, Nickel et al. (2011) propose a different approach that computes the similarity between two entities and use the score to calculate the likelihood that two entities refer to the same object. This method works even if the relation *EqualTo* is not encoded in the KG.

KG embeddings can also be applied to other application domains beyond KGs. Three most popular out-of-KG applications are relation extraction, question answering, and recommendation systems.

- Relation extraction tries to discover relations from text where entities have already been identified. Weston et al. (2013) propose a method to extract relations by combining TransE and text, showing that the integration of TransE and a traditional

text-based extractor can actually improve the performance of relation extraction.

- Question answering refers to the task of answering questions over KGs. Given a question in plain text, a fact or a set of facts containing the correct answer is extracted as an answer. This task is challenging because of the extended variability of natural language text used to formulate the question and of the extensive size of the KGs. A successful solution that involves KG embedding is proposed by Bordes et al. (2014a), which learns embeddings in order to put questions and corresponding answers closer in the vector space. Given a question and an answer, the model generates a high score if the answer is correct, low score otherwise. The results show that, by involving the KG, the task is successfully performed without using any rules or additional tagging step as most traditional question answering applications do.
- Recommendation systems suggest users a list of items according to the users' preferences. Collaborative filtering techniques are often used to perform recommendations based on the historical interaction between users and items. However, user-item interactions are often sparse, leading to unsatisfactory performance. To alleviate this issue, hybrid recommendation systems were developed by adding auxiliary information (Yu et al. 2014). Zhang et al. (2016) propose a hybrid recommendation system that integrates a KG. More precisely, the hybrid recommendation system models structural knowledge by applying a KG embedding technique such as *TransR* in order to learn the representation of each item. Similarly, the users are represented by vectors, and each item is represented by its KG vector representation plus an offset. Finally, the preference of a user for a specific item is computed as a product of the user and item vectors. In this way, the hybrid recommendation system automatically extracts semantic representations from facts in the KG to improve the quality of the recommendation system.

Conclusion

With the booming of multi-relational data on the Web, knowledge graphs have become an important data source empowering many applications. However, the symbolic and logical representation of KGs makes it difficult to take them as input to machine-learning or processing pipelines. To tackle this issue, knowledge graph embedding techniques were proposed to project entities and relations from a KG into a low-dimensional continuous vector space while still preserving the inherent structure of the KG and reasoning capabilities over the KG. The learnt embeddings have been successfully used in both KG-reasoning applications, such as link prediction, triple classification, entity classification, and entity resolution, and out-of-KG applications, such as relation extraction, question answering, and recommendation systems.

Knowledge Graphs in the Libraries and Digital Humanities Domain

Bernhard Haslhofer¹, Antoine Isaac², and Rainer Simon¹

¹Austrian Institute of Technology, Vienna, Austria

²Europeana Foundation, The Hague, The Netherlands

Definitions

Knowledge graphs represent concepts (e.g., people, places, events) and their semantic relationships. As a data structure, they underpin a digital information system, support users in resource discovery and retrieval, and are useful for navigation and visualization purposes. Within the libraries and humanities domain, knowledge graphs are typically rooted in *knowledge organization systems*, which have a century-old tradition and have undergone their digital transformation with the advent of the Web and Linked Data. Being exposed to the Web, metadata and concept definitions are now forming an interconnected and decentralized global knowledge network that can be curated and enriched by community-driven editorial processes. In the future, knowledge graphs could be vehicles for formalizing and connecting findings and insights derived from the analysis of possibly large-scale corpora in the libraries and digital humanities domain.

Overview

The term “knowledge graph” was popularized in 2012 (Singhal 2012) with the announcement of the “Google Knowledge Graph,” which gathers and formalizes information from several sources in order to enhance search results. Knowledge graphs can be generic and cover a broad range of domains, or they can be tailored to a specific

domain or application context. They typically integrate data from multiple, heterogeneous sources and provide both a human-interpretable representation and a formalized machine-readable basis for information retrieval tasks, such as (latent) semantic indexing, classification, or query recommendation. Well-known examples for openly available, generic knowledge graphs are DBpedia (Bizer et al. 2009a), Freebase (Bollacker et al. 2008), or Wikidata (Vrandečić and Krötzsch 2014).

Within the libraries and digital humanities domain, the concept of a knowledge graph is deeply rooted in *knowledge organization systems*, which is an umbrella term for vocabularies such as a classification schemes, thesaurus, or glossary.

Knowledge organization systems have a centuries-old tradition in the library domain, where they have been used in metadata descriptions to organize resources and facilitate their discovery and retrieval. With the advent of Linked Data (Bizer et al. 2009b), knowledge organization systems – and metadata descriptions making use of them – have undergone a digital transformation and entered the realm of the World Wide Web. By linking them with semantically related Web resources within and outside the library domain, they are now forming an interconnected and decentralized global knowledge graph.

The development of knowledge graphs also has a long-standing tradition in the humanities. For a long time, scholarly efforts have been concerned with the curation of authoritative data on, e.g., places or people within a specific domain, resulting in taxonomies, gazetteers, and prosopographies. In terms of their digital transformation, these knowledge graphs have been following a similar pattern as knowledge organization schemes in libraries: they are increasingly being published according to Linked Data principles and connected to other knowledge graphs on the Web, using shared semantic concepts.

Members of both domains soon realized that knowledge graphs can be curated and enriched

by community-driven editorial processes, similar to those of Wikipedia. As a result, processes emerged that either allow users to directly edit a knowledge graph or provide mechanisms such as *semantic tagging* to support enriching corpora with concepts from knowledge graphs.

Cross-domain knowledge graphs, as they are emerging in the libraries and digital humanities domain, open a whole new spectrum of research opportunities. They can, for instance, inform the design of quantitative analytics tasks being applied on possibly large-scale document corpora. Taking into account the numerous digitization efforts in the library and humanities domain, knowledge graphs can be vehicles for connecting and exchanging findings as well as factual knowledge gained by applying those task on corpora. This can also stimulate the development of novel, mixed-method research methodologies.

K

Knowledge Organization Systems in Libraries

Libraries have long identified the value of maintaining (meta)data about their holdings. Over centuries the classical form of the book-based catalog has evolved into card-based catalogs and then electronic catalogs organized around the *record* unit, representing data about one of the library's holdings (a monograph, a journal issue, etc.). Library science developed resources and methods to rationalize the way these data were produced and exploited. The first of them were designed for classification and subject indexing, such as the Dewey Decimal Classification (DDC), the Universal Decimal Classification (UDC), or the Library of Congress Subject Headings (LCSH). Classification schemes, subject heading lists, thesauri, and other taxonomies were engineered to guide the description of the subjects of library assets (or their type). Name authority files and gazetteers played a similar role as organized listings of names for persons, organizations, and places. All these are composed

of elements (classes, concepts, names, etc.) that are provided with lexical information (variants, synonyms) or semantic information (especially, hierarchical or associative links), which qualifies them as knowledge organization systems. They also constitute vast bodies of knowledge, with dozens of thousands of concepts (LCSH contained 342,107 authority records in April 2017) that are richly described (UDC classes exist in over 40 languages).

In parallel, the structure of records was also the subject of much rationalization efforts, with description rules being agreed at the level of thematic or geographic communities. As libraries became (early) adopters of electronic information systems, these gave rise to formats geared for exchange of bibliographic metadata, such as MARC, which defines lists of codes for the fields in records (title, author, subject, etc.).

The need for structure and control within library systems came at the same time as a need to share and collaborate. Rather than each developing their own knowledge organization systems, libraries sought to share and reuse existing ones: classifications like UDC, thesauri like AGROVOC, and subject heading lists like LCSH or RAMEAU are used in entire networks of libraries. They can be seen as collaboratively built systems, as all the organizations that use them can contribute updates, even as one of them plays a leading role for maintenance and quality control. A similar form of sharing happens at the level of the datasets describing assets: *union cataloging* systems have been put in place so that consortia of libraries can refer to an existing description of a book, possibly after adding to it, rather than creating a new – probably poorer – one from scratch. This pooling of data gives even more importance to the knowledge organization systems backing these datasets and raised the motivation for enhancing their coverage and quality over time.

Of course, full standardization is not attainable, and overlapping vocabularies have been built, e.g., specific to a (sub-)domain or a (group of) country(ies). This became a problem when libraries needed a higher level of interoperability for their data. In some cases it has been ad-

dressed: the Virtual International Authority File (VIAF) has managed to consolidate links between the reference lists of persons and organization from dozens of (mostly national) libraries into a multilingual dataset (43 million clusters of links in 2014). MACS (Multilingual Access to Subjects) was another notable project, in which the national libraries of Switzerland, France, and Germany have teamed with the British Library to create thousands of links across the subject heading lists LCSH, RAMEAU, and SWD.

Considering the long-standing knowledge organization tradition in libraries, one can conclude that libraries have established systems resembling the characteristics of today's knowledge graphs. And indeed the Mundaneum, an early twentieth-century attempt to build a universal repository of facts, heavily inspired by library science, has been sometimes acknowledged as a precursor of the Semantic Web notion. Yet, as the W3C Incubator Group on Library Linked Data (W3C 2011) has put it, more than 20 years after the invention of the Web, the library and Semantic Web communities had similar metadata concepts but still different terminology; traditional library standards were designed only for the library community; library data was not well integrated with Web resources and still expressed primarily in presentation-oriented, natural-language text.

Library Linked Data

The adoption of the Linked Data principles is a major step in the transition from library-centric knowledge organization systems to domain-spanning, openly available, and easily accessible knowledge graphs. These principles postulate a conceptual representation of library objects and concepts as first-class Web resources and then propose (i) the assignment of unique Web identifiers (URI) to these resources, (ii) the provision of machine-readable metadata describing these resources, and (iii) linkage of resources with semantically related resources in other datasets or knowledge organization

systems. Those principles are being adopted in the publication of *metadata element sets* and *value vocabularies*, as detailed in the reports of the W3C Library Linked Data Incubator Group. This provided the basis for a number of data aggregation, linkage, and exposure efforts producing a large variety of *library linked datasets*.

Metadata Element Sets

A metadata element set provides elements (e.g., title, date, subject) to be used to describe a resource (e.g., a book), like the aforementioned MARC. Within the scope of Linked Data, metadata element sets are typically defined using RDF Schema (Brickley and Guha 2014) or the OWL Web Ontology Language (Hitzler et al. 2012). Besides supporting the definition of elements (properties), those schema or ontology definition languages also provide primitives for describing groups of related resources (classes) and the relationships between these resources. Important metadata element sets within the Library Linked Data field are the Dublin Core Metadata Element Set (DCMI 2012), the Bibliographic Framework Initiative (BIBFRAME) vocabulary, or the Resource Description and Access (RDA) element set. Interestingly, Dublin Core was developed at the time when the notions of the Semantic Web were articulated, with several key people involved in both initiatives, which positioned it as one of the most used vocabularies in Library Linked Data and beyond.

Value Vocabularies

A value vocabulary defines concepts that are used in the value space of bibliographic metadata records – cataloging rules in libraries often require terms of certain vocabularies to be used with certain metadata elements. Value vocabularies include knowledge organization systems such as introduced above, and their semantic expressiveness ranges from flat term definition lists (glossaries), over hierarchical structures such as classification schemes and taxonomies, to more connected vocabularies like thesauri.

Within the context of Linked Data, concepts defined as part of value vocabularies should be first-class resources identified by dereferenceable HTTP URIs. Concepts can be linked to other concepts within the same value vocabulary as well as to other concepts, possibly defined by another domain. The Simple Knowledge Organization System (SKOS) (Baker et al. 2013) has become the de facto standard for expressing the basic structure and content of controlled value vocabularies.

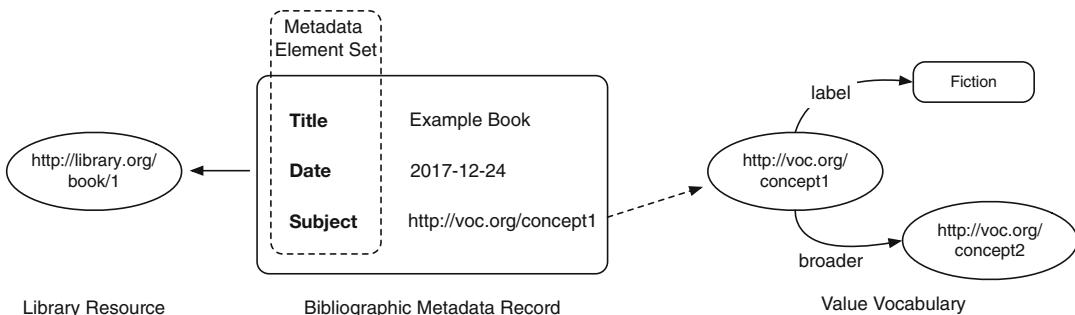

A number of value vocabularies established in the library field were made available as Linked Data: LCSH (Summers et al. 2008), the multilingual AGROVOC thesaurus (Caracciolo et al. 2013), VIAF, several national authority files (e.g., German GND), the Getty vocabularies (Getty 2017), as well as parts of the Dewey Decimal Classification (OCLC 2017).

The terms “ontology” and “vocabulary” are often used to refer both to metadata element sets and value vocabularies. Their role in the making of Linked Data differs quite significantly however. Descriptions typically reuse elements from standard metadata element sets in combination with elements from value vocabularies. Figure 1 shows an example of bibliographic metadata description with metadata fields taken from a metadata element set and a value vocabulary concept.

Library Linked Datasets

Within the last decade, a number of institutions have published collections of metadata records as Linked Data on the Web. Such records typically describe books, but other types of cultural objects can be described too.

The Hungarian and Swedish National (Malmsten 2008) libraries, who opened and exposed their OPAC catalog and corresponding authority files around the year 2008, were among the earlier adopters of the Linked Data principles. The British National Bibliography (BNB) (Deloit 2014) is a prominent Linked Library example which also links to external sources such as VIAF or LCSH. This was followed by many other data publication initiatives on an institutional or service level, including the Amsterdam

Knowledge Graphs in the Libraries and Digital Humanities Domain, Fig. 1 Library linked data example and notions

Museum (De Boer et al. 2012b), the CrossRef service, the Linked Open Library Data project, or Linked Art, which is a community working together to create a shared Linked Data model to describe art.

In parallel to institution- and service-level Linked Data publication initiatives, major metadata aggregation hubs across libraries and other institutions, such as Europeana (Haslhofer and Isaac 2011) and the Digital Public Library of America (DPLA) (DPLA 2017), started to expose collected cross-domain metadata records as Linked Open Data on a larger scale (as of 2017 Europeana and DPLA provide access to over 51 and 18 million objects, respectively) and to link them with other sources such as Wikidata. An important milestone achieved by these efforts was the wider adoption of public domain and (standard) open licenses (like the ones of Creative Commons) for the metadata. This has not only been a major business shift for libraries but also fulfilled two important preconditions for building large-scale, cross-domain knowledge graphs: the ability to mix and match library data with data from other sources and the possibility to edit and enhance knowledge graphs under control of a larger community.

Community-Driven Knowledge Graph Enrichment

In the early days of Linked Data, most knowledge graphs were published out of existing in-

stitutional repositories or extracted from public knowledge sources (e.g., Wikipedia) in a rather static, “push” fashion. The community soon realized however that knowledge graphs can be curated by community-driven editorial processes similar to those of Wikipedia.

A strong form of community-driven knowledge graph enrichment was provided by Freebase (Bollacker et al. 2008), which allowed users to enhance existing and add new facts to their knowledge graph. However, Freebase was acquired by Google and shut down its public API in 2016. An even stronger form is implemented by Wikidata (Vrandečić and Krötzsch 2014), in which the user community controls not only the data and schema but also the entire editorial process. Wikidata is also important as a case of interlinking vocabularies, tackling one of the issues in traditional library data. The Wikidata community-developed alignment tool Mix’n’Match, for instance, allows users to upload a vocabulary to Wikidata and create an alignment for it, which has helped to position Wikidata as a huge hub for Library Linked Data and beyond. Near-systematic references are now available between Wikidata entities and resources from vocabularies like VIAF and GND.

Within the digital libraries and digital humanities domains, community-driven knowledge graph enrichment mostly focused on involving users in linking resources from existing corpora with concepts in knowledge graphs. One possible enrichment technique is *semantic tagging*, which supports users in associating digital items or

fragments thereof with concepts expressed in existing knowledge graphs. That technique has been used for semantic tagging of historical maps (Haslhofer et al. 2013), images, and texts (Simon et al. 2015).

Knowledge Graphs in the Digital Humanities

The development and curation of domain-specific knowledge structures has traditionally been an important element of humanities scholarship. In many cases, these structures emerge as an implicit research output, e.g., when studying the interrelation between actors and events in a specific historical setting. In other cases, the development of a knowledge organization system as such – or components of it – is the main objective of the research endeavor. This is the case, for example, for the development of domain taxonomies, *gazetteers*, or *prosopographies* (dictionaries of people or groups of people). Initiatives such as the Tabula Imperii Romani (TIR-FOR 2016), the Tabula Imperii Byzantini (TIB 2017), the Prosopography of the Byzantine World (PBW 2011), the Great Britain Historical GIS (GBHGIS 2012), or the Treasury of Lives (ToL 2017) have been concerned exclusively – sometimes over a significant timespan, and long before the digital transformation – with the curation of authoritative data on places or people within their domain. Other efforts have focused on the translation of existing analog authority information to digital, some of them, such as the Pleiades Gazetteer of the Ancient World (Pleiades Contributors 2017) specifically as Linked Data.

The motivation behind the development of classification schemes and authority information in the humanities is much the same as in the library domain: a need for structure, control, and a common vocabulary to facilitate collaboration. Arguably, however, scholarly humanities research differs insofar as there is a much higher degree of specificity to particular – sometimes even niche – domains. The heterogeneous nature of research outputs, the interpretative quality of humanities research, and the fact that work is

often organized around the efforts of a single individual or small group, funded through time-limited grants, make a “global knowledge graph of the humanities” seem an unachievable goal. Yet the need to publish data under open licenses and build connections between datasets based on shared value vocabularies and metadata element sets is increasingly perceived in the community as key for enabling reuse, for the transparency of scholarly methods, and, ultimately, for sustainability of results. This trend is reflected in the rise of Linked Data as a theme at digital humanities events, conferences, and curricula, as much as in the emergence of community initiatives dedicated to establishing common interlinking standards and practices.

By and large, such initiatives advocate the idea of cross-domain linkage by means of shared name authority files, along with recommendations on metadata element use. Crucial to this effort are, on the one hand, generic knowledge graphs – DBpedia and Wikidata in particular. On the other hand, linked datasets from libraries or museums, such as VIAF, the Getty Thesaurus of Geographic Names, or the Getty Art and Architecture Thesaurus, have been gaining traction as an interconnecting “spine” through which community-specific datasets can build outbound links to contribute to a global graph.

As these networking efforts are enabling the aggregation of increasingly large corpora of cultural heritage content, the use of computational methods to study larger cultural phenomena is becoming more feasible (cf. Schich et al. 2014; Cook et al. 2012). New tools are transforming traditional scholarship, enabling scholars to identify and answer new research questions (cf. Siemens and Schreibman 2008; Bodenhamer et al. 2010; Bodard and Romanello 2016). Michel et al. (2010) popularized the term *culturomics* as “the application of high-throughput data collection and analysis to the study of human culture.” In this context, knowledge organization systems represent the crucial connecting medium within an ecology of independent initiatives that is gradually increasing mutual connectivity by creating and using Linked Open Data (Isaksen et al. 2014).

Future Directions of Research

Large-scale knowledge graphs, as they have been emerging in the libraries and digital humanities domain, and the publication of seminal papers (e.g., Michel et al. 2010) demonstrate how the application of quantitative analysis to large-scale corpora opens up a spectrum of possible new research questions that, up until now, were hard to answer with existing methods and primary sources. Data was manually curated and often bound to an institution or the scope of an individual researcher's project. Most studies in the humanities and related disciplines have focused on rather small corpora, while the constitution and maintenance of institutional knowledge organization systems and related datasets in libraries required years of work for a highly skilled and trained workforce.

Exploiting the opportunities of quantitative analysis methods poses a number of methodological, technical, and organizational challenges: first, novel serial analysis methods and tools are needed that support scholars in viewing, annotating, and systematically analyzing relevant parts of possibly large digitized corpora. Scholars could express relevance by selecting corresponding concept definitions in knowledge graphs. Second, scalable text-mining and machine-learning techniques are needed to systematically and efficiently analyze and compare the characteristics, contents, and relationships of concepts expressed in knowledge graphs within and across corpora. Third, algorithms are needed that support scholars in detecting, contextualizing, and analyzing various forms of expressions and associated narrative techniques in corpora spanning a long time period, in which the syntax and semantics may have been subject to constant change. Under this premise, future research could focus on:

- the development of tools and scalable techniques for aligning large-scale, possible multimedia corpora with concepts expressed in knowledge graphs
- the investigation of text mining algorithms that can learn from scholar's annotations and

support them in investigating semantic relationships extracted from large corpora

- the investigation of novel reconciliation mechanisms that ensure that institutional and community-curated knowledge graphs produced in different context are truly interoperable and do not lead to "competing" data offers
- the design of appropriate provenance tracking, crowd- or niche-sourcing (De Boer et al. 2012a) approaches, and validation mechanisms that ensure trust in data quality when data are curated by humans with different levels of expertise and/or result from automatic processes

The possible research directions described above show that there is a clear need for collaborative research among researchers from humanities, computer science, as well as library information science. This will also result in novel mixed qualitative and quantitative methods for the analysis of large-scale digitized corpora relevant to the humanities and related disciplines.

Definitions

In this chapter, some of the most common tools for Big Data analytics are surveyed, inter-alia, Apache Spark, Flink, Storm, and Beam. They are compared against well-defined features concerning programming model (language expressivity and semantics), and execution model (parallel behaviour and run-time support). The implementation of a running example is provided for all of them.

Overview

Boosted by Big Data popularity, new languages and frameworks for data analytics are appearing at an increasing pace. Each of them introduces its own concepts and terminology and advocates a (real or alleged) superiority in terms of performances or expressiveness against predecessors. In this hype, for a user approaching Big Data analytics (even an educated computer scientist), it might be difficult to have a clear picture of the programming model underneath these tools and the expressiveness they provide to solve some user-defined problem.

To provide some order in the world of Big Data processing, a toolkit of models to identify their common features is introduced, starting from data layout.

Data processing applications are divided into *batch* vs. *stream* processing. Batch programs process one or more *finite* datasets to produce a resulting finite output dataset, whereas stream programs process possibly unbounded sequences of data, called *streams*, doing so in an incremental manner. Operations over streams may also have to respect a total data ordering – for instance, to represent time ordering.

In order to compare the expressiveness of programming models for Big Data, analytics are mapped onto a unifying (and lower-level) computation model, viz. the *dataflow model* (Lee and Parks 1995). As shown in Misale et al. (2017), the dataflow model is able to capture

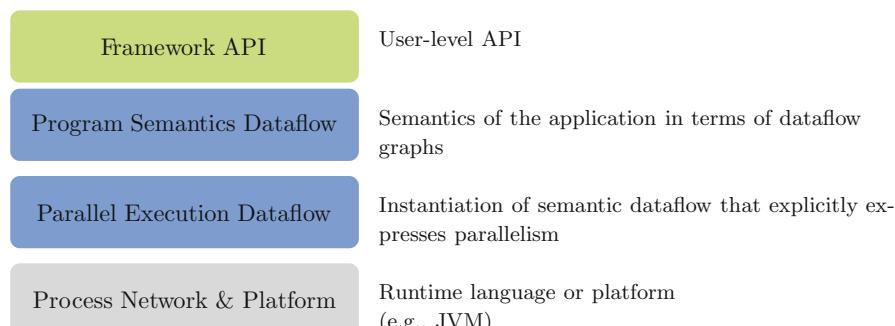

the distinctive features of all frameworks at all levels of abstraction, from the user-level API to the execution model. In the dataflow model, an application acts as a directed graph of actors. In its “modern” macro-data flow version (Aldinucci et al. 2012), it naturally models independent (thus parallelizable) kernels starting from a graph of true data dependencies, where a kernel’s execution is triggered by data availability.

The dataflow model is expressive enough to describe batch, micro-batch, and streaming models that are implemented in most tools for Big Data processing. Also, the dataflow model helps in maturing the awareness that many Big Data analytic tools share almost the same base concepts, differing mostly in their implementation choices.

In the next section, the key finding of this chapter is introduced, i.e., the layered dataflow model. On this ground, the mainstream languages and frameworks for Big Data analytics are then introduced; they are Spark, Storm, Flink, and Beam. According to the layered dataflow model, they will be discussed at two successive levels of abstractions, i.e., (1) *API and semantics* and (2) *parallel execution and runtime support*. This section draws future direction for research.

Key Research Finding: The Layered Dataflow Model

In order to compare different Big Data frameworks, a revised version of the layered dataflow model is adopted (Misale et al. 2017).

Languages for Big Data Analysis, Fig. 1 Layered model representing the levels of abstractions provided by the frameworks that were analyzed

This model, sketched in Fig. 1, presents four layers. The top layer captures the framework API. The two intermediate layers are dataflow models with different semantics, as described in the paragraphs below. The bottom layer is the *process network and platform*, which embodies the network of processes used to implement a given framework together with their programming language runtime support (e.g., Java and Scala in Spark), a level which is beyond the scope of this work.

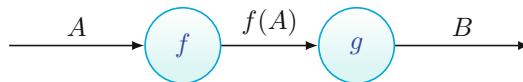

The stacked dataflow layers are as follows.

Framework API

At the top of the stack, the API is the concrete primitives provided by each framework, in which data processing applications are written. Within the Big Data analytic domain, APIs can be regarded as domain-specific languages (DSLs), expressed in some host language (e.g., Python, Scala, Java).

Program Semantic Dataflow

The API exposed by all major Big Data frameworks can be explained in terms of a dataflow graph, that is, a pair $G = \langle V, E \rangle$ where actors V represent operators, channels E represent data dependencies among operators, and tokens represent data to be processed. For instance, consider to process a collection A by a function f followed by a function g . This is represented by the graph in Fig. 2, which represents the semantic dataflow of a program computing the functional composition $f \circ g$.

Languages for Big Data Analysis, Fig. 2 Semantic dataflow graph for $f \circ g$, expressing data dependencies

Moreover, although not extensively discussed here, it is remarkable that also nonfunctional aspects (e.g., window-based stream processing, stateful operators, iterations) can be conveniently represented by means of the proposed dataflow setting (Misale et al. 2017).

Parallel Execution Dataflow

This level represents an instantiation of the semantic dataflows in terms of processing elements (i.e., actors) connected by data channels (i.e., edges). The most straightforward source of parallelism comes directly from the dataflow model, namely, independent actors can run in parallel. Furthermore, some actors can be replicated to increase parallelism by making replica work over a *partition* of the input data – that is, by exploiting full *data parallelism*. Both the above schemas are referred as *embarrassingly parallel* processing, since there are no dependencies among actors. Finally, in case of dependent actors that are activated multiple times (e.g., by further splitting a partition into multiple tokens), parallelism can still be exploited by letting tokens “flow” as soon as each activation is completed. This well-known schema is referred to as *stream/pipeline* parallelism.

Process Network Dataflow and Platform

This level describes how the program is effectively deployed and executed onto the underlying platform. Actors are concrete computing entities (e.g., processes), and edges are communication channels. The most common approach is for the actual network to be a master-worker task executor.

Examples of Application

In this section, some mainstream frameworks for Big Data processing are discussed, within the layered dataflow setting. “Google MapRe-

duce” is commonly considered as the first widespread tool in this domain. “► [Apache Spark](#)” provides a richer API (e.g., also targeting streams) and an implementation optimized for iterative processing. “► [Apache Flink](#)” is similar to Spark, but it exploits more parallelism by means of a stream-based runtime. “Apache Storm” is focused on stream processing, and differently from the previous frameworks, Storm programs are defined as interconnected processing units, rather than functional compositions. Finally, “Apache Beam” provides an alternative API for unifying batch and stream processing under a single programming model.

Google MapReduce

Google can be considered the pioneer of Big Data processing, as the publication of the MapReduce framework paper (Dean and Ghemawat 2004) made this model mainstream. Based on the *map* and *reduce* functions, commonly used in parallel and functional programming (Cole 1989), MapReduce provides a native key-value model and built-in sorting, which made it successful for several Big Data analytics scenarios.

API

A MapReduce program is built on the following user-defined functions: (1) a map function, which is independently applied to each item from an input key-value dataset to produce an *intermediate* key-value dataset; (2) a reduce function, which combines all the intermediate values associated with each key (together with the key itself) into lists of reduced values (one per key); and (3) a partitioner function, which is used while *sorting* the intermediate dataset (i.e., before being reduced), so that the order over the key space is respected within each partition identified by the partitioner.

Figure 3 shows a source code extract from a MapReduce implementation of the Word Count application that counts the occurrences of each word in an input text and is generally considered as the “Hello World!” for Big Data analytics. In the code extract, only map and reduce functions are specified; thus, a default implementation-dependent sorting is used.

```

1 public class WordCount {
2
3     public static class TokenizerMapper
4             extends Mapper<Object,Text,Text,IntWritable> {
5         private final static IntWritable one = new IntWritable(1);
6         private Text word = new Text();
7
8         public void map(Object key, Text value, Context context)
9                 throws IOException, InterruptedException {
10            StringTokenizer itr = new StringTokenizer(value.toString());
11            while (itr.hasMoreTokens()) {
12                word.set(itr.nextToken());
13                context.write(word, one);
14            }
15        }
16    }
17
18    public static class IntSumReducer
19            extends Reducer<Text,IntWritable,Text,IntWritable> {
20        private IntWritable result = new IntWritable();
21
22        public void reduce(Text key, Iterable<IntWritable> values, Context
23        context)
24                throws IOException, InterruptedException {
25            int sum=0 ;
26            for (IntWritable val: values) {
27                sum += val.get();
28            }
29            result.set(sum);
30            context.write(key, result);
31        }
32    }
33 }

```

Languages for Big Data Analysis, Fig. 3 The map and reduce functions for a Java Word Count class example in MapReduce

Semantics

The semantics of MapReduce is defined by the following chain of higher-order operators, where f , h , and \oplus correspond to the map, partitioner, and reduce API functions, respectively:

$$\begin{aligned} \text{map-reduce } f \ h \ R \oplus \\ = (\text{flat-map } f) \circ (\text{sort } h \ R) \circ (\text{reduce } \oplus) \end{aligned}$$

When applied to an input multiset (i.e., a finite unordered collection, possibly containing duplicated items) of key-value pairs, flatMap applies the kernel to each item and collapses all the results into a single intermediate multiset. Formally, $f : K \times V \rightarrow \mathcal{P}(K' \times V')$ is the kernel and m is a collection with $(K \times V)$ -typed items:

$$\text{flat-map } f \ m = \cup \{f(k, v) : (k, v) \in m\} \quad (k', v') \in m'$$

The intermediate multiset is processed by the sort operator to produce a multiset of partially ordered multisets (called intermediate *partitions* in MapReduce terminology). This partial sorting is parametric with respect to the number of partitions and the partitioning function, the latter mapping key-value input pairs to a partition. Formally, where I is the partition identifier space, R is the number of partitions, and $h: K' \times \mathbb{N} \rightarrow P$ is the partitioning function (e.g., hash-based), the partition identified by $\iota \in I$ from the intermediate multiset m' is defined as:

$$\sigma_\iota^h(R, m') = \{(k', v') : h(k', R) = \iota,$$

Moreover, each partition p is partially ordered according to the keys, such that:

$$\begin{aligned} \forall (k'_a, v'_a), (k'_b, v'_b) \in p, k'_a < k'_b \\ \Rightarrow (k'_a, v'_a) \text{ precedes } (k'_b, v'_b) \text{ in } p \end{aligned}$$

However, no ordering is guaranteed “internally” to each given key. Then, the semantics of sort follows:

$$\text{sort } h R m' = \left\{ \sigma_i^h(R, m') : \sigma_i^h(R, m') \neq \emptyset \right\}$$

Finally, the reduce operator synthesizes the partitions on a per-key basis, according to a reduction kernel, respecting the ordering within each partition.

First, the reduce-by-key operator is defined. Given a collection of key-value pairs, it produces a collection of synthesized collections, one for each key. Formally, given $\oplus : K' \times P(V') \rightarrow P(V'')$ denoting the reduction kernel:

$$\begin{aligned} \text{reduce-by-key } \oplus p = \\ \{(k', \oplus(k', \{v' : (k', v') \in p\})) : \exists (k', v') \in p\} \end{aligned}$$

Moreover, when applied to partitions (i.e., multisets partially ordered based on a per-key base), reduce-by-key operator produces a *totally ordered set*, where all the values with a given key are combined into a single key-value(s) pair and the ordering is kept among keys. Then, the reduce operator is defined as follows, where m'_s is a multiset of partitions and the big union operator respects the ordering:

$$\text{reduce } \oplus m'_s = \cup \{\text{reduce-by-key } \oplus p : p \in m'_s\}$$

Parallel Execution

A simple form of data parallelism can be exploited on the flatMap side, by partitioning the input collection into n chunks and having n executors process a chunk. In dataflow terms, this corresponds to a graph with n actors, each processing a token that represents a chunk. Each flatMap executor emits R (i.e., the number of intermediate partitions) chunks, each containing

the intermediate key-value pairs mapped to a given partition.

The intermediate chunks are processed by R reduce executors. Each executor (1) receives n chunks (one from each flatMap executor); (2) merges the chunks into an intermediate partition and partially sorts it based on keys, as discussed above; and (3) performs the reduction on a per-key basis. Finally, a downstream collector gathers R tokens from the reduce executors and merges them into the final result.

A key aspect in the depicted parallelization is the *shuffle* phase, in which data is distributed between flatMap and reduce operators, according to an *all-to-all* communication schema. This poses severe challenges from the implementation standpoint.

Runtime Support

The most widespread implementation (i.e., *Hadoop*) is based in a *master-worker* approach, in which the master retains the control over the global state of the computation and informs the workers about the tasks to be executed.

A cornerstone of Hadoop is its distributed file system (HDFS), which is used to exchange data among workers, in particular upon shuffling. As a key feature, HDFS exposes the *locality* for stored data, thus enabling the principle of moving the computation toward the data, to minimize the communication. However, disk-based communication leads to performance problems when dealing with iterative computations, such as machine learning algorithms (Chu et al. 2006).

Apache Spark

Apache Spark (Zaharia et al. 2012) was proposed to overcome some limitations in Google MapReduce. Instead of a fixed processing schema, Spark allows datasets to be processed by means of arbitrarily composed primitives, referred to as the application directed acyclic graph (DAG). Moreover, instead of relying exclusively on disks for communicating data among the processing units, in-memory caching is exploited to boost the performance, in particular for iterative processing.

API and Semantics

Apache Spark uses a *declarative processing style* expressed as methods on objects representing collections. More precisely, Apache Spark implements batch programming with a set of operators, called *transformations*, that are uniformly applied to whole datasets called *resilient distributed datasets* (RDD) (Zaharia et al. 2012), which are immutable multisets. A Spark program can be characterized by the two kinds of operations applicable to RDDs: *transformations* and *actions*. Transformations are lazy functions (i.e., they do not compute their results right away) over collections – such as map, reduce, and flatMap – that are uniformly applied to whole RDDs. Actions effectively trigger the DAG execution, and they return a value to the user.

Listing 4 shows the source code for a simple Word Count application in the Java Spark API.

For stream processing, Spark implements an extension through the Spark Streaming

module, providing a high-level abstraction called *discretized stream* or *DStream*. Such streams represent results in continuous sequences of RDDs of the same type, called *micro-batches*. Operations over DStreams are “forwarded” to each RDD in the DStream; thus, the semantics of operations over streams is defined in terms of batch processing according to the simple translation $\text{op}(a) = [\text{op}(a_1), \text{op}(a_2), \dots]$, where $[\cdot]$ refers to a possibly unbounded ordered sequence, $a = [a_1, a_2, \dots]$ is a DStream, and each item a_i is a micro-batch of type RDD.

When mapping a Spark program to a semantic graph, tokens represent RDDs and DStreams for batch and stream processing, respectively. Actors are operators – either transformations or actions – that transform data or return values (in-memory collection or files). Actors are activated only once in both batch and stream processing, since each collection (either RDD or DStreams) is represented by a single token (Fig. 4).

```

1 JavaRDD<String> textFile=sc.textFile("hdfs://...");  

2  

3 JavaRDD<String> words =  

4     textFile.flatMap(new FlatMapFunction<String, String>() {  

5         public Iterable<String> call(String s) {  

6             return Arrays.asList(s.split(" "));  

7         }  

8     });  

9  

10 JavaPairRDD<String, Integer> pairs =  

11     words.mapToPair(new PairFunction<String, String, Integer>() {  

12         public Tuple2<String, Integer> call(String s) {  

13             return new Tuple2<String, Integer>(s, 1);  

14         }  

15     });  

16  

17 JavaPairRDD<String, Integer> counts =  

18     pairs.reduceByKey(new Function2<Integer, Integer, Integer>() {  

19         public Integer call(Integer a, Integer b) {  

20             return a + b;  

21         }  

22     });  

23  

24 counts.saveAsTextFile("hdfs://...");
```

Languages for Big Data Analysis, Fig. 4 A Java Word Count example in Spark from its example suite

Parallel Execution and Runtime Support

From the application DAG, Spark infers a parallel execution dataflow, in which many parallel instances of actors are created for each function and independent actors are grouped into *stages*. Due to the Spark batch-oriented implementation, each stage that depends on some previous stages has to wait for their completion before execution, according to the classical Bulk Synchronous Parallelism (BSP) approach. Therefore, a computation proceeds in a series of global *supersteps*, each consisting of (1) concurrent computation, in which each actor processes its own partition; (2) communication, where actors exchange data between themselves if necessary (the *shuffle* phase); and (3) barrier synchronization, where actors wait until all the other actors have reached the same barrier.

Similarly to the MapReduce implementation, Spark's execution model relies on the master-worker model: a cluster manager (e.g., YARN) manages resources and supervises the execution of the program. It manages application scheduling to worker nodes, which execute the application logic (the DAG) that has been serialized and sent by the master.

Apache Flink

Apache Flink (Carbone et al. 2015) is similar to Spark, in particular from the API standpoint. However, Flink is based on *streaming* as a primary concept, rather than a mere linguistic extension on top of batch processing (as is in Spark). With the exception of iterative processing, stream parallelism is exploited to avoid expensive synchronizations among successive phases, when executing both batch and stream programs.

API and Semantics

Apache Flink's main focus is on stream programming. The abstraction used is the *DataStream*, which is a representation of a stream as a single object. Operations are composed (i.e., pipelined) by calling operators on *DataStream* objects. Flink also provides the *dataset* type for batch applications that identifies a single immutable multiset – a stream of one element. A Flink program, either for stream or batch processing, is a term from an algebra of operators over *DataStream*s or *dataset*s, respectively.

Figure 5 shows Flink's source code for the simple Word Count application.

```

1 public class WordCountExample {
2     public static void main(String[] args) throws Exception {
3         final ExecutionEnvironment env =
4             ExecutionEnvironment.getExecutionEnvironment();
5         DataSet<String> text =
6             env.fromElements("Text...\"");
7         DataSet<Tuple2<String, Integer>> wordCounts =
8             text.flatMap(new LineSplitter())
9                 .groupBy(0)
10                .sum(1);
11
12         wordCounts.print();
13     }
14
15     public static class LineSplitter
16         implements FlatMapFunction<String, Tuple2<String, Integer>> {
17         @Override
18         public void flatMap(String line, Collector<Tuple2<String, Integer>> out) {
19             for (String word : line.split(" ")) {
20                 out.collect(new Tuple2<String, Integer>(word, 1));
21             }
22         }
23     }
24 }
```

Languages for Big Data Analysis, Fig. 5 A Java Word Count example in Flink from its example suite

Flink applications can be applied to semantic dataflow graphs in the same way as for Spark, by treating datasets and datastreams as, respectively, RDDs and DStreams.

Parallel Execution and Runtime Support

Flink transforms a JobGraph into an execution graph, in which the JobVertex contains ExecutionVertexes (actors), one per parallel sub-task. A key difference compared to the Spark execution graph is that, apart from iterative processing (that is still executed under BSP), there is no barrier among actors or vertexes: instead, there is effective pipelining.

Also Flink's execution model relies on the master-worker model: a deployment has at least one job manager process that coordinates checkpointing and recovery and that receives Flink jobs. The job manager also schedules work across the task manager processes (i.e., workers) which usually reside on separate machines and in turn execute the code.

Apache Storm

Apache Storm (Nasir et al. 2015; Toshniwal et al. 2014) is a framework targeting only stream processing. It is perhaps the first widely used large-scale stream processing framework in the open source world. Whereas Spark and Flink are based on a declarative data processing model – i.e., they provide as building blocks for data collections and operations on those collections – Storm is instead based on a “topological” approach in that it provides an API to explicitly build graphs.

API and Semantics

Storm's programming model is based on three key notions: *spouts*, *bolts*, and *topologies*. A spout is a source of a stream that is (typically) connected to a data source or that can generate its own stream. A bolt is a processing element, so it processes any number of input streams and produces any number of new output streams. Most of the logic of a computation goes into bolts, such as functions, filters, streaming joins, or streaming aggregations. A topology is the composition of spouts and bolts resulting in a network.

Storm uses *tuples* as its data model, that is, named lists of values of arbitrary type. Hence, bolts are parametrized with per-tuple kernel code. It is also possible to define cyclic graphs by way of feedback channels connecting bolts. Figure 6 shows Storm's source code for the simple Word Count application.

As for mapping applications to dataflow graphs, whereas in the previously described frameworks the graph is implicit and tokens represent whole datasets or streams, Storm is different: (1) the dataflow graph is already explicit, as it is constructed using the provided API; (2) each token represents a single stream item (tuple), and the actors, representing (macro) dataflow operators, are activated each time a new token is available.

Parallel Execution and Runtime Support

At execution level, each actor is replicated to increase the inter-actor parallelism, and each group of replicas corresponds to the bolt/spout in the semantic dataflow.

Each of these actors represents independent data parallel tasks, on which pipeline parallelism is exploited. Eventually, tasks are executed by a master-worker engine, as in the previous frameworks.

Google Cloud Platform and Apache Beam

Google Dataflow SDK (Akidau et al. 2015) is part of the Google Cloud Platform. Google Dataflow supports a simplified pipeline development via Java and Python APIs in the Apache Beam SDK, which provides a set of windowing and session analysis primitives as well as an ecosystem of source and sink connectors. Apache Beam allows the user to create pipelines that are then executed by one of Beam's supported distributed processing back ends, which include, among others, Apache Flink, Apache Spark, and Google Cloud Dataflow, which are called *runners*.

API and Semantics

Apache Beam programming model is centered around the concept of *pipeline*, which represents a data processing program consisting of

```

1  public class WordCountTopology {
2      public static class SplitSentence extends ShellBolt implements IRichBolt {
3          public SplitSentence() {
4              super("python", "splitsentence.py");
5          }
6
7          @Override
8          public void declareOutputFields(OutputFieldsDeclarer declarer) {
9              declarer.declare(new Fields("word"));
10         }
11
12         @Override
13         public Map<String, Object> getComponentConfiguration() {
14             return null;
15         }
16     }
17
18     public static class WordCount extends BaseBasicBolt {
19         Map<String, Integer> counts = new HashMap<String, Integer>();
20
21         @Override
22         public void execute(Tuple tuple, BasicOutputCollector collector) {
23             String word = tuple.getString(0);
24             Integer count = counts.get(word);
25             if (count == null) count = 0;
26             count++;
27             counts.put(word, count);
28             collector.emit(new Values(word, count));
29         }
30
31         @Override
32         public void declareOutputFields(OutputFieldsDeclarer declarer) {
33             declarer.declare(new Fields("word", "count"));
34         }
35     }
36
37     public static void main(String[] args) throws Exception {
38         TopologyBuilder builder = new TopologyBuilder();
39         builder.setSpout("spout",
40             new RandomSentenceSpout(), 5);
41         builder.setBolt("split",
42             new SplitSentence(), 8).shuffleGrouping("spout");
43         builder.setBolt("count",
44             new WordCount(), 12).fieldsGrouping("split", new
45             Fields("word"));
46
47         Config conf = new Config();
48         conf.setDebug(true);
49         conf.setNumWorkers(3);
50
51         StormSubmitter.submitTopology(args[0], conf, builder.createTopology());
52     }
53 }
```

Languages for Big Data Analysis, Fig. 7 Java code fragment for a Word Count example in Apache Beam from its example suite

a set of operations that can read a source of input data, transform that data, and write out the resulting output. A pipeline can be linear, but it can also branch and merge, thus making a pipeline a DAG defined through conditionals, loops, and other common programming structures. A pipeline stage is a *transform*, which accepts one or more *PCollections* (i.e., a possibly unbounded immutable collection, either ordered or not) as input, performs an operation on its elements, and produces one or more new PCollections as output. The *ParDo* is the core element-wise transform in Apache Beam, invoking a user-specified function on each of the elements of the input PCollection to produce zero or more output elements (*flatMap* semantics) collected into an output PCollection.

When mapping a Beam program into a semantic graph, tokens represent PCollections and actors are transforms accepting PCollections in input and producing PCollections in output.

Figure 7 shows how to create a Word Count pipeline.

Parallel Execution and Runtime Support

The bounded (or unbounded) nature of a PCollection also affects how data is processed. Bounded PCollections can be processed using batch jobs that might read the entire dataset once and perform processing as a finite job. Unbounded PCollections must be processed using streaming jobs – as the entire collection will never be available for processing at any one time – and bounded subcollections can be obtained through logical finite size windows.

As mentioned, Beam relies on the *runner* specified by the user. When executed, an entity called *Beam Pipeline Runner* (related to execution back end) translates the data processing pipeline into the API compatible with the selected distributed processing back end. Hence, it creates an execution graph from the pipeline, including all the transforms and processing functions. That graph is then executed using the appropriate distributed processing back end, becoming an asynchronous job/process on that back end; thus, the final parallel execution graph is generated by the back end.

The parallel execution dataflow is similar to the one in Spark and Flink, and parallelism is expressed in terms of data parallelism in transforms (e.g., *ParDo* function) and inter-actor parallelism on independent transforms. In Beam's nomenclature, this graph is called the execution graph. Similarly to Flink, pipeline parallelism is exploited among successive actors.

Future Direction for Research

In this chapter, some of the most common tools for analytics and data management were presented. One common drawback of all of them is that their operators are not polymorphic with respect to the data model (e.g., stream, batch). This means analytics pipelines should be either re-designed or simulated to match a different data model, as in the *Lambda* or *kappa* architectures, respectively. This is often hardly acceptable either in terms of effort or performance.

The PiCo framework has been recently proposed to overcome this problem. PiCo's programming model aims at making easier the programming of data analytics applications while preserving or enhancing their performance. This is attained through three key design choices: (1) unifying batch and stream data access models, (2) decoupling processing from data layout, and (3) exploiting a stream-oriented, scalable, efficient C++11 runtime system. PiCo proposes a programming model based on pipelines and operators that are polymorphic with respect to data types in the sense that it is possible to reuse the same algorithms and pipelines on different data models (e.g., streams, lists, sets, etc.). Being PiCo designed as a C++11 header-only library, it can be easily ported in any general-purpose or specialized device supporting vanilla C++ runtime, including any low-power device in the edge of computing. Preliminary results show that PiCo can attain equal or better performances in terms of execution times and hugely improve memory utilization when compared to Spark and Flink in both batch and stream processing (Misale 2017; Misale et al. 2018).

Large-Scale Entity Resolution

Erhard Rahm and Eric Peukert

[Data deduplication](#); [Link discovery](#); [Object matching](#); [Record linkage](#)

Definitions

The goal of entity resolution is the identification of semantically equivalent objects within one data source or between different sources. In the context of Big Data, there is a growing need for large-scale entity resolution to find matching entities within very large and between many data sources. This requires effectively parallelizing entity resolution tasks within cluster environments.

Overview

Entity resolution (ER) is the task to identify semantically equivalent entities referring to the

same real-word object (e.g., persons, products, publications, or movies) within one data source or between different sources. This task is also known as data deduplication, object matching, record linkage, or link discovery. ER is of core importance for data cleaning and data integration and has been addressed for a long time in practice and research (Rahm and Do 2000; Elmagarmid et al. 2007; Christen 2012).

The traditional focus of ER was on structured data in relational databases. The example in Fig. 1 shows two input relations from different sources with address data that contain duplicates. The example illustrates some of the challenges of data deduplication tasks such as heterogeneous attribute names and value differences due to different conventions (e.g., for gender), abbreviations, omissions, nick names, and errors in the data. Typically, ER requires to first determine comparable attributes and then computing and combining the similarity for multiple attributes, e.g., for name, gender, and address in the example.

Large-scale entity resolution for Big Data introduces a number of challenges:

- Data sources can be very large with many millions of entities making it hard to achieve both effective and efficient entity resolution. Effectiveness asks for a good match quality so that only truly matching entities are identified (good precision) and that all matches are found (good recall). Efficiency is a problem since it is not feasible to pairwise compare all entities with each other for large datasets. Hence, it is imperative to reduce the number of comparisons (by filtering and blocking

techniques) and to also apply parallel entity resolution on many processors.

- Relevant data can be spread over thousands of data sources so that determining pairwise matches between two sources is not sufficient. Rather, a more holistic entity resolution is necessary in such cases where matching entities of all sources are grouped or clustered together such that all entities in such clusters match with each other (Rahm 2016). An example for such large-scale entity resolution is product offers from thousands of web shops that should be matched with each other, e.g., to allow a price comparisons (Köpcke et al. 2012).
- Entities especially from the web or from social networks are often only semi-structured and contain free text and also image content. Data quality is further reduced due to the frequent use of heterogeneous names and abbreviations as well as missing values.
- Data sources can change quickly such that existing entities are changed and deleted and new entities are added. As a result, entity resolution should be an incremental process such that previously computed matches are retained and the match result is only updated for changed or new entities.

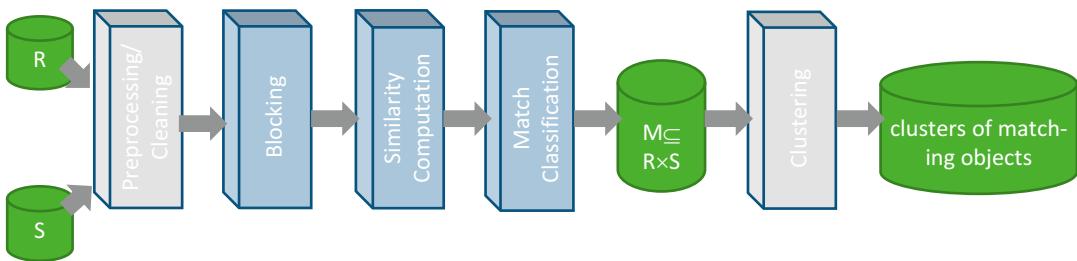

L

Entity resolution is typically implemented as a complex workflow to identify the matches within one data source or in several data sources. The output is either a set of pairwise correspondences (links) of matching entities, also called mapping. Alternatively all matching entities can be grouped or clustered together which is especially useful for more than two data sources. Figure 2

Large-Scale Entity Resolution, Fig. 2 Entity resolution workflow for two input sources R and S

shows the main steps of typical ER workflows that include preprocessing/data cleaning, blocking, similarity computation, and match classification (Christen 2012; Elmagarmid et al. 2007; Dong and Srivastava 2015). Optionally, the results of pairwise matching can be clustered to group all directly or indirectly matching entities.

In the **preprocessing** phase, missing attributes can be computed or values are cleaned with the help of background knowledge. Textual content can be harmonized by removing capital letters, replacing special characters, tokenizing textual values, or applying NLP techniques such as stemming or stop word removal. Furthermore, names or keywords relevant for matching (so-called features) can be extracted from textual attributes for further processing. For example, matching product offers can benefit from extracting manufacturer information and so-called product codes from the product descriptions for later similarity computation (Köpcke et al. 2012).

The **blocking** phase is crucial to scale ER to large datasets to reduce the number of match comparisons. Similar entities are grouped within blocks, e.g., based on approaches such as Standard Blocking or Sorted Neighborhood (Christen 2012). With Standard Blocking entities are grouped into partitions or blocks based on a blocking function on the values of one or more attributes. The subsequent similarity computation is restricted to the pairwise matching of entities from the same block. For product offers one could use manufacturer as a blocking key so that only offers for products of the same manufacturer need to be compared with each other. This significantly reduces the search space but often reduces recall. Multipass blocking applies multiple block-

ing functions to reduce the loss on recall at the expense of more comparisons (Christen 2012).

The **similarity computation** phase computes pairwise similarities based on attribute level matching with domain-specific or general similarity functions, e.g., utilizing string similarity metrics (edit distance, n-gram, TF/IDF, etc.). Moreover, context-based matchers are applicable that incorporate the entity neighborhood for similarity computation, e.g., related products such as the cameras for which an accessory product such as a replacement battery can be used.

In the **match classification** phase, the computed entity similarities are used to decide whether a pair of entities matches or not. The classification can be expressed as rules based on a weighted combination of similarity values and a similarity threshold or it can be derived from a machine learning-based classifier that has been determined for suitable training data. The match candidates can be further postprocessed or filtered, e.g., to only consider the best matches if there are several match candidates per entity. For clean datasets without duplicates, there should be at most one matching entity in another dataset.

In the **clustering** phase, the computed matches (correspondences) can be used to group all directly and indirectly matching entities. The simplest approach of Connected Components computes a transitive closure of all correspondences. It can achieve a high match recall but often suffers from poor precision since a single wrong link can lead to large clusters. More sophisticated approaches such as correlation clustering (Pan et al. 2015) try to maximize the entity similarities within clusters and to minimize

similarities between clusters. Hassanzadeh et al. (2009) and Saeedi et al. (2017) comparatively evaluate several approaches for entity clustering.

These phases are implemented within many tools for entity resolution and link discovery as surveyed in (Köpcke and Rahm 2010; Christen 2012; Nentwig et al. 2017). The comparative evaluation of several tools in Köpcke et al. (2010) showed that learning-based match classification mostly achieves better match quality than rule-based approaches especially for more complex match tasks such as for product matching. Most of the previous tools, however, lack support for parallel processing making them insufficiently capable to meet the performance and scalability requirements of Big Data applications.

Key Research Findings

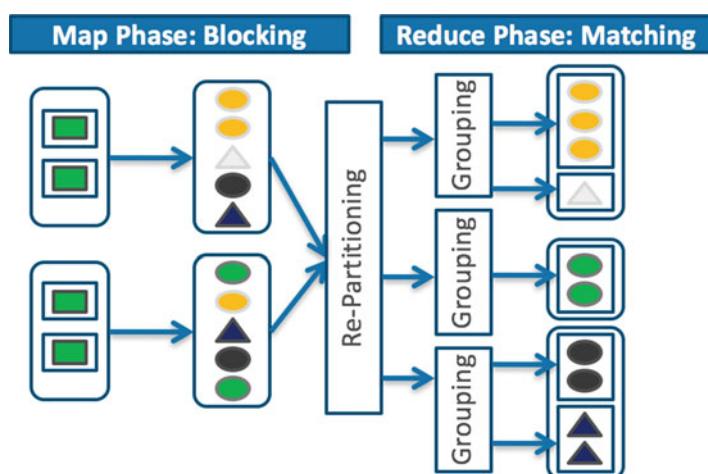

The performance and scalability requirements for Big Data applications require parallel entity resolution approaches in addition to the use of blocking. Kolb et al. (2012) have therefore investigated the utilization of Hadoop clusters and the MapReduce paradigm for parallel entity resolution. As illustrated in Fig. 3, there are two main phases. In the map phase, the input records are read in parallel and the blocking function is applied to the input data entities. The blocking key is used to distribute and group entities of the

same block to the same processing node for the matching phase. In the reduce phase, a pairwise matching is performed on all record pairs of the same block. Different blocks are processed in parallel.

Such a parallel entity resolution approach faces a potential load balancing problem in the reduce phase since the block sizes may vary to a large degree. The slowest reducer dominates the overall execution time and large blocks prevent the effective utilization of more than a few nodes. For load balancing, Kolb et al. (2012) propose two solutions called BlockSplit and PairRange. BlockSplit splits large blocks such there are multiple smaller match tasks that can be processed on different reducer nodes without creating overload situations. The approach leads to the replication of a subset of the entities that are part of several match tasks. The alternate PairRange approach globally enumerates all pairwise comparisons and evenly distributes these over all reducers. In both approaches, an additional MapReduce-Job is needed to compute the number and sizes of blocks for the configured blocking scheme. The load balancing approaches achieved a high scalability and proved to be stable against data skew. They are part of the DeDoop match tool that additionally offers machine-learning-based classification and a web-based UI for managing entity resolution tasks (Kolb and Rahm 2013).

Large-Scale Entity Resolution, Fig. 3

Parallel entity resolution with Map Reduce

Recently, alternative processing models such as Apache Flink and Apache Spark have become popular which provide a richer set of operators than MapReduce and in-memory computing for improved performance. Saeedi et al. ported many of the Dedoop features to Apache Flink within the FAMER system (Saeedi et al. 2017). In contrast to DeDoop, FAMER also supports multisource (holistic) entity resolution with more than two input sources. For this purpose, it offers parallel implementations for several entity clustering schemes.

Further proposals for holistic (multisource) entity resolution with entity clustering include Böhm et al. (2012), Pershina et al. (2015), and Nentwig et al. (2016). Gruenheid et al. (2014) studied incremental entity resolution that can improve scalability since new entities and sources are compared to existing clusters rather than with all other sources and entities.

Directions for Future Research

Novel machine learning techniques such as *deep learning* have been very successful in areas such as face or speech recognition and text mining. Such approaches are also promising for entity resolution, especially for web entities with textual descriptions, where deep neural networks may be able to automatically identify match-relevant features within such descriptions without extensive and complex preprocessing. Initial approaches in this direction are promising (Ebraheem et al. 2017) but do not yet fully exploit the potential of deep learning. Both the training of such methods and the model application need to be parallelized to be applicable for Big Data Integration tasks. The approaches should also be extended to include not only text attributes but also image content for matching.

Another area deserving more attention is scalable (parallel) entity resolution for graph-structured data where graphs (networks) can include entities and relationships of different types (e.g., publication and author entities with author and cite relationships). Here, the

similarity between entities of different graphs should consider not only the entity attributes but also the graph neighborhood. Furthermore, both entities (vertices) and relationships (edges) of the different types need to be matched and possibly fused within an integrated data graph. Moreover, holistic matching with more than two graphs and incremental entity resolution should be supported (Rahm 2016).

Another dimension that is beginning to gain interest is temporal record linkage that pays attention to the evolution of entities over time such as address changes (Li et al. 2011; Chiang et al. 2014; Christen et al. 2017). Such techniques should also become scalable to large and many data sources, e.g., within an incremental approach that keeps track of different entity versions.

Large-Scale Schema Matching

Erhard Rahm and Eric Peukert
University of Leipzig, Leipzig, Germany

Synonyms

- ▶ [Large-scale ontology alignment](#)

Definitions

Schema matching aims at identifying semantically corresponding elements in two or more schemas, e.g., database schemas or ontologies. Large-scale schema matching focusses on the challenging cases of matching large schemas or more than two schemas. Matching multiple (>2) schemas is also known as holistic schema matching.

Overview

Schema matching aims at identifying semantic correspondences between metadata structures or models, such as database schemas, XML message formats, and ontologies. Solving such match problems is a key task in numerous application fields, in particular for data exchange and virtually all kinds of data integration. For example, in the two simple database schemas DB1.Student (Name, Major, Marks) and DB2.Grad-Student (LastName, FirstName, Major, Grades), simple (equivalence) correspondences would be DB1.Student \approx DB2.Grad-Student, DB1.Major \approx DB2.Major, and DB1.Marks \approx DB2.Grades, while DB1.Name is related to both DB2.LastName and DB2.FirstName (part-of correspondences “DB2.LastName – DB1.Name” and “DB2.FirstName – DB1.Name”). The inherent semantic heterogeneity in different schemas makes it difficult for automatic approaches to correctly determine the correspondences so that there is a need for user involvement. The complexity is especially

high for Big Data applications that frequently involve *large-scale schema matching* where large schemas with thousands of elements or many data sources with different schemas have to be dealt with. In this entry, we will focus on the pairwise matching of large schemas while matching of multiple schemas is treated under *Holistic schema matching*, sometimes also called *collective schema matching* (Rahm 2016).

Most approaches for schema matching focus on 2-way or pairwise matching where two related input schemas are matched with each other. As shown in Fig. 1, automatic matching may also make use of instance data for the input schemas or background knowledge such as dictionaries or previous match results that simplify the identification of corresponding elements in the input schemas. The result of pairwise schema matching is usually an equivalence *mapping* containing the identified semantic correspondences, i.e., pairs of semantically equivalent schema elements (e.g., schema attributes or ontology concepts). Some match approaches for ontologies also try to determine different kinds of semantic correspondences, such as is-a and part-of relationships between concepts (Euzenat and Shvaiko 2013; Arnold and Rahm 2014). Due to the typically high semantic heterogeneity of schemas, algorithms can determine approximate mappings only. The automatically determined mappings may thus require the inspection and adaptation by human domain experts (deletion of wrong correspondences, addition of missing correspondences) to obtain the correct mapping. Mapping results are useful input for further data integration tasks such as merging or integrating the respective schemas since a mapping indicates

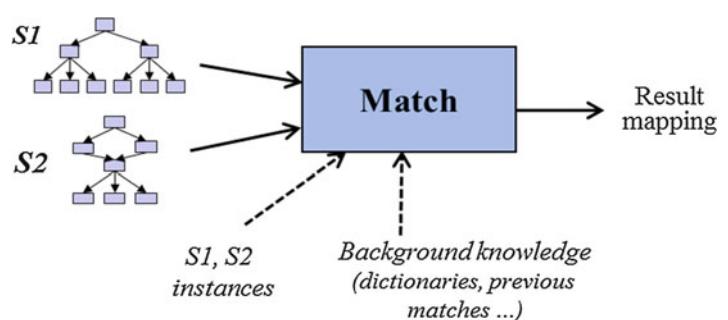

the elements that should be represented only once in the integrated result. In fact, several such mapping-based merge approaches have been proposed for both schemas and ontologies (Pottinger and Bernstein 2003; Raunich and Rahm 2014).

Schema matching has been a very active research area in the last decades, and numerous techniques and prototypes for automatic matching have been developed (Rahm and Bernstein 2001; Euzenat and Shvaiko 2013). Matches are usually identified by a combination of techniques (also called *matchers*) to determine the similarity of elements. These include

- Linguistic matchers that focus on the similarity of element names based on string similarity measures or synonym information from background knowledge resources such as dictionaries
- Structural matchers that determine the similarity of elements based on the similarity of their schema neighbors, e.g., ancestors and/or descendants
- Instance matchers that determine the similarity of elements based on their associated instance data, e.g., attribute values or entities of a concept

Despite the advances made, current match systems still struggle to deal with large-scale match tasks. In particular, achieving both good efficiency and good effectiveness are two major challenges. Further challenges for large-scale schema matching include benchmarking and evaluation as well as suitable approaches and interfaces for user involvement. The latter issues are further

Large-Scale Schema Matching, Fig. 1 Input and output of an automatic schema matching system

discussed in Hung et al. (2013) and are beyond the scope of this entry.

Key Research Findings

We focus on recent approaches to improve efficiency and effectiveness for large-scale pairwise schema (and ontology) matching.

The main performance (efficiency) problem for matching large schemas is the potentially huge search space if one has to compare every element of the first with every element of the second input schema. For schemas and ontologies with thousands or tens of thousands of elements, this leads to a search space of many million comparisons. This cannot only result in long execution times for the evaluation of several matchers but will also make it difficult to find the relatively few correspondences under so many possible candidates. Hence, it is imperative for large-scale matching to reduce the search space. Furthermore, one can apply parallel matching to improve runtimes. Note that these techniques (reduction of the search space and parallel matching) are also common for large-scale entity matching (Kolb and Rahm 2013; Dong and Srivastava 2015).

Parallel matching is relatively straightforward but has been applied in only few prototypes for schema matching, e.g., in Gomma (Gross et al. 2010) and SPHeRe (Amin et al. 2016). It can be used to speed-up single matchers, e.g., by partitioning the search space (set of element pairs from the input schemas) and evaluating different partitions in parallel on different processors. Furthermore, different matchers can be evaluated in parallel to each other.

Reducing the search space for matching large schemas has found more interest. One idea is to apply several matchers in sequence and to initially use fast matcher(s) (e.g., a string matcher on element names) with a low similarity threshold to already eliminate most element pairs before applying further matchers (Ehrig and Staab 2004; Peukert et al. 2010). Several other approaches are based on a partitioning of the input schemas and restrict the search of similar schema elements to

a subset of these partitions. Such *partition-based matching* can achieve a significant reduction of the search space and thus improved efficiency. Furthermore, matching the smaller partitions reduces the memory requirements compared to matching the full schemas. The partition-based match tasks can also be performed in parallel for additional performance improvements (Amin et al. 2016).

There are many possible ways to perform partitioning and finding the most effective approaches is still an open research problem. COMA++ was one of the first systems to support partition-based schema matching by a so-called fragment matching (Do and Rahm 2007). Fragment matching works in two phases. In the first phase, the fragments of a specified type (e.g., subschemas such as relational tables) are determined and compared with each other to identify the most similar fragments from the other schema worth to be fully matched later. The search for similar fragments is some kind of light-weight matching, e.g., based on the similarity of the fragment roots. In the second phase, each pair of similar fragments is matched independently to identify correspondences between their elements.

The ontology matching system Falcon-AO (Hu et al. 2008) uses a structural clustering to initially partition the ontologies into relatively small, disjoint blocks. Matching is then restricted to the most similar blocks from the two ontologies. To determine the block similarity, Falcon-AO utilizes so-called anchors, i.e., highly similar element pairs that are determined before partitioning by a combined name/comment matcher. Matching is then limited to pairs of blocks sharing at least one anchor. Further approaches for partition-based matching used different kinds of clustering for the input schemas/ontologies, e.g., hierarchical clustering in Albergawy et al. (2011).

The taxonomy matching system AnchorFlood implements a dynamic partition-based matching that avoids the a-priori partitioning of the ontologies (Hanif and Aono 2009). Like in Falcon-AO, the approach utilizes anchors (similar concept pairs) but takes them as a starting point to incrementally match elements in their structural

neighborhood until no further matches are found or all elements are processed. Thus, the partitions (called segments) are located around the anchors and their size depends on the continued success of finding match partners for the considered elements.

Several approaches considered the case when one of the input schemas/ontologies is much smaller than the other one so that only the larger input is partitioned (Zhong et al. 2009; Gross et al. 2012). In GOMMA (Gross et al. 2012), a fast name matcher is initially applied between the small and larger ontology. Matching is then limited to the subontologies from the larger ontology for which the number of correspondences exceeds a certain ratio of all correspondences.

Effectiveness (high match quality) is another key challenge that requires the correct and complete identification of semantic correspondences. This problem becomes more difficult for larger search spaces. Furthermore, the semantic heterogeneity is typically high for large-scale match tasks, e.g., the schemas may largely differ in their size and scope making it difficult to find all correspondences and to avoid false match candidates. In addition to the combined use of several matchers, the following techniques are especially promising to improve match effectiveness for large-scale schema matching (Rahm 2011):

- *Postprocessing and repair of proposed correspondences.* The individual matchers typically generate a large number of possible correspondences from which the final ones need to be selected before they are included in the match result, e.g., for possible validation by a domain expert. The selection step should not only consider different ways to aggregate matcher results (union, intersection, weighted similarity values, etc.) and similarity thresholds but should also consider global constraints, e.g., if there should be at most 1 or a small number k of match partners in the other schema. So it is reasonable for 1:1 mappings to enforce so-called stable marriages or to only accept the mutually best match candidates, i.e., a correspondence $c1-c1'$ is only

accepted if $c1'$ is the most similar element for $c1$ and vice versa (Max-Both selection in COMA).

For semantically expressive ontologies, e.g., specified in the language OWL-DL, the determined mapping M between two ontologies may introduce inconsistencies so that axioms in the input ontologies may be violated if one combines $O1$ and $O2$ with the correspondences of M within a merged ontology. For example, for relations “ $O1.Customer$ is-a $O1.Person$ ” and “ $O2.Person$ is-a $O2.Member$ ” the equality correspondences “ $O1.Person \approx O2.Person$ ” and “ $O1.Customer \approx O2.Member$ ” would result in an inconsistency because “ $O1.Person$ is-a $O1.Customer$ ” could then be derived. The task of *mapping repair* (Meilicke et al. 2007) is to eliminate correspondences during post-processing that would cause such inconsistencies (e.g., “ $O1.Customer \approx O2.Member$ ” in the example). Mapping repair is supported in some ontology matching systems, e.g., LogMap and AlComo. It has to be noted that mapping repair can reduce recall by eliminating correct correspondences. Furthermore, the input ontologies may follow partially conflicting way in the representation of a domain that cannot be resolved by automatic repair actions but only with manual interaction.

- *Utilization of background knowledge.* The information within the input schemas itself is insufficient for large-scale matching with heterogeneous inputs so that it becomes necessary to find correspondences with the help of general or domain-specific background knowledge in dictionaries and thesauri (e.g., Wordnet, UMLS).
- *Reuse of previous match results.* Already matched schemas and the match results can be maintained in a repository for later reuse, in particular when modified versions of the schemas or other similar schemas have to be matched. Reusing such already found correspondences is a special form of utilizing background knowledge that holds high promise but also requires a complex infrastructure to find the reusable

correspondences and schema mappings. The corpus-based match approach of (Madhavan et al. 2005) uses a domain-specific corpus of schemas and match mappings and focuses on the reuse of element correspondences. They augment schema elements with matching elements from the corpus and assume that two schema elements match if they match with the same corpus element(s).

COMA was the first match tool to reuse entire schema mappings and to support indirect matching by composing already existing mappings (Do and Rahm 2002). For example, a mapping between schemas S1 and S3 can be obtained by combining preexisting S1-S2 and S2-S3 mappings involving another schema S2. Such derived mappings can also be combined with the results of regular matchers. The reuse and composition approach of COMA also allows the adaptation of an old mapping S1-S2 after one of the schemas evolves, e.g., S2 to S2', by composing the previous match result with the newly determined mapping S2-S2' between the old and new version of S2. The reuse and composition approach has also been incorporated and extended within the GOMMA prototype for ontology matching (Gross et al. 2011).

- *Semi-automatic tuning of match strategies.* In most current systems, the match strategy needs to be manually specified and configured, in particular the choice of matchers and the method to combine matcher results as well as critical parameters such as the weights of different matchers and similarity thresholds. Obviously, these decisions have a significant impact on match effectiveness but are difficult to make even for expert users. Semi-automatic tuning approaches aim at reducing this problem either by using learning-based or rule-based approaches. While supervised machine learning methods are very successful for semi-automatically configuring entity matching strategies, they are less applicable for learning schema matching configurations due to the difficulty to provide a sufficiently high number of correct schema mappings for training.

Several match systems including RIMOM analyze the schemas to be matched and determine their linguistic and structural similarity. These similarity characteristics are then used to select matchers or to weight the influence of different matchers in the combination of matcher results. Peukert et al. (2012) proposed a rule-based approach to tune entire match workflows based on features of the input schemas and of intermediate matcher results. There are different kinds of rules representing expert knowledge, in particular to select the matchers based on schema features and to combine matcher results based on schema and mapping features.

Future Directions

Despite the huge amount of research on schema matching, current products for data exchange and data integration typically include only simple linguistic approaches for automatically finding correspondences but still rely to a large degree on manual match decisions (Rahm 2011). As a result, they are ill-suited for large-scale match problems pointing to the need of bringing more proposed match approaches into products and practical application.

There is still a need for more research. In particular, it would be worthwhile to comparatively evaluate proposed approaches for mapping repair, reusing previous match results, and for self-tuning match strategies. Based on the observations, we envision possibilities to improve previous approaches in these areas.

Further topics for future research include improved user interfaces for controlling schema matching processes and providing expert feedback as well as holistic schema matching for multiple (>2) schemas.

Definitions

Link analytics is a set of specialized data analysis and graph mining techniques that discover, examine, and evaluate the *relationships* or *inter-linked* structures of graphs.

Overview

Graph-structured data are ubiquitous (Aggarwal and Wang 2010; Cook and Holder 2006), which consist of *vertices* (or *nodes*) representing physical, technological, conceptual, and societal entities or objects and *edges* (or *links*) illustrating connections, relationships, or dependencies between vertices in application-specific ways. Noteworthy examples of graphs and networked data include the World Wide Web, where webpages are vertices and hyperlinks are edges (Kleinberg et al. 1999), and social networks, where individuals are vertices and friendship relations are edges (Pitas 2015). In response to the growing popularity and wide applicability of graphs, a proliferation of link analysis techniques has emerged, focusing primarily on the modeling, quantification, mining, and evaluation of potentially useful, structure-enriched information from graphs, including, but not limited to, **link-based ranking** and **link prediction**.

Key Research Findings

Link-Based Ranking

Given a graph G , link-based ranking methods aim to rank vertices of G based upon their *structure significance* modeled and quantified based in particular on the edges of G . Specifically, each vertex v of G is associated with (relative) quantitative assessment values indicating the significance of v throughout G . Representative link-based ranking methods include PageRank (Brin and Page 1998), Personalized PageRank (Jeh and Widom 2003; Page et al. 1998), HITS (Kleinberg 1999), and SimRank (Jeh and Widom 2002).

PageRank

PageRank is a link-based ranking algorithm, the objective of which is to assign a numerical score, called *PageRank score*, to each vertex by exploiting interlinked structures of the graph G . The PageRank score of a vertex v can be regarded as a “vote”, by all the other vertices of G , about how important v is. Empirically, A link to v counts as a vote of support for v . A vertex with a high PageRank score is usually considered more “important” or more “influential” than a vertex with a low PageRank score. In principle, to compute the PageRank score of a vertex v , denoted as $P(v)$, we consider all the vertices u that links to v , i.e., for each such u , there exists an edge (u, v) in the graph G . If the degree of u , $\deg(u)$, is n , then u contributes $\frac{1}{\deg(u)}$ of its PageRank score to that of v :

$$P(v) = \sum_{u:(u,v) \in G} \frac{P(u)}{\deg(u)} \quad (1)$$

To account for the vertices with no outbound links, their PageRank scores can be regarded as being divided evenly among all the other vertices of G . As a result, a parametric damping factor d is introduced, and the PageRank formulation is refined as

$$P(v) = \frac{1-d}{N} + d \sum_{u:(u,v) \in G} \frac{P(u)}{\deg(u)} \quad (2)$$

where N is the number of vertices of G .

Based on the random surfer model (Chebolu and Melsted 2008), PageRank measures the stationary distribution of one specific kind of random walk that starts from a random vertex u of G ; and in each iteration, with a predefined probability $p = 1 - d$, jumps to a random vertex; and, with probability $1 - p = d$, follows a random outgoing edge of the current vertex u . PageRank scores can be approximated by the Power method with a high degree of accuracy (Bahmani et al. 2010; Berkhin 2005). It has been reported that the PageRank algorithm, once ran upon a graph of 322 million edges, converged within a tolerable limit in just 52 iterations (Brin and Page 1998).

Personalized PageRank

Personalized PageRank is the personalized, ego-centric version of the PageRank algorithm (Lofgren et al. 2014). Given a graph G and a starting vertex v , Personalized PageRank assigns a score to every other vertex u of G . This score models how much v is interested in u or how much v trusts u . From the perspective of random Markov theory, Personalized PageRank is almost the same as PageRank, except that all the random jumps, with a predefined probability p , are made to the starting vertex v for which we are personalizing the PageRank, as opposed to any vertex of the graph G .

The exact personalized PageRank scores for all vertices of G with respect to a particular source vertex v can be computed by the Power method (Maehara et al. 2014; Page et al. 1998), which involves costly matrix multiplication operations. Furthermore, materializing the personalized PageRank score for each vertex v of G is clearly infeasible for large graphs. As a result, most existing methods have focused on approximate personalized PageRank computation for large personalized PageRank scores with accuracy guarantees (Wang et al. 2016; Fujiwara et al. 2013).

HITS

The Hyperlink-Induced Topic Search (HITS) algorithm is a link analysis method that was initially designed for webpage search. Given a user-specified query, a subgraph G of all relevant vertices to the query is first selected from the original graph. For each vertex v of G , two scores are further assigned to indicate the importance of v : *authority* and *hub*. Intuitively, v is considered an authority if it provides direct answers to specific information needs, and there exist many hub vertices linking to it. Likewise, v is considered a hub if it provides a good list of links to the high-quality vertices; that is, v points to many other authoritative vertices. As a result, authority and hub values are defined in terms of one another in a mutually recursive fashion: the authority of v is computed as the sum of the hub values for the vertices that point to v :

$$\text{authority}(v) = \sum_{u:(u,v) \in G} \text{hub}(u) \quad (3)$$

and the hub value of v is the sum of the authority values for the vertices to which v points:

$$\text{hub}(v) = \sum_{u:(v,u) \in G} \text{authority}(u) \quad (4)$$

The HITS algorithm iterates by updating the two scores for each vertex of G . In order to ensure convergence of the HIT algorithm, both the authority and hub scores are scaled and normalized within each iteration. In practice, after a number of iterations when both the authority and hub scores of vertices do not vary significantly, the HITS algorithm can be considered to have converged (Kleinberg 1999).

Consider the adjacency matrix A of the graph G , which is an $N \times N$ symmetric matrix, where N is the number of vertices of G . The matrix entry A_{ij} ($1 \leq i, j \leq N$) is 1 if there exists an edge from vertex v_i to v_j and 0 otherwise. We further denote the hub vector $\mathbf{hub} = \{\text{hub}(v_1), \dots, \text{hub}(v_N)\}$, where $\text{hub}(v_i)$ ($1 \leq i \leq N$) is the hub score of the vertex v_i . Likewise we denote the authority vector $\mathbf{authority} = \{\text{authority}(v_1), \dots, \text{authority}(v_N)\}$. The HITS algorithm in matrix notations can therefore be formulated as

1. computer $\mathbf{hub} = A \times \mathbf{authority}$;
2. computer $\mathbf{authority} = A^T \times \mathbf{hub}$;
3. Iterate until convergence.

By substitution, it is immediate that

$$\mathbf{hub} = A \times A^T \times \mathbf{hub} \quad (5)$$

and

$$\mathbf{authority} = A^T \times A \times \mathbf{authority} \quad (6)$$

That is, \mathbf{hub} is an eigenvector of AA^T and $\mathbf{authority}$ is an eigenvector of A^TA . As a result, the HITS algorithm is actually a special case of the power method, and both

HITS and PageRank algorithms formalize link-based ranking into the eigenvector problems of designated matrixes (Ding et al. 2002).

SimRank

Given a graph G , it is important to assess the similarity of vertices based upon the pure, interlinked graph topology. Among a number of similarity measures, SimRank has been recognized as one of the most well adopted (Jiang et al. 2017; Tian and Xiao 2016). SimRank is proposed based on the following intuitive argument: “*two vertices are considered similar if they are referenced by similar vertices.*” As the base case, we consider a vertex maximally similar to itself, to which we can assign the SimRank score of 1. Furthermore, the similarity between two different vertices u and v is defined as:

$$s(u, v) = \frac{c}{|I(u)| \cdot |I(v)|} \sum_{a \in I(u), b \in I(v)} s(a, b) \quad (7)$$

where $I(v)$ denotes the set of neighboring vertices pointing to v and $c \in (0, 1)$ is a decay factor. A solution to the SimRank equation can be reached by an iterative computation to a fixed-point (Lizorkin et al. 2008).

SimRank can also be interpreted in terms of coupled random walks. Consider any two vertices u and v of G , and we start random walks from u and v , respectively, such that the two random walks are always with the same length t and they meet, for the first time, at a vertex w of G . Then the SimRank score $s(u, v)$ is equivalent to the expected f -meeting distance (Jeh and Widom 2002):

$$s(u, v) = \sum_{t=0}^{\infty} c^t \times \sum_{w \in G} \Pr(u, v, w) \quad (8)$$

where $\Pr(u, v, w)$ is the probability of two random walks originated from u and v , respectively, that meet at w for the first time.

Link Prediction

Real-world graphs are not static but dynamically evolving with new vertices and edges added all the time. It is therefore fundamental and critical to understand the dynamics and evolution of graphs. In particular, consider two vertices u and v of a graph G , where u and v are not connected via an edge. An interesting problem that has fused intensive research interest and found widely varying applications is to predict, given the current state of the graph G , the likelihood of a future connection between u and v , that is, a new edge (u, v) (Liben-Nowell and Kleinberg 2003). This problem is commonly referred to as the *link prediction* problem (Martínez et al. 2016; Duan et al. 2016; Barbieri et al. 2014; Hasan and Zaki 2011).

We can model the link prediction problem as a supervised classification task, where the current graph snapshot is used as the training data to build the link prediction model and the predictions of future links can be made afterward. This is a typical binary classification task, in that our main goal is to tell, given two nonadjacent vertices u and v , if or not there will be an edge (u, v) in the near future. As a result, the existing supervised classification methods, including naive Bayes, neural networks, support vector machines (SVM), and k -nearest neighbors, can be used. The key challenge here is to select a set of appropriate, link-based features for classification.

The link-based features that are leveraged for link prediction are primarily based on the pure graph topology. Typically, they define vertex-wise similarity based on linked structures, or the ensembles of paths, between vertices (Liben-Nowell and Kleinberg 2003). The most well-known link-based features are discussed below.

- **Common Neighbors.** Given two vertices u and v , the size of their common neighboring vertices in G is defined as $|N(u) \cap N(v)|$, where $N(\cdot)$ denotes the set of adjacent vertices for a given vertex. Intuitively speaking, if u and v share a lot of common neighboring vertices (e.g., friends), then u and v will connect with each other with high probability in the future;

- **Jaccard Coefficient.** The Jaccard coefficient metric normalizes common neighbors as follows,

$$\text{Jaccard}(u, v) = \frac{|N(u) \cap N(v)|}{|N(u) \cup N(v)|} \quad (9)$$

Equivalently, Jaccard coefficient can be interpreted as the probability of selecting a common neighbor of u and v from the union of the neighbors of u and v ;

- **Preferential Attachment** In social networks, the users who have had many friends already tend to connect more in the future, which is commonly referred to as the *rich-get-richer* phenomenon. We can quantify “richness” of a vertex by its degree, and the preferential attachment measure is thus defined as

$$\text{P-A}(u, v) = |N(u)| \cdot |N(v)| \quad (10)$$

Note that preferential attachment does not require any detailed information for vertex neighbors; therefore, it has the lowest computational complexity;

- **Adamic-Adar.** The Adamic-Adar weighs the common neighbors of u and v with smaller degrees more heavily,

$$\text{Adamic}(u, v) = \sum_{w \in N(u) \cap N(v)} \frac{1}{\log|N(w)|} \quad (11)$$

Intuitively, if both u and v share a common neighbor w , which turns out to be a high-degree vertex connecting to many other vertices as well, the effect of influencing the future connection between u and v , in terms of w , should be dampened;

- **Shortest Path Distance.** Empirically speaking, the shorter the distance between u and v in G , the higher the probability u and v will be directly connected in the future. Due to the small-world phenomenon (Watts and Strogatz 1998), however, most vertex pairs in real-world graphs are separated by fairly short distances. As a result, this path-based feature sometimes leads to poor link prediction performance;

- **Katz.** The Katz measure can be viewed as a variant of shortest path distance:

$$\text{Katz}(u, v) = \sum_{l=1}^{\infty} \beta^l \cdot |\text{paths}_{u,v}^l| \quad (12)$$

where $\beta (\leq 1)$ is a dampening parameter to penalize the paths with long path lengths, l denotes the length of a path, and $\text{paths}_{u,v}^l$ is the set of all the paths of length l between u and v in G . Katz considers the ensemble of all paths between u and v and thus generally works much better than shortest path distance in link prediction. However, computing Katz in real-world graphs turns out to be very expensive;

- **Hitting Time.** Given two vertices u and v in a graph G , the hitting time, $H(u, v)$, is the expected number of steps of a random walk starting at u to reach v . A shorter hitting time means that u and v are more similar, and thus there exists a higher probability that u and v will be linked together in the future. It is easy to compute $H(u, v)$ by initiating a sample of random walks. However, its value may have high variances. As a result, link prediction based on hitting time may result in poor prediction performance;

- **Rooted PageRank.** The hitting time measure is sensitive to the vertices that are far away from u and v to be examined, even if u and v are very close to each other in G . To alleviate this problem, we allow the random walk from u to v to periodically restart back to u with a fixed probability α at each random step. This way, distant part of G that is far away from u and v will almost never be explored. This approach results in the Rooted PageRank measure, which is reminiscent of Personalized PageRank in the link-based ranking methods.

Besides the aforementioned link feature-based methods, there are also Bayesian probabilistic methods, probabilistic relational methods, and linear algebraic methods for link prediction. Readers are referred to the link prediction surveys for more technical details (Hasan and Zaki 2011).

Examples of Applications

Link analytics involves data analysis techniques used in network science to evaluate the relationships in graphs. It is essentially a kind of knowledge discovery that can be used in widely varying real-world, graph-structured applications, including search engine optimization, security analysis, and medical research.

The analysis of hyperlinks and the graph structure of the Web has been instrumental in the development of web search. The use of hyperlinks for ranking web search results is probably one of the most noteworthy examples (Brin and Page 1998; Page et al. 1998). PageRank and HITS algorithms have been the key factors considered by web search engines in computing a composite score for a web page on any given query. Over the last decade, both of them have emerged as a very effective measure of reputation for web graphs and social networks (Liu et al. 2017).

Giving higher weights to the nearby vertices in Personalized PageRank has enabled it to find many applications in different real-world graphs, including friend recommendation in social networks (Gupta et al. 2013; Backstrom and Leskovec 2011) and graph partitioning (Andersen et al. 2006). Personalized PageRank has also been used to rank items in bipartite graphs for recommendation (Bahmani et al. 2010). Furthermore, it has also been applied from biology to chemistry and to civil engineering (Fogaras et al. 2005).

SimRank is a general link-based similarity measure, which is computed solely based on the vertices' structural context. SimRank has been successfully employed in many graph-based applications, such as sponsored search and web spam detection (Antonellis et al. 2008) and schema matching (Melnik et al. 2002).

Link prediction has found a series of applications in social networks. For instance, in numerous social media websites, with the “friend recommendation” feature, they will suggest users connected with other potential friends in real life, or they may suggest friends you already know but just not yet connected. Beyond social network applications, link prediction has been used to find interactions between proteins (Airoldi et al.

2008). In the security domain, link prediction can help identify hidden groups of terrorists or criminals (Hasan and Zaki 2011).

Future Directions for Research

Link analytics has been a promising research direction in data science and graph mining and thus generated a series of disruptive and influential techniques and methodologies that have significantly shaped the modern networked world. There exist quite a few research frontiers for link analytics that are worthy of systematic and thorough studies in the future:

1. Real-world graphs and networks are often-times enormous in sizes and scales, making existing solutions for link analytics hard to adapt to the so-called big graphs. New link analysis principles and methodologies that can scale up or scale out upon Internet-scale graphs will be of great importance in the Big Data Era;
2. Real-world graphs are typically generated from disparate, heterogeneous data sources, thus resulting in heterogeneous, multidimensional graph data. The synergy and unification of graph topology and heterogeneous contents will enhance both the effectiveness and efficiency for existing link analysis methods;
3. Real-world graphs are not static but dynamically evolving in fast rates and speed. Enabling real-time and accurate link analytics upon fast, dynamically evolving graphs will further spur extensive research interest and potential applications for dynamic graphs and graph streams.

Definitions

The term *Linked Data* refers to data that is made available on the Web in a structured, directly

machine-processable form via the following four principles:

1. Use URIs as names for things
2. Use HTTP URIs so that people [and machines] can look up those names.
3. When someone looks up a URI, provide useful information, using the standards (RDF, SPARQL)
4. Include links to other URIs, so that they can discover more things. (Berners-Lee 2006; Bizer et al. 2009)

Per these principles, given a URI that names something (e.g., a person, a book, a concept, an abstract idea) [Principle 1], it is possible to look up this URI using the HTTP protocol [Principle 2] and retrieve a document with RDF data describing the thing [Principle 3]. This data may include other URIs to refer to other things, and these URIs can be looked up in the same manner [Principle 4].

L

Overview

When applying the abovementioned principles, data becomes interlinked on the Web. These links may not only point to additional data from the same website but also to other websites. This results in the emergence of a decentralized, globally distributed Web of Linked Data.

Since their introduction, these Linked Data principles have been adopted by various publishers (Bizer et al. 2009). Today, there are significant amounts of Linked Data accessible on the Web (Mika and Potter 2012; Schmachtenberg et al. 2014).

In addition to publishing data on the Web via a Linked Data interface, many data publishers also support other RDF-based mechanisms to access their datasets. One approach is in the form of *RDF dumps* that provide the complete dataset as a single downloadable file serialized in an RDF format. Another approach is through *SPARQL endpoints*, which are Web services that can be called to obtain the result of executing any given SPARQL query over the dataset (Feigenbaum et al. 2013). Alternative query interfaces have become available that are deliberately limited in

the expressiveness of the queries they support; the purpose of these limitations is to achieve a restricted, more predictable server load per request and, thus, to increase the overall availability of the query-based interfaces. The most prevalent of these alternative query interfaces is the *Triple Pattern Fragment (TPF)* interface (Verborgh et al. 2016).

While all these data publishing approaches are based on the RDF data model, it has to be emphasized that an isolated set of RDF triples (e.g., in an RDF dump or behind a SPARQL endpoint) is not Linked Data per se; what would make it Linked Data is the possibility to discover it on the Web by the aforementioned principles. Hence the fourth principle of including links between different RDF datasets is vital.

The remainder of this article first provides a general overview of different data management options to make use of Linked Data in applications and, thereafter, focuses on approaches to query Linked Data live on the Web by relying solely on the Linked Data publishing principles (i.e., URI lookups).

are a number of commercial triple stores such as AllegroGraph, Amazon Neptune, Blazegraph, GraphDB, MarkLogic, Stardog, and Virtuoso. For an overview of research on techniques to build highly scalable triple stores, refer to other entries in this encyclopedia (see the cross-references section).

In contrast to the following options, copying data into a dedicated triple store setup for the sole purpose of supporting a particular application is perhaps the most efficient option in terms of query performance. A possible downside is that the triple store has to be maintained and the copied data may have to be kept in sync with the data in the original data sources on the Web.

Distributed Client-Server Processing. If the application uses a single dataset only (or multiple in isolation) and the maintainer of this dataset provides a Web interface to query the dataset, the application can be built based on queries to be executed via this interface.

Such an interface may be a *SPARQL endpoint* (see above). However, Buil-Aranda et al. (2013) have shown empirically that public SPARQL endpoints on the Web may have availability issues.

The aforementioned *Triple Pattern Fragment interface* is a more reliable option (Verborgh et al. 2016). In this case however, to execute SPARQL queries over the dataset exposed via this TPF interface, the application requires a client-side query execution engine that is capable of processing such queries based on TPF requests. A number of TPF-based query execution approaches have been proposed (Verborgh et al. 2016; Van Herwegen et al. 2015) with the state of the art being an adaptive approach by Acosta and Vidal (2015) that adopts the idea of using Eddy operators (Avnur and Hellerstein 2000).

In addition to using pure TPF interfaces, some authors propose extended versions of this interface with the goal of reducing the shortcomings of TPF (e.g., significant network load) by retaining (or even increasing) the overall query throughput of TPF-based client-server systems. Examples of such proposals are to augment *TPF responses with membership metadata* such as

Key Research Findings

Various approaches toward Linked Data management and querying have been proposed in the literature. To provide an overview, we have categorized them into general approaches, foundations, source selection, source ranking strategies, query execution, and query optimization.

General Approaches to Make Use of Linked Data

Centralization. A first option to use Linked Data in an application is to obtain the application-relevant data (e.g., by crawling or by downloading the respective RDF dumps) and load this data into a database management system (DBMS) for RDF data that is set up for the application. DBMSs for RDF data, often referred to as *triple stores*, enable applications to query the data using SPARQL, the RDF query language. There

Bloom filters (Vander Sande et al. 2015) and the *bindings-restricted Triple Pattern Fragment* (*brTPF*) interface that allows client-side query engines to use variations of the semijoin algorithm (Hartig and Buil-Aranda 2016).

Federated Processing. Federated query processing engines go beyond the aforementioned client-server setting by supporting the execution of queries over a federation of multiple servers. Each of these servers typically provides access to a different dataset. Therefore, given a SPARQL query, the goal of a federated query execution is to return a query result that is the same as if the query was executed directly over the union of the datasets in the federation.

Existing approaches to federated query processing in the Linked Data context can be categorized into three classes.

The first class consists of approaches that assume Linked Data can be accessed via query-based Web interfaces (e.g., SPARQL endpoints, TPF). These approaches are discussed in more detail in the “► [Federated RDF Query Processing](#)” entry in this encyclopedia.

Approaches in the second class rely only on the Linked Data publishing principles (i.e., URI lookups) and, thus, do not require the additional availability of query-based interfaces to access the Linked Data. Such approaches, called *Linked Data query processing*, this article and will be discussed in the next sections.

The third class comprises *hybrid query approaches* which aim to leverage query-based interfaces to access Linked Data in combination with Linked Data query processing techniques. To date, the only proposals in this direction are by Umbrich et al. (2012) which combines Linked Data query processing with access to a SPARQL endpoint that serves as a query-able cache of Linked Data. Additionally, Lynden et al. (2013) propose to integrate data retrieval from a SPARQL endpoint into a Linked Data query execution process.

Foundations of Linked Data Queries

A *Linked Data query* is a query over a Web of documents of RDF data that can be retrieved by

URI lookups as per the Linked Data publishing principles. Such queries may be not only about the topology of the interlinked RDF documents but also, and perhaps more interesting, about the data in and across these documents. In particular, existing approaches to process Linked Data queries (as discussed in the next sections) focus on queries that are expressed using the conjunctive fragment of the SPARQL query language and that are to be evaluated in terms of the union of the data in the interlinked documents. An initial approach to providing a formal semantics for these queries has been proposed by Bouquet et al. (2009). More recently, Hartig (2012) has improved this work in three ways: (i) covering the whole core fragment of SPARQL (i.e., OPTIONAL, FILTER, UNION), (ii) showing formally that completeness of query results w.r.t. all Linked Data cannot be guaranteed, and (iii) introducing a more restrictive formal query semantics for which completeness can be guaranteed.

As an alternative to adopting SPARQL expressions as a language for Linked Data queries, a number of dedicated Linked Data query languages have been proposed, namely, LD-Path (Schaffert et al. 2012), NautiLOD (Fionda et al. 2015), and LDQL (Hartig and Pérez 2016). However, with the exception of the swglet approach (Fionda et al. 2014) for NautiLOD, techniques for processing Linked Data queries have focused on (conjunctive) SPARQL expressions.

Source Selection Strategies for Linked Data Queries

Any execution of Linked Data queries involves the retrieval of data by looking up URIs. Existing approaches for selecting the URIs to be looked up during the execution of a given query can be classified into the following three classes:

Index-based approaches determine the URIs to look up during query execution by using a pre-populated index (Harth et al. 2010; Umbrich et al. 2011). A typical example of such an index uses patterns of RDF triples as index keys (Ladwig and Tran 2010). Given such a pattern, the corresponding index entry is a set of URIs where

each of these URIs, when looked up, allows the query engine to retrieve some data that contains an RDF triple that matches the pattern. Further index structures for selecting URIs in Linked Data query processing have been studied by Harth et al. (2010), Umbrich et al. (2011), Tian et al. (2011), and Paret et al. (2011).

After such an index has been populated and can be used for query processing, the index has to be maintained. Maintenance may comprise indexing additionally discovered URIs and ensuring that the index is up to date (Umbrich et al. 2011). The latter is necessary because the data to be retrieved from indexed URIs may change over time. While such an index maintenance is similar to maintaining materialized views in a data warehouse, no work exists that explicitly studies approaches to maintain source selection indexes for Linked Data queries.

Live exploration approaches leverage the characteristics of Linked Data, in particular, the existence of data links. That is, to execute a given Linked Data query, live exploration systems perform a URI lookup process during which they incrementally discover further URIs that may be scheduled for lookup (Hartig et al. 2009; Hartig 2011b; Ladwig and Tran 2011; Schmedding 2011; Miranker et al. 2012). The data retrieved during this process is used not only to discover more URIs, but it also provides the basis for constructing the query result. Assuming the queries are expressed using SPARQL, live exploration approaches support naturally the aforementioned restrictive semantics for such queries as introduced by Hartig (2012), which also gives a well-defined boundary for the URI lookup process.

In comparison to index-based source selection approaches, live exploration approaches have the interesting characteristic of being able to discover initially unknown data sources *at query execution time*. Additionally, live exploration systems can readily be used without having to wait for the completion of an initial data load phase, index creation, or any other type of preprocessing.

However, given that the general ideas of index-based source selection and of live exploration

may be implemented in various ways, respectively, comparing both types of approaches in a fair manner is a nontrivial open problem.

Hybrid source selection approaches combine the two aforementioned ideas. So far, only one hybrid approach has been proposed in the literature. This approach uses an index to create a (ranked) list of URIs to look up; additional URIs discovered during the query execution process are then added into this list (Ladwig and Tran 2010).

Source Ranking Strategies for Linked Data Queries

In addition to selecting URIs that are to be looked up for a given Linked Data query, the selected URIs may be ranked in terms of the order in which these URIs have to be looked up. The goal of such a data source ranking may be to maximize the subset of the query result that can be found in a given amount of time.

Harth et al. (2010) and Ladwig and Tran (2010) have proposed data source ranking approaches for index-based source selection. These approaches rely on additional information about the data sources; the assumption is that this information is available in the index.

For selecting URIs using a live exploration approach, Hartig and Özsü (2016) have studied various heuristics to prioritize URI lookups; none of these heuristics uses any *a priori* information.

Linked Data Query Execution

Existing approaches to execute Linked Data queries as proposed in the literature can be classified into two categories:

Two-phase execution approaches separate the query execution process into two phases: During the first phase, all required data is retrieved from the Web (by looking up URIs, which may be selected using any of the aforementioned source selection approaches). Then, during the second phase, the query result is produced from the data retrieved in the first phase. Harth et al. (2010), Umbrich et al. (2011), and Paret et al. (2011) have adopted such a two-phase execution pro-

cess to study their index-based source selection approaches. While such a two-phase process is straightforward to implement, having to wait for the completion of the data retrieval phase may not be practical; it may even exceed the resources of the query execution system.

Integrated execution approaches integrate the retrieval of data with the result construction process. This allows a query engine to return query results incrementally, i.e., before data retrieval has been completed. As for the two-phase execution approaches, it is possible to use any type of source selection strategy as a basis for an integrated execution approach. Integrated execution approaches that use some form of live exploration are also referred to as *traversal-based query execution* approaches. A number of such approaches have been proposed where each of them is based on different implementation techniques: The first approach made use of the well-known iterator model (Hartig et al. 2009; Hartig 2011b, 2013). In contrast to such a pull-based implementation, Ladwig and Tran (2010, 2011) proposed a push-based implementation using the symmetric hash join operator. Other push-based implementations adapt the Rete match algorithm (Miranker et al. 2012) and the idea of an Eddy-style tuple routing operator (Hartig and Özsü 2016).

Query Optimization for Linked Data Queries

Besides the aforementioned source ranking techniques, which can be understood as a form of query optimization, the topic of query optimization for Linked Data queries is largely unexplored. In fact, there does not yet exist any work that investigates cost-based query optimization techniques in this context.

For traversal-based query execution, cost-based query optimization is particularly challenging because information to assess query plans may only be obtained incrementally during query execution. Hence, selecting an initial plan requires heuristics. Hartig (2011b) has proposed such plan selection heuristics for the aforementioned, iterator-based approach to

implement traversal-based query execution. For the same implementation approach, Hartig et al. (2009) introduce an extension of the iterator model to support a form of adaptive query optimization. This extension avoids a blocking behavior of iterators that may otherwise happen when waiting for the completion of particular URI lookups.

Future Directions for Research

Query optimization. As mentioned in the previous section, query optimization in the context of Linked Data query processing is a largely unexplored area. Possible topics for contributions are cost-based query optimization, multi-objective query optimization (i.e., taking into account not only the overall execution time but also, e.g., the time until the first output when returning query results incrementally or network traffic), techniques for adaptive query processing, and optimization for subsequent queries (e.g., collecting statistics as a side-product of traversal-based query executions and leveraging these statistics to optimize future queries).

Experimental comparisons. While a number of approaches for the different aspects of Linked Data query processing have been proposed, there exists little research that compares these approaches in a comprehensive and fair manner.

Benchmarks. Related to the previous point, there are no well-defined and well-understood benchmarks to test Linked Data query processing systems (neither for specific aspects of Linked Data query processing such as source selection, nor for the process of Linked Data query execution in general).

Techniques for more expressive query languages. All existing techniques for Linked Data query processing focus on queries expressed using the conjunctive fragment of SPARQL. However, the foundations of using more expressive fragments of SPARQL are well understood (Har-

tig 2012), and there even exist more fitting languages that have been specifically designed for Linked Data queries (Fionda et al. 2015; Hartig and Pérez 2016). It is an open question what are effective techniques for executing queries in these languages.

Hybrid query approaches. While there exists initial work on combining Linked Data query processing with other query paradigms such as query federation or queries over a centralized collection of data (Ladwig and Tran 2011; Umbrich et al. 2012; Hartig 2011a; Lynden et al. 2013), more research on such combinations is necessary. In particular, contributions can be made in terms of both establishing and understanding the foundations of such hybrid approaches as well as techniques for implementing hybrid approaches.

Definitions

Linked geospatial data is data about geographic objects made available on the Web using linked data technologies such as RDF and SPARQL and interlinked with other Web data to increase its value for users and applications.

Overview

Huge amounts of geospatial data have been made freely available recently on the Web, for example, maps from geospatial search engines like Google Maps, images from satellites, open geospatial data from national cartographic agencies, and user-contributed geospatial content from social networks. This article surveys the state of the art in the area of linked geospatial data, i.e., geospatial data made available on the Web using linked

data technologies such as RDF and SPARQL and interlinked with other Web data to increase its value for users and applications.

Key Research Findings

The research contributions of academia and industry in the area of linked geospatial data include data models and query languages, implemented systems, visual user interfaces, and applications. These contributions are surveyed in the rest of this article.

Data Models and Query Languages

Early works in the area of linked geospatial data include papers by Perry, Kolas, Koubarakis, and their colleagues (Perry et al. 2006, 2011; Kolas and Self 2007; Koubarakis and Kyzirakos 2010). Based on these early papers, two extensions of SPARQL were defined in 2012: the Open Geospatial Consortium (OGC) standard GeoSPARQL for querying geospatial data expressed in RDF and the stSPARQL language for querying linked geospatial data that changes over time. In 2013, RDFⁱ, a general extension of the RDF data model for representing incomplete information was introduced (Nikolaou and Koubarakis 2013, 2016). RDFⁱ can model incomplete geospatial information using vocabulary introduced by GeoSPARQL, so it is also covered below.

GeoSPARQL

The GeoSPARQL standard defined by OGC (2012) provides vocabulary (classes, properties, and functions) that can be used in RDF graphs and SPARQL queries to represent and query geospatial data. GeoSPARQL follows a modular design and consists of the following components:

- *Core*. This component defines top-level classes that provide users with vocabulary for modeling geospatial information. The classes offered by this component are geo:SpatialObject and geo:Feature. Class geo:SpatialObject is the top

- class defined by GeoSPARQL and has as instances everything that can have a spatial representation. Class `geo:Feature` is the class of all features; *feature* is the term used for geographic objects in the literature of geographic information systems (GIS). Class `geo:Feature` can be a superclass of any class of features users might want to define. Class `geo:SpatialObject` is a superclass of `geo:Feature` and `geo:Geometry` (to be defined in the geometry extension component below).
- *Topology vocabulary extension.* This component provides vocabulary for asserting and querying topological relations between spatial objects. Three families of topological relations are supported coming from the large body of previous research on this topic by GIS, databases, and artificial intelligence researchers. These families are the topological relations for simple features defined in the OGC standard “OpenGIS Simple Feature Access – Part 2: SQL Option” (e.g., `geo:sfTouches`), the Egenhofer topological relations defined by Egenhofer and Franzosa (1991) (e.g., `geo:ehMeet`), and the RCC-8 relations defined by Randell et al. (1992) (e.g., `geo:rcc8ec`). An important point here is that these topological relations can relate not just geometries but also features. They can be asserted by a triple of an RDF graph (e.g., `dbpedia:Athens geo:sfWithin dbpedia:Greece`) but also used in a triple pattern of a SPARQL query (e.g., `?x geo:sfWithin dbpedia:Greece`). The query rewriting extension discussed below provides a mechanism to derive topological relations between features from the topological relations that are satisfied by their corresponding geometries. In this way, GeoSPARQL caters to users that are more interested in qualitative spatial reasoning applications (Randell et al. 1992) but also to more traditional GIS or DBMS users interested in geospatial computations.
 - *Geometry extension.* This component provides vocabulary for asserting and querying

information about geometries. A crucial design decision of GeoSPARQL is to use *literal values* to encode geometries as a single unit and introduce the new data types `sf:wktLiteral` and `gml:gmlLiteral` for these literals. The former data type enables the serialization of geometries using the OGC standard well-known text (WKT) while the latter using the Geography Markup Language (GML).

The geometry extension also defines the class `geo:Geometry` as the superclass of all geometry superclass. It also defines properties for representing metadata of geometries (e.g., `geo:dimension` that captures the topological dimension), for associating features with geometries (e.g., `geo:hasGeometry`) and for associating geometries with their literal serializations (`geo:asWKT` and `geo:asGML`). In addition, this extension defines functions for performing non-topological operations on geometries (e.g., `geof:distance`, `geof:buffer`, `geof:convexHull`, etc.). These functions, which can be used in SPARQL queries, are taken from the OGC standard “OpenGIS Simple Feature Access – Part 2: SQL Option”. • *Geometry topology extension.* This component provides three families of Boolean functions that operate on geometries and can be used in a SPARQL query to check whether given topological relationships hold for these geometries. These Boolean functions correspond to the topological relations of the topology vocabulary extension presented above (simple features, Egenhofer, and RCC-8) and can be applied to geometry literals encoded in WKT or GML (e.g., the Boolean function `geof:ehMeet` that corresponds to the Egenhofer topological relation `geo:ehMeet` mentioned above). In addition, the extension defines the general function `geof:relate` that can be used to specify any topological relation one might be interested in that can be expressed using the Dimensionally Extended 9-Intersection Model (Clementini et al. 1993).

- *RDFS entailment extension.* This component provides a mechanism for realizing the RDFS entailments that follow from the RDFS class and property axioms that hold for the classes and properties introduced by GeoSPARQL and presented in the extensions above.
- *Query rewrite extension.* This component provides a collection of Rule Interchange Format (RIF) rules that derive any of the topological relations of the topology vocabulary extension between two pairs of spatial objects (features or geometries), whenever the corresponding Boolean function of the geometry topology extension holds between the corresponding geometry literals. As an example, the component has a RIF rule named `geor:sfWithin` that can be used to derive the triple `dbpedia:Athens geo:sfWithin dbpedia:Greece` from the fact that the Boolean function `geof:sfWithin` returns true when evaluated with arguments the WKT encodings of the geometry literals corresponding to features `dbpedia:Athens` and `dbpedia:Greece`. The name of the extension (query rewrite) comes from one of its possible implementations which would be to rewrite a given SPARQL query with a triple pattern involving a topological relation between two features, into one that checks whether the corresponding Boolean function holds between the geometry literals corresponding to the features.

stRDF/stSPARQL

The model stRDF is an extension of RDF for representing geospatial information that changes over time (Kyzirakos et al. 2012; Bereta et al. 2013). Similarly to GeoSPARQL, stRDF uses literals of data types `strdf:WKT` and `strdf:GML` to represent geometries serialized using the OGC standards WKT and GML. The data type `strdf:geometry` is also introduced as the union of data types `strdf:WKT` and `strdf:GML`.

The time dimension of stRDF is used to model the *valid time* of triples originally introduced by

the pre-RDF knowledge representation language Telos (Mylopoulos et al. 1990) and rediscovered by Semantic Web researchers (Gutierrez et al. 2007). stRDF allows the use of quads of the form (s, p, o, t) to model the information that t is the time when the fact represented by the RDF triple (s, p, o) is valid in reality. Valid times can be encoded by using literals of the new data type `strdf:period`; these literals represent points or intervals with closed or open endpoints which are themselves literals of type `xsd:dateTime`.

The query language of the model stRDF is stSPARQL (Kyzirakos et al. 2012; Bereta et al. 2013). stSPARQL is an extension of SPARQL 1.1 with essentially the same topological and non-topological functions for simple features introduced by the geometry and the geometry topology extension of GeoSPARQL (only the name space changes: `strdf` instead of `geof`). These functions can be used in the SELECT, FILTER, and HAVING clause of a SPARQL 1.1 query. In addition to these functions, stSPARQL offers four topological functions based on the bounding box of the involved regions (e.g., `strdf:mbbIntersects`), four cardinal direction relations (e.g., `strdf:above`), and three aggregate functions (`strdf:union`, `strdf:intersection`, and `strdf:extent`). Since stRDF supports quads, stSPARQL also allows quad patterns (s, p, o, t) in queries. In addition, stSPARQL offers the following families of temporal functions: functions corresponding to the 13 interval-to-interval relations of Allen (1983) and three point-to-interval relations of Meiri (1996) (e.g., `strdf:after`), period constructors (e.g., `strdf:period_intersect`), and temporal aggregates (e.g., `strdf:maximalPeriod`).

Comparing GeoSPARQL with stSPARQL, we can see that stSPARQL offers slightly more geospatial functionality than the geometry and geometry topology extensions of GeoSPARQL but also temporal functionalities not offered by GeoSPARQL.

RDFⁱ

The RDFⁱ framework (Nikolaou and Koubarakis 2013, 2016) (where “i” stands for “incomplete”)

is an extension of RDF for representing values of properties that exist but are either unknown or partially known. To model this kind of incomplete information, RDF^i extends RDF with the ability to define a new kind of literals for each data type. These literals are called *e-literals* (where “e” comes from the word “existential”) and are allowed to appear only in the object position of triples. RDF^i allows partial information regarding property values represented by e-literals to be expressed by a quantifier-free formula of a first-order constraint language \mathcal{L} . The modeling capabilities of RDF^i have been demonstrated by Nikolaou and Koubarakis (2016) with a number of constraint languages \mathcal{L} that allow RDF^i to express (i) incomplete information corresponding to *marked nulls*, (ii) incomplete temporal information, (iii) spatial properties of abstract or polygonal regions of \mathbb{Q}^2 , and (iv) spatial and metric constraints involving rectangles with sides parallel to the axes in \mathbb{Q}^2 .

RDF^i extends the concept of an RDF graph to the concept of an RDF^i database which is a pair (G, ϕ) , where G is an RDF graph possibly with e-literals and ϕ is a quantifier-free formula of \mathcal{L} . The semantics of RDF^i is inspired by the seminal work of Imieliński and Lipski (1984) and assigns to an RDF^i database (G, ϕ) an infinite set of RDF graphs. Each such graph corresponds to a possible state of the real world represented syntactically by the RDF^i database (G, ϕ) . Query answering for SPARQL queries and RDF^i databases (G, ϕ) amounts to computing the set of certain answers, that is, those answers that are present in the result of the evaluation of the query over each possible RDF graph corresponding to (G, ϕ) . It turns out that the data complexity of checking whether an answer is certain increases from LOGSPACE (the upper bound of evaluating SPARQL graph patterns over RDF graphs) to CONP-complete for all of the aforementioned constraint languages. This result is in line with similar complexity results for querying incomplete information in relational databases.

Comparing GeoSPARQL with RDF^i , we can see that both proposals allow for the assertion of geometric and topological information of features, but only RDF^i is able to reason about the

topology of features when geometrical information about them is missing. The kind of spatial information modeled in RDF^i can be also modeled in appropriate spatial extensions of description logics and the Web Ontology Language (OWL). Closest to RDF^i are the approaches choosing to separate terminological knowledge expressed in some description logic or OWL from spatial knowledge expressed as data assertions (Wessel and Möller 2009). Other approaches follow a tighter integration of terminological and spatial knowledge by equipping description logics with a spatial concrete domain that offers the reasoning capabilities of RCC-8 (Lutz and Milicic 2007). Finally, approaches similar to GeoSPARQL extend the vocabulary of OWL with the topological relations of RCC-8 and propose a model for the representation of qualitative spatial information (Batsakis and Petrakis 2010). In contrast to GeoSPARQL, the semantics of spatial relations is encoded as a set of rules, while reasoning in this extension of OWL can be realized by off-the-self OWL reasoners.

Implemented Systems

One of the very early works in the area of geospatial RDF stores is the implementation described by Brodt et al. (2010) which is built on top of RDF-3X. It does not offer GeoSPARQL support, but it allows for the representation of geometries as WKT typed literals. It also supports spatial operators defined in the OGC standard “OpenGIS Simple Feature Access – Part 2: SQL Option” and it uses an R-tree index.

Another early work is described by Perry et al. (2011) in which the language SPARQL-ST was proposed. SPARQL-ST is a spatial and temporal extension of the SPARQL query language, and it considers spatial and temporal variables and filters, respectively. The query engine for SPARQL-ST was implemented on top of Oracle 10g.

Parliament was the first GeoSPARQL implementation and it supports the following components of GeoSPARQL: core, topology vocabulary, geometry, geometry topology, and RDF entailment. It also supports multiple coordinate reference systems (CRS) and uses an R-tree for indexing geometries.

Strabon is the state-of-the-art spatiotemporal triple store (Kyzirakos et al. 2012; Bereta et al. 2013). It supports both stSPARQL and a subset of GeoSPARQL (core, geometry extension, and geometry topology extension). Strabon is built by extending the well-known triple store Sesame and uses a spatially enabled DBMS as back end (currently PostGIS and MonetDB are supported, but PostGIS is the DBMS used by default).

USeekM is an open-source spatial plugin for Sesame developed by Open Sahara. It supports the following GeoSPARQL components: core, topology vocabulary, geometry, geometry topology, and RDFS entailment. GraphDB is another commercial RDF store that offers GeoSPARQL support by integrating part of the USeekM geospatial functionalities. USeekM uses an R-tree index, while GraphDB uses an Apache Lucene index, which is a general purpose index that also includes spatial support.

There are also systems with geospatial functionalities that offer limited or zero GeoSPARQL support. AllegroGraph is a commercial quad store that offers limited geospatial functionalities: it implements only a few spatial operators, and it supports only point geometries. OpenLink Virtuoso also includes a few geospatial features, for example, it supports point geometries serialized as typed literals and a small subset of the equivalent operations defined in SQL/MM but does not have support for GeoSPARQL. Finally, Stardog is another system with limited GeoSPARQL support in its

commercial edition. It supports point geometries natively. Polygons are supported optionally, if the user configures the system to load the JTS library. It supports only a few spatial operators (`geof:relate`, `geof:distance`, `geof:within`, `geof:nearby` and `geof:area`).

Despite the existence of many geospatial RDF stores, especially after the establishment of GeoSPARQL as an OGC standard, a geospatial ontology-based data access (OBDA) system did not exist until the creation of Ontop-spatial, the geospatial extension of OBDA system Ontop. Ontop performs on-the-fly SPARQL-to-SQL translation on top of relational databases using ontologies and mappings (Calvanese et al. 2017). Mappings express how relational data can be translated into RDF terms, and they can be encoded in the W3C standard R2RML. Ontop-spatial extends Ontop by performing on-the-fly GeoSPARQL-to-SQL translation on top of a spatially enabled DBMS (e.g., PostGIS, SpatiaLite) (Bereta and Koubarakis 2016).

Finally, another system with GeoSPARQL support is Oracle Spatial and Graph. It supports multiple coordinate reference systems, and the recent version Oracle 12c release 2 contains also support for on-the-fly GeoSPARQL-to-SQL translation using R2RML mappings without needing to materialize the data as RDF triples.

Table 1 shows an overview of the geospatial functionality supported by geospatial RDF stores, and Table 2 shows the respective functionalities

Linked Geospatial Data, Table 1 Functionality of geospatial RDF stores and OBDA systems

System	Language	Index	Geometries	CRS support	Relation families in geometry topology
Strabon	stSPARQL, GeoSPARQL	R-tree over GiST	WKT, GML	Yes	Simple features (SF), Egenhofer, RCC-8
Parliament	GeoSPARQL	R-tree	WKT, GML	Yes	SF, Egenhofer, RCC-8
Brodt et al. (RDF-3X)	SPARQL	R-tree	WKT	No	SF
Perry	SPARQL-ST	R-tree	GeoRSS, GML	Yes	RCC-8
Oracle spatial and graph	GeoSPARQL	R-tree	WKT, GML	Yes	SF, Egenhofer, RCC-8
USeekM	GeoSPARQL	R-tree over GiST	WKT	No	SF, Egenhofer, RCC-8
GraphDB	GeoSPARQL	Lucene	WKT	No	SF, Egenhofer, RCC-8
Ontop-spatial	GeoSPARQL	R-tree	WKT, GML	No	SF, Egenhofer, RCC-8

Linked Geospatial Data, Table 2 Functionality of geospatial RDF stores offering limited geospatial support

System	Language	Index	Geometries	CRS support	Available functions
AllegroGraph	Extended SPARQL	Distribution sweeping technique	2D point geometries	Partial	Buffer, bounding box, distance
Virtuoso	Extended SPARQL	R-tree	2D point geometries (in WKT)	Yes	SQL/MM (subset)

offered by systems that provide limited geospatial support.

Geographica is a benchmark that was developed in order to evaluate geospatial RDF stores. The results of the experimental evaluation described by Garbis et al. (2013) show that Strabon is not only a rich geospatial RDF store in terms of functionality, but it is also the most efficient. Strabon, in most cases, outperforms USeekM, Parliament, and Virtuoso, as well as three commercial triple stores with geospatial support (due to license considerations, the names of these commercial systems are not disclosed). In the area of OBDA systems, Ontop-spatial was evaluated by Bereta and Koubarakis (2016), where it was compared with Strabon. The results showed that, in most cases, Ontop-spatial outperforms Strabon because it is able to generate SQL queries that can be very efficiently executed by the underlying geospatial DBMS.

Visual User Interfaces

In addition to the storage and querying systems presented above, many interesting visualization systems for linked geospatial data have been proposed. Some follow the Linked Data Visualization Model principles (Klímek et al. 2014; Thellmann et al. 2015), while others rely on vocabularies (Mutlu et al. 2013; Atemezing and Troncy 2014). All systems support visualization for geospatial data, but only one (Nikolaou et al. 2015) provides support for GeoSPARQL/stSPARQL.

The Linked Data Visualization Model (LDVM) (Brunetti et al. 2013) allows the connection of different datasets with various visualizations in a dynamic way. The process follows a four-stage workflow: source data,

analytical abstraction, visualization abstraction, and view. This model has been adopted by Payola (Klímek et al. 2014) that provides a refined implementation of the LDVM. It consists of various analyzers for automatically classifying datasets and transformers for mapping the data to visualization abstractions. Users can connect to a SPARQL endpoint, load their data, and perform analysis and visualization on a Web browser.

Another tool is CODE Vis Wizard (Mutlu et al. 2013) that relies on the RDF Data Cube Vocabulary, a W3C standard for representing statistical data as RDF. Vis Wizard is a Web-based system that is able to analyze multiple datasets using brushing and linking methods. Similarly, LDVizWiz (Atemezing and Troncy 2014) uses a semiautomatic way to produce possible visualizations of a dataset. LDVizWiz performs ASK queries to categorize data in order to understand the features of a dataset, but this requires adaptation of the queries to new vocabularies when they are detected.

LinkDaViz (Thellmann et al. 2015) is another approach in the same context as the previous two. This framework uses heuristic data analysis and a visualization model in order to automatically bind data and visualization options. The workflow guides the user through the process of visualizing data and starts with the exploration of a dataset. After the user has selected the part of the dataset to be visualized, a ranked list of recommended visualizations is computed. When one of the recommendations is selected, the resulting visualization is displayed, ready for customization.

While most of the visualization tools rely on the ontology of the datasets to produce views, some allow the use of SPARQL queries and vi-

sualize the results. Sextant (Nikolaou et al. 2015) is an open-source visualizer that also supports GeoSPARQL and stSPARQL. The features that distinguish Sextant from other Semantic Web visualization tools are the ability to create, share and edit thematic maps, by combining information from different SPARQL endpoints and enrich them with other well-adopted geospatial file formats, like KML, GML, GeoJSON and GeoTIFF, as well as visualizing the temporal dimension of data. Sextant heavily utilizes Semantic Web technologies, but the user-friendly interface, combined with features like predefined queries, allows both domain experts and non-experts to handle this tool.

Applications

The linked geospatial data technologies discussed above have been used in many interesting applications, e.g., wild fire monitoring (Koubarakis et al. 2013), developing semantic catalogues for Earth observation data archives (Karpasiotaki et al. 2014; Espinoza-Molina et al. 2015), maritime security (Brüggemann et al. 2016), and precision farming (Burgstaller et al. 2017). In the context of these applications, many Earth observation and geospatial datasets have been made available on the Web as linked open data therefore increasing the potential for development of more interesting applications in the future.

Management of Time

Ted Dunning
MapR Technologies, Santa Clara, CA, USA

Definitions

The management of time in streaming systems refers to how streaming computations make use of the explicit and implicit times associated with messages used in the computation.

Background

In a streaming data system, the data consists of messages that enter the system and then undergo various operations such as filtering, transformation, and aggregation. Between processing steps, these messages are transported by message streams such as those provided by Apache Kafka (Apache Software Foundation 2016c). When messages come from disparate sources via different paths, they may be reordered, delayed, or even lost entirely due to propagation delay or hardware or software failures. Processing steps themselves may also delay, reorder, or lose messages due to multi-threading or various kinds of faults in processing.

It is desirable that the processing of these messages be as reliable and timely as possible, but delay, loss, and reordering of messages can make this difficult or even impossible. In fact, the desire for timeliness is often in conflict with the desire for accuracy forcing a less than perfect trade-off.

Over the life of a message, there are implicit times associated with each step of processing of the message starting with the creation or ingestion of the message and continuing on until the message is no longer of interest and is discarded. These times may not be explicitly recorded, but they still can be considered to exist, at least conceptually. There may also be times associated with the real-world events that may have given rise to a message. Many processing steps make use of different times associated

with messages, particularly for creating what are known as windowed aggregates. Such aggregates are themselves data streams containing messages with a value for each distinct window along with information describing the window.

For instance, we might want to count the number of sales made in each month. To do so, we need to know, of course, about all sales that are made, but we also need to know when each sale is made so that we can credit it to the correct month. Moreover, we can't know the total for any month until it is certain that there are no more sales to be reported. When there is a delay in reporting sales in some month, there must be a corresponding delay before we can report the precise total of sales for that month. In addition, if the reports of sales are delivered out of order with respect to the time the sale occurred, we may have to accumulate counts for multiple months since sales for the new month will be reported even though some sales have not yet been reported for the previous month or months.

The desire for timely results can conflict with the desire for accurate results. Taking the sales example again, it might be that a report could be delayed by as much as a month, even though delays of more than a day or two are quite rare. In this case, we could report a total for a month a few days after the end of the month that is usually correct. A result that is "usually correct" might well be good enough, especially if we can put a bound on how wrong the result might possibly be. It might also be acceptable to report a corrected total the following month as long as the correction is small relative to the originally reported value. Clearly, we need some guide to know when we have seen enough data to output an aggregated value.

Foundations

From the example of sales reports, it is clear that there are many events associated with a sale that could be said to be the moment when the sale occurred. This could be when a handshake is made, when the customer signs the order, when the order is approved by the vendor, when the

order is shipped, or even when full payment is received. It is quite plausible that many or even most sales could involve events that span multiple months. For the purposes of computing some particular quantity, however, it is customary to appeal to some accounting standard to arbitrarily define one of these events as the key point in time that a sale is made. Nothing prevents using a different time in a different computation for a different purpose, but for any given computation, it is typical to define an "event time" when it is said that the event represented by a message in a stream actually happened, but it should be recognized that this definition is entirely specific to a particular user requirement.

There are other times that are much more associated with the computational process itself. For instance, the moment that the message has been received is typically known as "ingestion time," and the moment when the message is actually processed is often known as "processing time." It should be noted that of these three times, only event time is independent of when a computation is done. As such, only computations that are defined in terms of event time are likely to be acceptable to users who need a result that can be reliably reproduced and audited. Such users will care little or not at all about details such as when a computation is run.

In most situations, it is also important that a computation produce precisely the same result if it is run more than once. This is typically only possible if the result is defined in terms of event time since ingestion and processing times are a function of when a program is run. Some stream processing systems such as Apache Storm (Apache Software Foundation 2013) conflated these different concepts, at least initially, and only allowed programs to be expressed in terms of processing time.

It should be noted, however, that computing with event time has its own risk since event time is typically defined outside the streaming system and thus errors in event time are outside the control of the streaming system. Times that are measured automatically are often subject to large systematic errors due to incorrect clock settings. Manually entered times are subject to

large errors due to typographical mistakes. For whatever reason, large errors in times seem one of the most common measurement error. Input validation as early as possible is necessary, and compensation for common errors such as bad clock settings and drained batteries is often necessary. Ingestion time may be subject to similar errors especially if ingestion is highly distributed, but such errors are typically more susceptible to correction. Processing time is least suspect in this regard but also generally least useful except for computing time differences. In general, all externally generated times should be carefully validated as early as possible in a streaming computation. Times in the future, times far in the past, and times on messages where message delay apparently changes discontinuously and by a large amount are all highly suspect.

Generally, computation on a stream is composed of three kinds of steps:

Stateless transformations and filtering of individual records Without any retained state between records, this can be done without any reference to event or any other time at all.

Re-ordering of records, such as sorting by event time Since the input is unbounded, a general sort is impossible. If the disordering of the input is limited, however, then the input can be sorted by event time with bounded storage, computation, and delay.

Computation of a function of a group of records known as a window Since streams are unbounded, windows are typically only useful if the records in a window are more or less localized in time. The grouping of records is known as windowing, and the computed values are called windowed aggregates.

In the context of time management, only sorting and windowed aggregates are of interest because stateless transformations can be done entirely without reference to time.

Watermarks

The use of event time raises some additional complications, however, because messages in a

streaming system are subject to variable and unpredictable amounts of delay, which can disorder records. Computations framed purely in terms of processing time have the great advantage that there is no need to consider the problem of delayed data. Considering only processing time, however, makes it nearly impossible to precisely reproduce a computation. Bringing event time into the conversation necessarily requires consideration of the problem of delay and that, in turn, makes sorting and windowing difficult because it isn't always clear how much messages may have been delayed.

It is often possible, however, to put a bound on how much delay there may have been. Rather than express this in terms of delay, it is handier to keep track of how much of the input stream is complete at any given time. That is, we want to know an event time that is guaranteed to be before the event time in any messages that we may receive in the future from a particular message stream. This time is known as the watermark for the stream. Clearly, if we know that a stream has a certain maximum possible delay, then the current time less this delay is a viable, although, usually, overly conservative, watermark for the stream. Usually we can do better than this and have a safe watermark that is much closer to the current time. Modern systems such as Google's Dataflow (Akidau et al. 2015), Apache Beam (Apache Software Foundation 2016a), and Apache Flink (Friedman and Tzoumas 2016; Apache Software Foundation 2016b) all associate watermarks with input streams. Apache Spark's structured streaming (Apache Software Foundation 2016d) component uses a single maximum delay for an entire computation to compute an estimated watermark for all input streams.

The point of a watermark is that we can know when it is safe to emit any windowed aggregates because the watermark will tell which windows may have pending messages and which windows cannot. Any window that is entirely older than the watermark for a stream will never receive any new data, and thus the corresponding aggregate value will never change. That means that once the watermark passes the end of a window, we can safely emit the current value of any

corresponding aggregates without worrying they will be superseded. If a watermark is precise, it is also clear that this is the best we can do if we want to only emit final values for aggregates and we want to do that as soon as possible.

It is also possible to define a watermark with a weaker guarantee that simply gives a non-zero bound for how much data might still be received with event times before the watermark. Such weak watermarks allow provisional values of aggregates to be emitted that are close to the final value.

Practically speaking, watermarks are often based on heuristic summaries of past system behavior. If messages are only transported using ordered streams and messages are coming from a known set of sources, then each source can inject heartbeat messages into the message stream and depend on the ordering of the stream itself to guarantee that no message is ever reordered behind a heartbeat from the same source. A watermark for the overall input consisting of multiple such streams can be computed by remembering most recently received heartbeat for each source stream. The earliest heartbeat time of any source is then the desired watermark for the composite.

Sorting by Event Time

Sorting messages by event time is the simplest “interesting” thing to be done with disordered streaming data. Messages in a stream subject to delay can be sorted if the delay is bounded, but unbounded delay implies unbounded required storage for temporary values. If watermarks are available and the delay is relatively small, sorting is relatively easy. All messages with event time after the current watermark can be kept in a sorted buffer such as a heap. As the watermark advances in time, messages that now have an event time before the watermark can be emitted in sorted order. The watermark will eventually pass every record because of the bounded delay, so the sort will eventually emit all messages (in order).

Obviously, the practicality of this procedure depends to a great degree on how much delay there might be in the stream since that determines

how many values need to be kept in the sort buffer either in memory or on disk.

Windows and Triggers

Windows specify how messages in a streaming system are grouped for aggregation. For instance, messages might be grouped hourly. Or messages from individual users might be grouped by day in terms of each user’s local time zone. The aggregation on a window can be as simple as a count of the number of records.

Since the input in a streaming system is unbounded, windows are necessary to bound the computation of aggregated values. This is because in a streaming system, any aggregate for a window that is not bounded in time can never be emitted. Different kinds of windows have different characteristics. Some kinds of windows allow different windows to overlap in time. Some kinds of windows reuse messages in multiple windows. Some kinds of windows are defined purely by event time without respect to the other content of messages. In all cases, however, the key point of any windowing definition is that it defines which messages belong to which windows.

Tuple-Based Windows

The simplest form of windowing is to retain the last n values seen. This can be valuable for summarizing gross measurements of overall activity, especially for alerting on system malfunctions. The time since the latest sample is a good way to detect missing data and the n -th last sample is useful in looking for changes in activity rate since it allows an optimum trade-off between detection time and false-positive rate. Tuple-based windows are commonly used for systems monitoring.

Tuple-based windows are defined independently of event time and are thus not usually suitable for producing aggregates for external consumers.

Time-Based Windows

Another common windowing scheme is to group messages by either processing time or event time. Grouping on processing time can be useful for monitoring the state of the streaming system itself, while grouping on event time is more

useful when analyzing the data instead of the streaming system. Though not strictly required, it is common that each window is characterized by a start time and an end time and all messages with event times greater than or equal to the start time and less than the end time will belong to that window. Commonly, such windows are of mostly constant duration and have start times separated by a constant stride. If the stride is equal to or greater than the duration, then there is no overlap in the windows. With a shorter stride, windows will overlap and messages will belong to multiple windows.

Complications can arise in this simple picture, especially when calendars are involved. For instance, a window that starts at the beginning of each month and ends at the end obviously has a variable stride and duration since months vary in length. Windows that start at the beginning of each day can have the same kind of problem due to daylight savings time. Leap seconds can cause similar, though much smaller, surprises.

Complex Time-Based Windows

Basing window membership of messages on the event time of each message independently is insufficient for some kinds of computation. The most prominent example of this are session-based windows in which successive messages are assigned to the same window as long as the time between messages is less than a specific threshold. To further complicate matters, session windows are also typically user specific, so an enormous number of windows can be active at the same time.

Complex windows such as user-specific sessions can be surprisingly resilient to certain data errors such as large offsets in event time, especially if such errors are consistent on a source by source basis.

Data-Defined Windows

In general, messages in a stream can be grouped into windows by stateful rules defined using any aspect of the messages being grouped. All of the windowing schemes discussed so far here can be defined as special cases of this. Support for general data-defined windows is still quite un-

common for streaming analytics systems. Apache Beam and Apache Flink are examples of systems that support data-defined windows.

Triggers

In the context of stream processing, windows define how messages are to be grouped together for aggregation but do not specify when the computation of an aggregate must happen. Triggers, on the other hand, define when such aggregations should actually be computed but are independent of the window definition itself. Ideally, the aggregated results for each window would be computed precisely when the last message in a window is processed. In practice, such a prompt computation may not be convenient or efficient. Delaying a bit so that many aggregates can be computed together at the same time might, for instance, make better use of computing resources.

Another good illustration of the value of alternative triggering of a window is session windows. For many uses of session windows, it is sufficient to only check every 10 min or so to see if any sessions have expired. This can be done using a single timer to periodically invoke a scan of all active windows, preferably in order of last contact. Detecting expired sessions exactly when they expire, on the other hand, typically requires a timer per active window and causes frequent small computations which are less efficient than larger but rarer computations.

Differences Between Time in Streams and Time in Databases

Temporal databases emphasize the processing of time values that represent and distinguish concepts such as when a fact is valid (valid time) and when a fact is known (transaction time). For instance, on the first of April, we may learn that Mark Twain was born in 1965 and died in 2003. Seven months later, in November, we might conclude after extensive investigation that he was actually born in 1835 and died in 1910.

Our first fact from April fool's day stated that Mark Twain's life spanned 1965–2003 but that "fact" had a validity period from April until November. The more authoritative (and actually correct) fact that he lived from 1835 to 1910 had a

validity period from November onward. Expressing the evolution of knowledge in a database can be very important in financial and legal settings where you may have to answer questions of the form “what did you know and when did you know it.”

In a streaming system, the situation is made a bit more complex by the fact that many big data systems are global in extent, and thus there is no single time when data is valid since there is typically no single database that is the repository of all truth. On the other hand, streaming does make things simpler as well since it is difficult for a database to store all old states, whereas a streaming system inherently does exactly that as long as all messages are retained. That means the state of what was known at any time in history can be recreated precisely if one can replay messages in historical order up to the desired point in time.

In spite of the difference, there is still a useful analogy to be drawn between transaction time in a temporal databases and event time in streaming systems. Likewise, valid time in a temporal database and processing time in a streaming system have an analogical function. The streaming concepts in each case are more general since a single message may have multiple event times associated with it as well as multiple processing times.

Metrics for Big Data Benchmarks

Alain Crolotte

Definitions

A big data (BD) benchmark metric is a standard measure indicating the adequacy and cost-effectiveness of the system under test (SUT) to perform a particular big data task or set of tasks.

Overview

The following section provides a survey of the big data benchmark and associated metrics evolution over the years until present day. In the foundations section we list all the main metrics while the following sections present the definitions and properties for each metrics category namely, response time and throughput, availability and reliability, price-performance and system-level metrics. We then go over the various methods to aggregate these individual metrics while the criticisms section reviews the metrics surveyed. We then list the key applications of these benchmarks. Finally cross-references and references are provided.

Historical Background

The need for computer performance metrics was identified as early as 1985 (Anon 1985) and led to debit-credit, the first benchmark with a standard and associated metrics, namely, throughput and price performance. The debit-credit benchmark was then used and extended by the Transaction Processing Performance Council (TPC) [www.tpc.org provides detailed information on all the TPC benchmarks] and became TPC-A followed by TPC-B and TPC-C, which had similar metrics: tpmC (transactions per minute in benchmark C) as the performance metric and dollars(tpmC) as the price-performance metric. Following the development of OLTP benchmark standards, the TPC started decision support benchmarks in the early 1990s, first TPC-D then TPC-H and finally TPC-DS. While there are differences between these benchmarks, the associated performance metrics are similar, namely, throughput in terms of queries per hour (QPH) and price performance. While the OLTP benchmarks involved only one test, the TPC decision support benchmarks involve several tests each associated with its own metric requiring an aggregation rule to define a final single performance metric.

Wikipedia defines big data as “a term for data sets that are so large or complex that traditional data processing application software is inade-

quate to deal with them” – big data therefore poses a challenge addressed as early as 2005 by the Apache Hadoop framework with its HDFS distributed file system and its tool suite including map reduce (MR). Initially contained in the kit were micro-benchmarks. These were WordCount, grep, Sort, Terasort (which became TPCx-HS), and in later releases, micro-benchmarks addressing the performance of its components such as the HDFS file system or the underlying network architecture or MR. For these built-in Hadoop benchmarks a result set are produced showing well-defined metrics for each test or subtest, e.g., bytes written or read per second. Unlike in the case of standard benchmarks such as the TPC benchmarks, users can aggregate and use the individual micro-benchmark metrics as they please. In the same vein, a number of Hadoop benchmark suites have been developed. An example is HiBench (Huang et al. 2010) which is a superset of the Hadoop-provided micro-benchmarks with targeted add-on workloads such as machine learning. Each domain or sub-domain has its own metric in these cases, but unlike for industry-standard benchmarks, there is no attempt to define a single performance metric.

Big data was eventually characterized by the 3Vs (volume/velocity/variety) (Laney and Deja 2012). The 3Vs became 4Vs and even 5Vs but without adding much to the data “bigness” argument, so we will stay with the 3Vs. TPC decision support benchmarks address volume by recognizing that size matters requiring that the scale factor be part of the metric and disallowing comparisons across scale factors. Those scale factors are bounded by 100 TB which is very small in the big data world as petabytes of data are commonly mentioned. They also address velocity by recognizing the importance of refreshing data, but the amount of new data, the frequency, and often near real-time requirement for BD maintenance functions far exceed what is covered by the TPC decision support benchmarks. Variety, a qualitative metric, is the ability to handle many types of data in addition to structured data accessible by SQL. Such data include semi-structured data such as weblogs or unstructured data such as text. The first integrated end-to-end big data

analytics benchmark including the 3Vs was BigBench (Ghazal et al. 2013), an extension of TPC-DS with semi-structured data (weblogs), unstructured data (product reviews), and 30 analytical queries representing the realities of decision support in a modern enterprise. Initially BigBench was implemented on Teradata Aster with SQL and SQL-MR. BigBench was proposed by the TPC as TPCx-BB with a complete kit typically running on Hadoop. The performance metrics for this benchmark are also a form of throughput combining the load time, the timing for the power test, and the timing of the throughput test and price/performance. The allowed scale factors in TPCx-BB follow the same pattern as those in TPC-DS, but the upper bound is now 1 petabyte. Like A major rework of BigBench was proposed that brings important variety improvements and incorporates the concept of late binding (Ghazal et al. 2017). The metrics for BigBench V2 are the same as those for TPCx-BB.

In Ivanov et al. (2015), a detailed survey of 20 BD benchmarks along with the associated metrics is provided. Time is by far the most popular metric in the form of query time or execution time closely followed by throughput and price performance. New metrics appeared such as client latency, data processed per second, and data processed per joule. Newer BD benchmarks addressing new data types (for instance, in BigBench V2 the semi-structured data is in JSON format) but also new structures such as streams or graphs may require the creation of new metrics. For instance, Graph 500 (<http://graph500.org/>), a public-domain benchmark addressing graph-based systems, introduces TEPS defined as the number of edge traversals per second yet another form of throughput. The field of BD benchmarks is an active area of research, but metrics are mainly aimed at measuring performance, and the only two dimensions of performance are time and accuracy.

Foundations

There are many BD benchmarks available: industry standard, public domain, or company-

sponsored. The associated BD benchmarks metrics, however, fall into broad categories. In Han et al. (2017), the authors propose a classification of BD benchmark metrics in which they distinguish between user-perceivable and non-observable performance metrics. Observable performance metrics include (1) response time, (2) throughput, (3) reliability, and (4) availability. Metrics that are not directly observable by a user are hardware architecture metrics dealing with CPU, memory, and connectivity. BD benchmarks can involve several types of metrics as portrayed in Han et al. (2017) and Ivanov et al. (2015).

Response Time and Throughput

Typical time-based performance measures in the context of computer benchmarks are either elapsed time for a fixed number of operations that are well-defined in advance or number of operations performed in a fixed amount of time. In both cases, by dividing the number of operations by the elapsed time, a throughput measure is obtained. While a typical performance measure is transactions per second, elapsed times are also commonly used. While a lower elapsed time is an indication of higher performance, a higher throughput indicates a higher performance. The performance is always proportional to the amount processed and inversely proportional to the elapsed time.

Availability and Reliability

Accuracy-based performance measures are typically reliability, i.e., the number of successful operations compared to the number of unsuccessful operations, and availability, which measures the percentage of time the system is up and running. All TPC benchmarks involve tests that insure system availability. Several built-in Hadoop micro-benchmarks are designed to stress the system and determine reliability and availability.

Price Performance Metrics

Performance usually comes at a cost or price, so it is important to determine not only the performance but also the cost of the system. Money is an obvious cost metric, but it is not the only

one. Another important price metric is power consumption. This led the TPC to introducing an optional energy component to all its benchmarks. The price performance metric is price divided by performance, e.g., dollars per operations per unit of time, such as dollar per transaction per query per hour. An example of a price performance metric is $$/HSph@SF$, used in TPCx-HS (Terasort). The scale factor SF is part of the metric to avoid comparisons at different scale factors.

System-Level Metrics

For special-purpose benchmarks and benchmarks addressing a large number of workloads such as HiBench and BigDataBench, it is appropriate to look at performance at a system level. Metrics at this level can be CPU utilization breakdown, processor intensity, processor memory level parallelism, or scale-out performance. These metrics do not provide an application-level metric such as a query per hour, but they do provide black box measures of performance that can be used to optimize resource allocation in a data center, for example, a subject addressed by DCBench (<http://prof.ict.ac.cn/DCBench/>).

M

Aggregation of Individual Metrics

In a BD benchmark, there can be several levels of aggregation. The first level involves individual homogeneous transactions, e.g., queries. In a benchmark test, each individual transaction has a measured elapsed time. The transactions can be run sequentially or in parallel – the difference between the end of the last executed transaction and the start time of the first executed transaction is the total elapsed time. To illustrate our point, we will use the TPC-H benchmark that can be considered as a very early BD benchmark. In TPC-H there are two tests: (1) a power test and (2) a throughput test. The power test runs 2 refresh functions and 22 queries sequentially in a prespecified order. The average transaction time during the power test would therefore be the sum of the elapsed times divided by 24 (22 queries + 2 refresh functions). Instead of the usual simple average, the geometric mean was used. The idea of using the geometric mean to

summarize *normalized* benchmark results was proposed in (Fleming and Wallace 1986). Unfortunately it is easy to forget that if the individual values are *raw* (e.g., elapsed times expressed in seconds in the case of TPC-H), then the arithmetic mean is much more appropriate (Crolotte 2009). An argument used by the proponents of the geometric mean is that the arithmetic mean is biased toward large values as a very large individual value in the calculation of the arithmetic mean will “overwhelm” the metric bringing the throughput down. However, the geometric mean has a similar property since an extremely low value will bring the metric down potentially very close to zero which will bring the throughput unrealistically high. These issues are discussed in detail in Crolotte (2009). Aggregating individual test metrics into a single figure of merit will face similar challenges.

Criticisms

The final metric for the TPC-H power test is queries per hour at scale factor (QpH@SF), i.e., SF*3600/g, where g is the geometric mean of the 24 power test elapsed times expressed in seconds and SF the scale factor expressed in gigabytes. Because of the use of the geometric mean, the TPC-H power metric is not a real query per hour, but it has the dimensions of a query per hour. The second test is the throughput test where queries are run in parallel and the metric is based on the total elapsed time which makes it a real query per hour rate. In order to aggregate the two tests, the geometric mean is used again. The use of the geometric mean in TPC benchmarks has been criticized mainly because the formula itself was complicated since the formula for the geometric mean of n values involves the product of those values to the power 1/n. Yet the final metric is scalable and has the dimension of a throughput albeit not a real one, but, as noted in Huppler (2009), this metric is relevant as it does provide a measure of performance for a system running the application on a database of a defined size. In spite of the criticisms about its metric, TPC-D was a very successful benchmark followed by TPC-H which remains a de facto standard

until today. TPC-DS has four performance tests each with an elapsed time, and these four tests are aggregated again with the geometric mean. It remains to be seen whether, for most cases, applying the geometric mean would result in an ordering different from that obtained by applying the arithmetic mean.

Key Applications

Metrics are a powerful way to provide a basis for comparison between systems and implementations on particular systems. However, unless there is a guarantee, the comparison may not be valid. The need for metrics appeared in the mid-1980s and led to the formation of the TPC which provided such a guarantee through a formal process involving well-defined standards, audits by certified auditors, and advertising rules preventing unfounded claims. The TPC benchmarks also come with benchmark kits making it easy to implement workloads quickly. For instance, even before TPC-DS was a full standard, several vendors used the workload and took some of the 99 TPC-DS queries in isolation in order to compare DBMS and Hadoop implementations. This led to many unfounded claims as to one implementation being better than the other and vice versa. When a workload consists of several types of operations, the only fair time measure that can be applied is either the total elapsed time or the average elapsed time per operation.

Response time and throughput are especially suited for comprehensive, end-to-end BD benchmarks. These benchmarks are useful at showing the power of a system to run a particular application, for instance, BigBench. They can also be used to tune a system such as a Hadoop cluster. GridMix (<https://hadoop.apache.org/docs/r1.2.1/gridmix.html>), for instance, is used for performance engineering of a Hadoop cluster by helping to identify bottlenecks and tune job and user priorities. Benchmark suites such as HiBench and its associated metrics are more targeted at evaluating hardware or optimizing Hadoop components especially map reduce.

Definitions

A microbenchmark is either a program or routine to measure and test the performance of a single component or task. Microbenchmarks are used to measure simple and well-defined quantities such as elapsed time, rate of operations, bandwidth, or latency. Typically, microbenchmarks were associated with the testing of individual software subroutines or lower-level hardware components such as the CPU and for a short period of time. However, in the BigData scope, the term microbenchmarking is broadened to include the cluster – group of networked computers – acting as a single system, as well as the testing of frameworks, algorithms, logical and distributed components, for a longer period and larger data sizes.

M

Overview

Microbenchmarks constitute the first line of performance testing. Through them, we can ensure the proper and timely functioning of the different individual components that make up our system. The term *micro*, of course, depends on the problem size. In BigData we broaden the concept to cover the testing of large-scale distributed systems and computing frameworks. This chapter presents the historical background, evolution, central ideas, and current key applications of the field concerning BigData.

Historical Background

Origins and CPU-Oriented Benchmarks

Microbenchmarks are closer to both hardware and software testing than to competitive benchmarking, opposed to application-level – macro – benchmarking. For this reason, we can trace microbenchmarking influence to the hardware testing discipline as can be found in Sumne (1974). Furthermore, we can also find influence in the origins of software testing methodology during the 1970s, including works such as Chow (1978). One of the first examples of a microbenchmark clearly distinguishable from software testing is the *Whetstone benchmark* developed during the late 1960s and published later by Curnow and Wichmann (1976).

The *Whetstone benchmark* is considered the first general-purpose benchmark suite that helped later to set industry standards in computer performance (Longbottom 2017). The first implementations of the benchmark were composed of a set of *ALGOL* and *FORTRAN* routines with the intention of comparing computer architectures and optimizing compilers (Longbottom 2017), in this case, by measuring the number floating point instructions per second of a system. *LINPACK* is another representative microbenchmark example from the late 1970s (Dongarra et al. 2003). *LINPACK* is still in use primarily in its parallel version – *HPL* – in high-performance computing (HPC) environments (A. Petitet 2004) and in the supercomputing Top500 list (TOP500.org 1993).

Another example of a benchmark with a long track of revisions and still in use today is the family of SPEC CPU benchmarks. *SPEC CPU* was standardized and is maintained by the Standard Performance Evaluation Corporation (SPEC 1989), and it is frequently used in official and academic publications (Nair and John 2008; Cantin and Hill 2001). Another early benchmark is UnixBench (1983), in this case, a suite or collection of different benchmarks including those from the Whetstone to graphics card microbenchmarks.

Disk and Network

Unlike HPC and CPU benchmarking, we can characterize BigData – at least the open source-based frameworks, as being GNU/Linux-based, 64-bit x86 architecture deployments over commodity hardware. As in BigData, the main bottlenecks were initially found in the storage and networking layers (Poggi et al. 2014). Due to being readily available, and already part of the system administration routines, the first level of benchmarking in a BigData system typically involves using popular Unix testing tools. In this category, we find the network testing tools such as ping (1983) and traceroute (1987) and disk management utilities including dd (1985) and hdparm (1994) available for most common Linux distributions. After network testing tools, we can find system benchmarks developed by the community, most notably in the disk/file system category: *Bonnie* (bonnie circa 1989), one of the first disk benchmarks with a later 64-bit for *Bonnie++* fork (bonnie++ 1999); *IOzone* another file system benchmark utility (iozone 2002); and Flexible I/O Tester (FIO), which was used in 2012 to set the world record in IOPS (benchmark 2012 IOPS world record) and continues to be popular among storage manufacturers. On networking, *netperf* by Hewlett-Packard (HP) (netperf 1995) has been a popular tool during the late 1990s and early 2000s. Another widely used tool involves the different versions of iperf (2003) still widely used in the field.

BigData

In the beginning there was Sorting (Rabl and Baru 2014)

While preceding the BigData era, we can track the influence of the *sort* benchmark in the original MapReduce paper proposed by Google (Dean and Ghemawat 2004). The sort benchmark led by Jim Gray in an industry-academia collaboration was first introduced in 1985 to measure the input-output (I/O) of a computer system (Anon et al. 1985) as part of the *DebitCredit database* benchmark (Rabl et al. 2014). The sort benchmark

was simple: generate and then sort one million, hundred-byte records stored on disk. Since its appearance, different versions – mainly increasing the input size – and the contests (Sortbenchmark.org 1987) organized around the benchmark have greatly influenced the data processing field. The introduction of the sort benchmark in the original MapReduce paper and its simplicity but also its usefulness of stressing I/O components (Poggi et al. 2014) of a system, sort – in its 1-terabyte format – became the defacto standard in big data benchmarks. TeraSort was later standardized by the Transaction Processing Performance Council (TPC) as TPCx-HS in 2014 (Nambiar et al. 2015) as a way to provide a technically rigorous and comparable version of the algorithm. Since the first releases of Hadoop – the open source implementation of MapReduce in Examples (2016) – the Hadoop examples package has been included with the distribution. Hadoop examples originally included the *Grep* (also listed in Dean and Ghemawat (2004)) and *WordCount* sample applications as microbenchmarks. The *WordCount* application has been widely used in educational contexts, becoming one of the first programs a user of Hadoop would implement. *WordCount* is CPU bound (Poggi et al. 2014), in that sense, not as useful as *TeraSort* to stress and benchmark a cluster. Since then, the Hadoop examples has grown to include an increasing number of microbenchmarks and test applications (Noll 2011), most notably the *dfsio* benchmark to measure the Hadoop Distributed File System (HDFS) throughput.

Other notably early Hadoop benchmark included in Hadoop v1 is *GridMix* by Douglas et al. (2007). *GridMix* simulates multiple users sharing a cluster and includes workloads of cache loads, compression, decompression, and job configuration regarding resource usage. The Hadoop microbenchmark suite designed by Islam et al. (2014) helps with detailed profiling and performance characterization of various HDFS operations. Likewise, the microbenchmark suite designed by Lu et al. (2014) provides detailed profiling and performance characterization of

Hadoop RPC over different high-performance networks. Similarly, *HiBench* (Huang et al. 2010) has extended the *dfsio* program to compute the aggregated throughput by disabling the speculative execution of the MapReduce framework. *HiBench* also adds machine learning and web crawling benchmarks to the suite. Similarly, *BigDataBench* from the ICT, Chinese Academy of Sciences (2014) provides a collection of over 33 microbenchmarks in different categories.

As BigData evolves closer to data warehousing and business intelligence (BI), so do the benchmarks. Most likely, the *Wisconsin benchmark* was the first database-like microbenchmark, designed to measure the performance of individual SQL operators (DeWitt and Levine 2008). *MRBench* by Kim et al. (2008) is an early example which provided microbenchmarks in the form of MapReduce jobs derived from *TPC-H* (Transaction Processing Performance Council 2014). The *CALDA* benchmark proposed by Pavlo et al. (2009) was developed to compare Hadoop against parallel database systems. It included five SQL-based queries which could be implemented to the target system. Both the AMPLab and Hivebench benchmarks are based on *CALDA*'s queries. The Yahoo! Cloud Serving Benchmark (YCSB) (Cooper et al. 2010) is a set of benchmarks for performance evaluations of key/value pair and cloud data-serving systems. YCSB was originally designed to compare Cassandra, HBase, and PNUTS in a cloud setting to a traditional database (MySQL). Over time, YCSB has been extended to support a variety of data systems (YCSB-Web 2017) and become the de facto benchmark for key/value stores. Also, YCSB is still frequently used in technical conferences such as in Poggi and Grier (2017).

M

Foundations

Most benchmarks can be classified into two categories: micro- and macro-benchmarks. (Waller 2015)

Performance testing is a subset of performance engineering (Jain 1991b; Testing 2017), where microbenchmarking – or simply benchmarking – is one of the main tools employed to verify reliability and speed of a system. Microbenchmarks are the first line of testing tools for determining the correct functioning and configuration of a node, the interconnect (networking), and then the cluster – a group of networked computers acting as one system. A microbenchmark is then either a program or routine to measure and test the performance of a single component, task, or algorithm.

Microbenchmarks are used to measure simple and well-defined quantities such as elapsed time, the rate of operations – throughput, bandwidth, or latency. Typical use cases for microbenchmarks involve comparing algorithms (i.e., *sorting*) or the performance of the same software routine tested in different hardware platforms but using the exact same input as in Waller (2015). Furthermore, microbenchmarks often follow a *white box* approach as they are implemented having the specification of the target system or the application's code available.

While there are several classifications of benchmarks, according to Ehliar and Liu (2004), there are two practical approaches to benchmarking: micro and application-level (macro). Furthermore, Ehliar et al. distinguishes between micro and application-level according to the ease of implementation and the testing of one aspect at a time, as in microbenchmarks, to creating a realistic and useful application (macro). However, other authors such as Seltzer et al. (1999) argue that many micro- and macro-benchmarks do not efficiently model real workloads. Thus part of the dangers of relying only on benchmark results as the only basis for high-level decisions.

Microbenchmarks in BigData

Traditionally microbenchmarks were associated with the testing only of a system or lower-level hardware components such as CPU, main memory, and I/O on a single node. In the networking context, including a couple of nodes or networking devices, but in both cases for a short period

of time. However, in the BigData scope, the term microbenchmarking is broadened to include the cluster of servers as the system under test and to include the testing of the frameworks or algorithms on which data applications are later built on.

Moreover, microbenchmarks in BigData include the testing of virtualized or logical components such as distributed memory and file systems provided by middleware and layers of abstractions at the software level opposed to the lower-level traditional system benchmarks. Within this context, the metrics of interest are either the total processing power, throughput, or bandwidth of the cluster as a whole, usually for a longer span of total test time which can last for several days (Poggi et al. 2014) and large input data sets to fully stress the total capacity of the system.

Properties of a Good Microbenchmark

On the topic of benchmarking, (Gray 1992) has identified four import criteria for a successful benchmark: relevance, portability, scalable, and simple. In particular, for microbenchmarks, simplicity is the main priority as it must perform a single, well-defined task, with reproducible results. In Gregg (2013), the author makes an emphasis of simplicity being the main advantage of microbenchmarks. In BigData and cloud computing, microbenchmarks also need to be scalable in both weak and strong scaling. Strong scaling refers to keeping the problem size – the data set – fixed but increasing the number of processing elements, typically the number of nodes or containers. In weak scaling, the data set is increased in proportion to the number of processing units. The weak scaling property of the microbenchmark is of particular importance to BigData, as it provides a way to increase the volume of data to be processed or scale factor as in TPC (2017) benchmarks.

In practice, when benchmarking weak scaling properties, the volume of data is also increased without adding more processing capacity, to measure in part the stability of the system and the rate in which performance decreases. Some examples of weak vs. strong scaling can be found in the

ALOJA project results (ALOJA-Web 2015). The property of portability in the BigData field is usually covered as most widely used frameworks, i.e., Hadoop and Spark, are based on the Java virtual machine (JVM), which is multi-platform compatible. Furthermore, GNU/Linux, Hadoop, and Spark are open sourced, as well as most of the aforementioned benchmarks. Relevance is the most challenging feature of a microbenchmark. Testing only a single task or component, a microbenchmark often does not represent a real-world application or use case. A microbenchmark can also misrepresent a system or measure an incorrect property.

The Dangers of Microbenchmarks

Several authors have raised the importance and of good practices in benchmarking and about the dangers of using only microbenchmarks for decision-making. In Traeger et al. (2008), authors perform a comprehensive evaluation of over 106 storage benchmark research papers. Traeger et al. (2008) claim that most benchmarks available at the time were flawed and that statistical analysis of results was mostly incomplete. Gregg (2013) adds to the dangers of benchmarking coining the term “benchmarking sins.” The list of *sins* includes casual benchmarking, benchmark faith, testing the wrong thing, using complex tools, cheating, and many statistical and numerical errors while benchmarking. In Jain (1991a), the author expands the list of “common mistakes in benchmarking,” including not taking into account the overheads of monitoring tools and not measuring transient performance. Traeger et al. (2008) recommend using a combination of several micro- and at least a macro-level benchmark should be run on the target system to understand better the performance.

Microbenchmarks, however, can excel in the repeatability, portability, speed of execution, and automation of the benchmarks as tests. For these reasons, microbenchmarks are often part of Continuous Integration (CI) development tools to detect performance regressions in new pieces of code.

Microbenchmarks in the Development Cycle

Microbenchmarks are often written as part of software development and testing cycle. When developing new functionality, the programmer may decide – most often not – to write a test that measures the performance of the new code. This process usually occurs alongside the coding of unit or functional code tests. As to performance tests – microbenchmarks – usually take longer to execute than unit tests; the tests might not be run with every iteration of the CI suite. For this reason, the performance tests are likely to be run manually and often is the case in practice that is not run frequently after the new feature is finished and shipped.

A relevant example of microbenchmarks in the development and testing process can be found in the Apache Spark’s SQL project source code repository (Apache Spark 2015). The benchmark’s folder contains a *base class* to encapsulate adding and running new benchmarks a set of microbenchmarks. The test classes embed the data generation step when needed and output the CPU architecture and time details, as well as the rate of operations achieved. These tests are meant to be run in the developer workstation or CI environment, as they are often single node or even single-threaded – opposed to a full Spark cluster setting. Moreover, most of these tests are marked as *ignored* in the code, which prevents the CI and testing such as *maven* or *sbt* tools to run them by default.

Key Applications

It was mentioned in the Historical Background Section that data processing benchmarks started with the *DebitCredit* database benchmark and specifically the included *sort* test (Rabl and Baru 2014). We can trace the influence of *sort* to the original MapReduce publication (Dean and Ghemawat 2004) and its *TeraSort* variant included in the Hadoop examples and the TPCx-HS standard (Nambiar et al. 2015). *TeraSort* is still frequently used to benchmark new cluster installations.

This section focuses on a selection of microbenchmarks that are still highly relevant to the industry and are part of the BigData Benchmarking Compendium by Ivanov et al. (2015) and the works of Rabl and Baru (2014) and Poggi et al. (2014). Here benchmarks are classified into system, functional, and database categories. Furthermore, several other early key microbenchmarks where mentioned such as Hadoop *Grid-Mix* and *MRBench*. Other benchmarks that have their own section in this publication, such as HiBench, SparkBench, and YCSB, are briefly discussed.

System

Disk and Filesystem Tools

For data processing, in particular, the storage – disk and file systems – is one of the most important resources to carefully design and tune to achieve high performance. Here the focus is on simple GNU/Linux tools that can be used to test that the target system can achieve a stable and desired operation. For input/output (I/O), the metrics of interest are bandwidth measured in megabytes-per-second MB/s, latency in microseconds, and the number of I/O operations per second or IOPS. IOPS and latency are metrics that are gaining importance (Poggi and Grier 2017) as BigData evolves from batch to more interactive use cases, i.e., streaming, also, to hardware advances such as flash-based storage technologies, e.g., SSDs and NVMe. The task of disk and network testing is usually assigned to system administrators while the functional and database to application roles. This situation leads to different teams not sharing the results or repeating the tests in the future, a situation which can lead to decreased performance over time.

dd (dd 1985) is a disk utility found in most Unix-like operating systems. Its primary purpose is to create, convert, and copy files. However, it can also be used for benchmarking raw disk devices and file systems, as the tool has multiple options and flags both for reading and writing files. Most notably, it contains options to access the raw devices directly and to bypass OS caches. In both cases, it performs only sequential operations

– opposed to random R/W. The sample output below is an example of a mounted networked volume from a popular cloud provider (Store 2017):

```
# dd sample output for writing
      10GB of data from EBS
10000+0 records in
10000+0 records out
10485760000 bytes (10 GB) copied ,
   83.3s , 126MB/s

#dd sample output for reading
      10GB of data from EBS
10000+0 records in
10000+0 records out
10485760000 bytes (10 GB) copied ,
   82.8s , 126MB/s
```

It is interesting to note that in this case, the drive wrote and read at the same rate of 126 MB/s. In this case, the volume is a networked-attached SSD. Magnetic drives (HDD) usually present a lower write than reading rate.

Flexible I/O Tester (FIO) (benchmark 2012 IOPS world record): FIO is the most widely used tool by drive manufacturers to measure device specifications. It was originally written by Jens Axboe to automate the testing of Linux schedulers and I/O subsystem. Since then it has been ported to several operating systems outside GNU/Linux including BSD, Solaris, and Windows. FIO allows testing file systems or raw devices directly. Also to do sequential and random read and write tests. Multiple-file reading and writing are also possible, as well as selecting the number of jobs, I/O queue depth, I/O library, and request (payload) size.

In addition to *dd* and *FIO*, which are single-node tools, cluster-oriented tools are needed to measure cluster-aggregated bandwidth for reading and writing files. For example, for Hadoop's HDFS, the *dfsio* microbenchmark is often used.

Networking

For networking, the most widely used tool is *iperf* (iperf 2003). *Iperf* can be started in client or server mode to measure the bandwidth and latency between two nodes. It has the limitation of only accepting connections from one client. To benchmark all of the nodes at the same time – and

stressing the switching infrastructure – several servers and clients need to be started pointing to different ports. Using this technique, it allows to test the whole cluster, but the aggregated metrics need to be calculated separately from the individual *iperf* reports.

Functional

Hadoop Examples and HiBench

On the BigData functional level, the most widely used benchmarks include the examples of the Hadoop examples package included in most Hadoop distributions. The examples have evolved from including only *grep* and *WordCount* to over 15 sample jobs to test a specific feature of the cluster or to aid in Hadoop’s framework development. Running Hadoop examples is discussed in depth in Noll (2011) blog. Also, benchmarking platforms such as ALOJA by Poggi et al. (2014) enables to easily run a selection of tests in a target cluster, as well as providing results of benchmarks ran in several architectures. In Hadoop versions 2.7 and higher, the example applications have been split into *MapReduce* and *common* packages. The continuously growing list of supported tests can be found at the examples repository (2018). Below is a list of the most representative benchmarks included and some of the extensions found in the first version of *HiBench* (Huang et al. 2010). *HiBench* started as a convenient package and extension to the Hadoop examples but has evolved into a multi-framework and custom benchmarking suite.

- **TeraSort** sorts 1TB of data generated by the TeraGen program distributed with Hadoop. TeraSort is widely used as a reference in research papers as well as in BigData competitions. TeraSort is I/O and CPU intensive.
- **Wordcount** counts the number of word occurrences in large text files. It is distributed with Hadoop and used in many MapReduce learning books. It is CPU bound.
- **Sort** uses the MapReduce framework to sort the input directory into the output

directory, being predominately I/O and shuffle intensive.

- **DFSIO** (or Enhanced DFSIO in HiBench) is an I/O-intensive benchmark to measure throughput in HDFS using MapReduce. It features separate read and write benchmarks.
- **Pagerank**, an implementation of Google’s web PageRanking algorithm. It crawls Wikipedia sample pages.

Additional benchmarks included in HiBench:

- **Bayes** Bayesian Machine Learning classification using the Mahout library. The input of this benchmark is extracted from a subset of the Wikipedia dump.
- **K-means** Mahout’s implementation of the k-means algorithm for knowledge discovery and data mining.
- **HiveBench** the OLAP-style Join and Aggregation queries are adapted from the CALDA benchmark (Pavlo et al. 2009). HiveBench has the goal to test the Hive SQL performance.

M

SparkBench

SparkBench (Li et al. 2015), developed by IBM, is a comprehensive Spark-specific benchmarking suite. The purpose of SparkBench is to analyze tradeoffs between different configurations in Spark and to guide system tuning. It is composed of over ten workloads in four categories including machine learning, graph processing, streaming, and SQL queries. SparkBench reports two metrics: *job execution time* (seconds) and *data process rate* (MB/second).

Database

Besides hardware and software testing, BigData benchmarking is heavily influenced by data processing and databases in general. Moreover, currently it is sometimes difficult to differentiate between a BigData system such as Spark with its SQL library and a massively parallel processing (MPP) database. Over time, what previously were considered functional (Chen et al. 2012) or even application-level benchmarks such as database benchmarks such as the *DebitCredit* (Anon et al. 1985) and the *Wisconsin* benchmark (DeWitt

and Levine 2008; Chen et al. 2012); by extracting specific queries, they can also be considered microbenchmarks. An early example of this fusion is the *CALDA* benchmark, a simple benchmark used initially to compare Hadoop to a distributed database. Over time, CALDA (and its variants) became the de facto benchmark for the early SQL-on-Hadoop (Poggi et al. 2016) systems such as Hive and Spark, with the later AMPLab (AMPLab 2013) adaptations of CALDA.

CALDA – Pavlo’s Benchmark and Adaptations

Pavlo’s benchmark (Pavlo et al. 2009; Stonebraker et al. 2010) consists of five tasks defined as SQL query testing scans, joins, aggregations, and a user-defined function (UDF). The benchmark was developed to specifically compare the capabilities of Hadoop with those of commercial parallel relational database management systems (RDBMS) but was used as a base to also compare newer emerging frameworks such as Hive and Spark.

AMP Lab BigData Benchmark extended CALDA to measure the analytical capabilities of BigData warehousing solutions in general. The hosted benchmark results currently provide quantitative and qualitative comparisons of five data warehouse systems: RedShift, Hive, Stinger/Tez, Shark, and Impala. It supports different data sizes to scale also in cluster size.

YCSB

The Yahoo! Cloud Serving Benchmark (YCSB) (Cooper et al. 2010; Patil et al. 2011) is a set of benchmarks for performance evaluations of key/value pair and cloud data-serving systems. YCSB was originally designed to compare Cassandra, HBase, and PNUTS in a cloud setting to a traditional database (MySQL). Over time, YCSB has been extended to support a variety of data systems (YCSB-Web 2017) also including MongoDB and Riak and has become the de facto benchmark for key/value stores. Also, YCSB is still frequently used in technical conferences such as in Poggi and Grier (2017).

Concluding Remarks

As final words, there is a fine distinction between micro- and macro-level benchmarks. What initially was presented as a complex, application-like benchmark, over time, as its behavior is understood and technology advances, microbenchmarks are usually extracted from the application, as is the case with BigData microbenchmarks, especially in the database-like properties of the systems. Microbenchmarks today are still the first line of performance testing during development and setting up a production system. Furthermore, the benchmarking field is constantly evolving, and microbenchmarking inheriting functionality from macro-benchmarks and expanding with technology.

Definitions

Mobile Big Data represents the discipline of acquiring, processing and managing various large volume, high velocity data streams derived from heterogeneous connected mobile devices and applications in a reliable and valuable manner.

Overview

Emerging ubiquitous mobile services and applications have unveiled the Mobile Big Data era in which the large volumes of data derived from mobile Internet traffics become valuable sources to support various personal and public services such as personal recommendation services, spatiotemporal event detection, social behavior analytics, network resource planning, and many more. While data scientists are aware of the value of Mobile Big Data, they also need to understand the challenges involved. In general, Mobile Big Data derives from different sources, including the mobile application services, the network services, and the mobile devices themselves. The heterogeneous data sources and the data acquisition paths can influence the quality of data and can further influence the overall performance of the big data services. In order to address the major research trends, this chapter provides a state-of-the-art discussion of concept, management technology, and challenges in Mobile Big Data.

Introduction

The increasing Internet-based mobile services and applications have extensively influenced the sources of data traffic in the global Internet. Today, a large amount of Internet data transmission comes from mobile devices for accessing Web contents, file transmissions with cloud storages, participating in online societies, and so forth. Ericsson Research (Ericsson 2017) forecasts that global mobile broadband subscriptions will reach 8.3 billion in the year 2022 and 6.8 billion of these subscriptions derive from smartphones. Further, Cisco forecasts by the year 2021, global mobile data traffic will reach 49 exabytes, and the annual mobile data traffic will exceed half a zettabyte (Cisco 2017). Additionally at the same year, 50% of connected devices in global level will be smartphones (including phablets) (Cisco 2017). Explicitly, this phenomenon has indicated the potential of mobile data and motivated the discipline of *Mobile Big Data*.

Mobile Big Data has three characteristics – spatiotemporal distribution, data aggregation properties, and social correlations (Zhang et al. 2016a) – which grant Mobile Big Data unique features to support extensive services for human society, including personal services and public services. In general, information systems utilize Mobile Big Data for various enhancements such as user-centric recommendations, predicting activities in order to provide proactive services, providing context-aware services based on environmental factors (Cheng et al. 2017), or improving the performance and quality of mobile e-healthcare (Wang et al. 2016). Further, Mobile Big Data also help public service in domains of networking (Zhang et al. 2016a), transportation (Algizawy et al. 2017), and urban living (Zhang et al. 2016b). For instance, by analyzing Mobile Big Data, one is capable to identify the crowd density and the common behaviors of residents in a specific period of time and location.

Similar to the general big data research domain, Mobile Big Data involves six fundamental challenges – *volume*, *velocity*, *variety*, *variability*, *veracity*, and *value*. To enumerate, *volume*

represents the most common descriptor of Big Data, due to the fact that the data is growing in a continuous manner with each day and beyond our capabilities of handling it (Jin et al. 2015); *velocity* involves receiving data streams and the challenge of managing them in real time; *variety* reflects the diversity of the nature of data and its forms; *variability* is related to the inconsistencies and uncertainties of incoming data stream; *veracity* property involves the correctness and authenticity of the data collected; and the *value* reflects the huge value behind Mobile Big Data and its promising market potential.

In order to address the challenges involved in the “6 Vs” mentioned above, system developers need to understand the fundamental concept of Mobile Big Data, where the data comes from, and how their systems manage the data in terms of data acquisition and processing. Accordingly, this chapter covers the foundations of Mobile Big Data, state of the art in management, and open challenges.

This chapter is organized as follows. Section “[The Origins of Mobile Big Data](#)” provides the fundamental concept of Mobile Big Data. Section “[Management of Mobile Big Data](#)” discusses the management technologies of Mobile Big Data. Afterward, we discuss the open challenges of Mobile Big Data in section “[Road Map: Challenges and Future Prospectives](#)”. This chapter is concluded in section “[Conclusion](#)”.

M

The Origins of Mobile Big Data

The staggering growth in the use of mobile devices and their capabilities is driving the production and consumption of Mobile Big Data in many different ways. With all the advancements in sensor technology, mobile devices are loaded with many embedded sensors, such as GPS, accelerometer, gyroscope, and magnetic field. Furthermore, mobile devices have the ability to manage external sensors and interact with or collect data from them. As a result, people and devices are generating large amounts of data related to their interactions with different devices

via the use of telecommunication services and mobile applications or by getting connected to Wi-Fi spots (Cheng et al. 2017). In general, the sources of Mobile Big Data can be resumed into four main categories: (a) application services, (b) mobile devices, (c) telecommunication services, and (d) Wi-Fi access points.

Data from Mobile Application Services

A considerable amount of work has been done, and projects are carried out with the aim of gathering data from mobile application services for research purposes. We can distinguish between two sources of data: internal sensors of a mobile device and data related to the use of mobile applications. For example, the project Mobile Millennium, carried out by the University of California, Berkeley (2008–2010), demonstrated the use of GPS-enabled mobile devices in estimating road traffic status and transit trip planning (Herring et al. 2010). This type of data can also be utilized to understand the end user behavior and its personality as shown in Chittaranjan et al. (2013), where the authors built up a personality profile based on the data collected from the internal sensors and interactions of the end user with the mobile application. The application and the use of this type of data can go beyond our imagination. For example, there are many innovative applications based on this type of data for developing smart transportation (Astarita et al. 2016), urban planning, mapping geographic information, etc.

Data from Mobile Devices

Mobile devices can also collect data from external sensors, due to the technological advancement of wireless devices as illustrated in El Khaddar et al. (2012), where the authors

present emerging wireless technologies for an e-health application. Most of the applications in e-health are focusing on the use of external sensors in collecting or processing data using mobile devices. For example, in Bellairs et al. (2016) the authors demonstrated the capability of transforming a mobile device into a mobile microplate reader by using an external sensor and a mobile application. It is clear that external sensors linked to mobile devices can generate interesting and large amounts of data which is applied in many interdisciplinary research activities, such as personalized medicine (Kwon et al. 2016), Internet of Things (Rathore et al. 2016), etc.

Data from Telecommunication Services

Considerable amount of data is also generated through the interactions between mobile devices and mobile networks. The most frequently used data in research and industrial applications are the call detail records (CDR) and the visitor location registry (VLR). CDR data is a set of information about telecom transactions that operator uses to generate customer billing. The collected records contain the following information (Table 1).

VLR data is a real-time stream data of all the technical logs and events generated by several base station controllers (BSC) in the mobile network. These technical logs are very dense data and contain information such as handover, cell subscribe, cell unsubscribe, packet data, etc. Mobile data has opened new doors for analyzing human mobility from all its aspects and angles. From this perspective, many investigations are done using mobile data in estimating tourists movement and constructing their daily trajectory with a focus on meaningful locations (Sikder et al. 2016). Another example is the use of

Mobile Big Data: Foundations, State of the Art, and Future Directions, Table 1

Example of CDR's data attributes

Attributes	Description
IMSI	International mobile subscriber identity
IMEI	International mobile equipment identity
CellID	The id of the transmitter providing the coverage
Timestamp	The registered time when the event occurred
Event	This is the type of event that triggered the registration of the record such as call, sms, browsing, etc

CDR data for forecasting mobile users movement within the mobile network (Hadachi et al. 2014) and extracting their exact location (Lind et al. 2017a). The idea behind all this analysis is to commence with building a continuous model for describing mobile users mobility patterns, social interactions (Lind et al. 2017b), and daily activities for the purpose of real-time target marketing and for enhancing the mobile users experience within the mobile operator network.

Data from Wi-Fi Access Points

Wi-Fi access points can also be sources of Mobile Big Data. This type of data contains information about devices interactions with Wi-Fi spots, such as fingerprints, signal strength, MAC addresses, etc. The applications developed behind this data are mainly focused on indoor localization and tracking. Commonly, Wi-Fi data can be used for localization in indoor environments (Cheng et al. 2005). In addition, this data can also be used for refining the accuracy of localization in the mobile network (Zandbergen 2009) and in orientation and navigation for emergency evacuation from buildings (Rueppel and Stuebbe 2008).

Management of Mobile Big Data

Mobile Big Data management involves two basic phases – data acquisition and data processing. In general, the data acquisition phase describes where the mobile device delivers its data and where the system stores the data. Further, the data processing phase illustrates where the system executes the data processing activities.

Data Acquisition

Global Centralized

Common mobile information systems collect data from mobile nodes to their global central data center and then provide the processed data to their requesters after the systems complete the data processing. Essentially, collecting data from mobile nodes involves a number of technologies, such as request/response-based approach using HTTP; Internet Engineering Task Force (IETF)

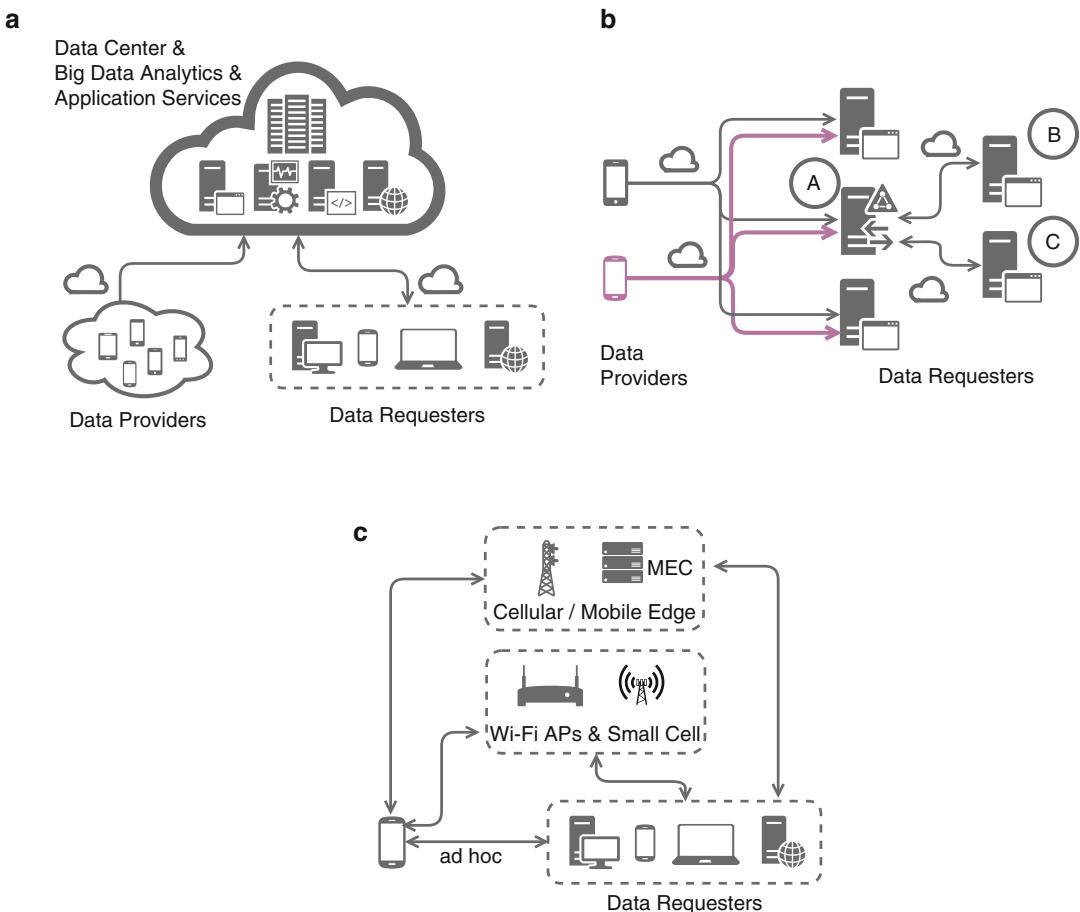

RFC 7252, Constrained Application Protocol (CoAP), TCP, or UDP; and publish-subscribe-based approach using Extensible Messaging and Presence Protocol (XMPP), Advanced Message Queuing Protocol (AMQP; ISO/IEC 19464), or Message Queue Telemetry Transport (MQTT; ISO/IEC PRF 20922). Alternatively, numerous industrial solutions are available, such as open-sourced global-based AllSeen Alliance, AllJoyn framework, and Open Connectivity Foundation (OCF), IoTivity. Centralized data collection is an ideal model for providing global big data services since the data is collected at a single point; with corresponding APIs, third-party service providers can easily request for the data they need. For example in Fig. 1a, data requesters such as application end users or third-party Web service providers may subscribe to the mobile data via the global big data analytics servers.

Global Peer to Peer

In many real-world scenarios, peer-to-peer (P2P) networking provides better efficiency and is more reliable than the centralized model. For example, considering the sensitiveness and the privacy issues, mobile healthcare data is commonly not available to a global repository which is accessible to third parties, and the corresponding mobile device commonly delivers its data directly to a specific receiver (e.g., a hospital data server) in a P2P manner. For another example, recent Internet of Things (IoT) systems also utilize P2P networking based on Blockchain, which is the core technology of the popular Bitcoin system (Nakamoto 2008). Explicitly, P2P-based data acquisition is becoming one of the major models in the Mobile Big Data field. Aside from Blockchain, general technologies to enable P2P-based data acquisition include JXTA technology, Universal Plug and Play (UPnP), BitTorrent protocol, and so forth.

Edge Networks

The edge network-based data acquisition approaches aim to improve the efficiency of data delivery in terms of reducing the data transmission latency and the burden of the global central servers. For example, mobile ad hoc and

Mobile Big Data: Foundations, State of the Art, and Future Directions, Fig. 1 Mobile Big Data acquisition approaches. (a) Data is managed by global data center; (b) mobile nodes have installed multiple service clients to deliver data to different nodes in P2P manner; the

P2P network also utilize data broker nodes to forward data, e.g., node A brokers data to node B and C; (c) mobile devices deliver data to nodes in three types of edge networks

mesh network in social or wireless sensing applications focus on routing the messages among the devices in physical proximity when they are encountered. Further, the mobile and wireless Internet gateway nodes such as Wi-Fi access points and their associated networks, small cell nodes, and cellular base stations are capable of providing Internet-less data delivering. Below, we discuss the three common edge network-based data acquisition models.

Proximity-Based Mobile Peer to Peer

Mobile devices such as smartphones are commonly integrated with Wi-Fi and Bluetooth tech-

nologies. These technologies allow devices to communicate with one another when they encounter in a physical proximity. Essentially, a small group of devices forming a proximity-based mobile P2P (PMP2P) network does not generate much data. However, a recent technology is known as Mobile Mesh Network (MMNET) (Shen et al. 2014) utilizing hybrid connectivity of mobile devices to extend the topology of mobile ad hoc network. It indicates that a peer within the MMNET may receive a large amount of data while it is moving.

Besides the ongoing industrial standard – IEEE 802.11s, which is a Wireless LAN

standard for mesh networking – different parties have introduced their MMNET frameworks. These frameworks include Serval Project (servalproject.org); Open Garden, FireChat (opengarden.com); HypeLabs (hypelabs.io); etc.

Wireless Local Area Network

Today, many areas of the world contain Wi-Fi access point (AP) networks with network virtualization technology, such as Cisco IOS platform, in which an area that consists of a large number of Wi-Fi AP is forming a single network. For example, the public Wi-Fi AP in urban areas, university campuses, business buildings, and industrial plants can form large-scope wireless local area networks (WLANs). Certainly, such networks generate a large amount of data continuously from the connected mobile devices. With the network virtualization technologies, data requesters within the WLAN can acquire data from mobile devices in high speed. Further, with the standards such as Internet Engineering Task Force (IETF) multicast DNS (RFC 6762) and DNS-Based Service Discovery (RFC 6763), which has been widely applied in today's dynamic service discovery within WLAN, nodes can discover and communicate with one another without maintaining static IP addresses.

Besides the Wi-Fi AP-based WLAN, the small cell facilities, which are used in telecommunication to assist the larger cellular network, can also apply network virtualization technologies such as European Telecommunications Standards Institute (ETSI) Network Functions Visualization (NFV) (Mijumbi et al. 2016) to support high-speed data acquisition within the edge networks.

Mobile Edge

The mobile edge refers to the coverage of telecommunication providers' base transceiver stations (BTS). Recent research efforts in mobile computing utilize the BTS colocated computational resources to improve the data delivery performance (Guo et al. 2017). For example, Internet service providers can improve multimedia stream data delivery to mobile devices by utilizing BTS-associated servers. Further, applying NFV together with

ETSI - Mobile/Multi-access Edge Computing (MEC) standard, which enables BTS servers to provide virtual machines for computing and networking, many mobile ubiquitous services and applications can enhance the speed of their data transmission by programming customised routing paths on MEC servers. Compared to PMP2P and WLAN, mobile edge provides wider coverage. Hence it is more feasible for city-wide or intercity-based Mobile Big Data acquisition. WLAN is suitable for inner-city-based data acquisition, and PMP2P is useful in an infrastructure-less environment such as an area after natural disaster or crisis (Gardner-Stephen et al. 2013).

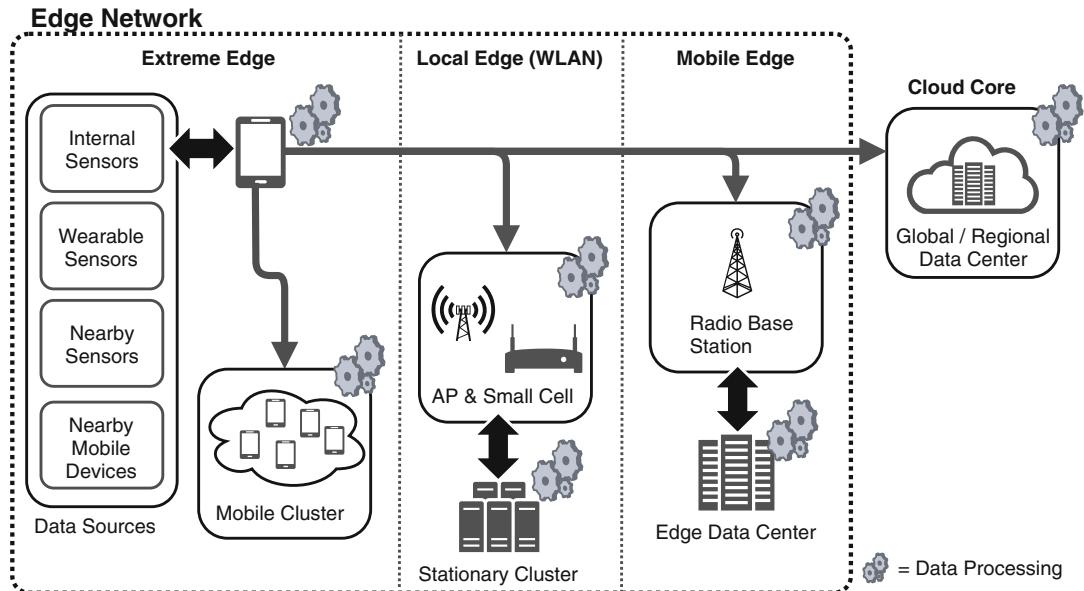

Data Processing

Recently, Mobile Big Data processing has two trends – the common global cloud-based processing and the edge-based data processing (Fig. 2).

Cloud-Centric Data Processing

As the amount of mobile data collected increased to the orders of tera- and petabytes, processing this huge data to extract relevant information became a complicated task. The first solutions looked at collecting the data at the cloud, as it provided unlimited data storage capabilities and processing power. On the cloud, distributed data processing approaches such as *MapReduce* were applied, producing relevant results. Earliest of these mobile data processing tasks included sensor data analytics and mining relevant to different domains such as healthcare, location-based services, etc. (Paniagua et al. 2012). Most of these tasks were batch-oriented and were ideal for cloud-centric data processing.

However, the next generation of mobile applications mainly dealt with streaming data and expected sub-second responses. The scenarios included processing stream data from multiple mobiles or data derived continuously from different regions, to generate novel results (Yang et al. 2013). To cope with these, streaming data analytic frameworks such as *Apache Flink*, *Apache Spark Streaming*, and *Apache Storm* have emerged. However, these solutions have introduced significant network latencies and

Mobile Big Data: Foundations, State of the Art, and Future Directions, Fig. 2 Data processing at the edge network comparing to cloud core. In order to achieve

performance needs, Mobile Big Data process can be distributed in different parts of edge network depending on the requirements of applications

failed to meet the application deadline demands. This has led to the edge analytics, where partial data processing such as error detection, filtering, and data consolidation have already happened at the edge devices. Further data analytic tasks requiring huge computational power still remained cloud-centric.

Edge-Based Data Processing

Recently, the needs of high-speed data processing for Internet of Things (IoT) systems, cyber-physical systems (CPS), and various mobile ubiquitous systems have motivated the fog computing architectures, which distribute the data processing tasks to computational resources located at different parts of edge networks (Chang et al. 2017). Similarly, edge analytics, which originally illustrate the importances of analyzing the big data derived from devices at the edge networks, has now involved distributing the edge analytic tasks to certain devices at the edge network in order to enhance the overall performance (IBM 2017). Further, edge-based data processing is also a major research trend in optimizing the performance of mobile cloud computing (Chen et al.

2016). To enumerate the recent models of edge-based data processing, we classified them in three types – extreme edge (i.e., PMP2P), local edge (i.e., WLAN), and mobile edge – corresponding to the three edge network types described in the previous section.

Extreme Edge

Extreme edge represents the devices located within WLAN or mobile edge (excluding the gateways), and they are capable of forming PMP2P. In mobile distributed computing domain, the devices of extreme edge are not only collecting or generating data, but they can also participate in data processing. Generally, depending on the environment and available resources, a system may distribute data processing in extreme edge network in two different models.

- **Sole Distribution.** Data stream, in cases that require rapid response, may push partial process to the mobile devices. Partitioning tasks to mobile devices, which is also the data source, is a common approach in mobile

cloud computing (Chang et al. 2016) and fog computing (Liyanage et al. 2016). Notably, dynamically allocating data process tasks among cloud and mobile nodes can improve the overall performance. For example, in a mobile sensing scenario where the mobile device is continuously collecting sensory data from its surrounding environment, the cloud-centric system can assign partial processes on the mobile device. Hence, it enables the corresponding mobile application to generate rapid results to the device user. Moreover, since the system distributes partial processes to mobile nodes, it reduces the burden of the central cloud server toward improving the throughput of the central server to serve more mobile nodes.

- **Group Distribution.** Today, in many crowded areas, people are surrounded with various mobile devices that have powerful computational, sensing, and storage capabilities. These devices are not only capable of providing data, they are also capable of forming cluster computing environments in an ad hoc manner. Specifically, architectures such as opportunistic computing (Conti et al. 2010), mobile edge cloud, or mobile ad hoc cloud computing (Chang et al. 2016) intend to introduce adaptive methods to enable Internet-less Mobile Big Data processing using proximity-based mobile ad hoc network resources. Although such an architecture faces challenges in incentive, reliability, and many mobility-related issues, it still shows a promising solution for situations that do not have accessibility to the Internet-based services. For example, the natural disaster may cause the network infrastructure corrupted. In such situation, the ad hoc-based network becomes a solution to swiftly establish an edge-based computing environment to collect and to process the data from all the participated mobile nodes.

Local Edge

The emerging fog computing architecture introduced by Cisco's research (Bonomi et al. 2012) was utilizing Internet gateway devices

(e.g., Cisco IR829 Industrial Integrated Router) to provide the similar model as utility cloud services in which the gateway devices provide virtualization technologies that allow system administrators to deploy software on them dynamically. Here, local edge represents Wi-Fi AP networks and small cells that cover various fog-compliant gateway devices. As mentioned previously, WLAN environments are commonly involved in large data transmission. Specifically, in IoT era, much data transmission in WLAN is derived from the systems that need to deliver the data to cloud for processing. Therefore, distributing such processes to local edge can enhance the overall performance and efficiency.

Local edge-based fog computing covers broad range of devices in WLAN. Essentially, the earlier proposal (Bonomi et al. 2012) illustrates the fog servers as the Internet routers or switches; recent research projects also experimented the feasibility of moving the data processes to the secondary gateway devices such as the gateway devices used to connect the non-Internet protocol (IP) network IoT devices (e.g., Bluetooth, IEEE 802.15.4, or Z-Wave devices) to IP network. Although these devices may not have ideal processing power and they do not involve large data transmissions, recent research project (Hajji and Tso 2016) has shown that adaptively utilizing these constraint gateway devices can still provide significant enhancement for the overall data processing. For example, an industrial plant may contain a large number of constraint gateway devices. If the system establishes a cluster computing environment using the constraint gateway devices, they can still provide a feasible computational resource to the mobile application nodes within the WLAN.

M

Mobile Edge

As mentioned previously, mobile edge denotes the BTS-based cellular mobile network environments. Since a large volume of mobile data derives from mobile Internet, the BTS networks are explicitly involving in large data transmission. Therefore, it motivates the MEC architecture in which the BTS nodes can integrate with virtualization technologies to provide edge-based utility

cloud services for computing and customized networking purposes to IoT/CPS and mobile ubiquitous applications.

MEC servers provide similar mechanism as fog servers in local edge. The major differences are the availability and coverage. Fundamentally, MEC servers have higher availability than local edge because MEC servers are within the cellular network infrastructure. On the other hand, local edge networks belong to specific parties such as university campus who have limited infrastructures.

Road Map: Challenges and Future Prospectives

Today, mobile data is not only large and massive, but it is also composed of various data types, including stream data and more. For these reasons, the challenges and future perspectives of innovation in the field of Mobile Big Data reside in its characteristics.

Volume

One of the characteristics of Mobile Big Data is the large volume of data. Till now, the increase of amount of data is managed by adding more storage (physical or online). For example, CDR data is in continuous increase, and there are many analytic applications performed based on them. Nevertheless, some types of information or attributes can be obsolete or unnecessary with proportion to their existence in time or to the analytic inputs. Therefore, by filtering or introducing some reduction methods such as preprocessing, graph theory, compression, redundancy elimination, and data mining, we can reduce some space (ur Rehman et al. 2016). However, we need to take into account the decompression overheads introduced to improve the efficiency. After all the volume still is not the most challenging aspect in Mobile Big Data, it is more on variety and velocity.

Velocity

The speed of executing and exchanging information is the most important factor in any ap-

plication. Since, the real-time information can make a huge difference in decision-making, it can affect the existence of markets, companies, industries, etc. Hence, the straightforward solution is to increase the central server capabilities by introducing load balancing techniques and optimization in defining a threshold to balance the load among data centers based on heterogeneity of data centers and also by minimizing the remote communication among them in order to improve the network infrastructure (Samadi and Zbakh 2017). An alternate solution is to reduce the data stream by applying data preprocessing. For example, in Neumeyer et al. (2010), the authors point to the challenges and the need for sophisticated approaches to apply real-time processing. From this perspective, the question is at which level we shall process the data, is it at the device level, the network level, or the server level. In some articles it was suggested to handle the streams at their first arrival and apply incremental techniques (Krempl et al. 2014) or by applying heterogeneity processing on the data (ur Rehman et al. 2017).

Variety

Mobile Big Data can take many forms such as messages, logs, records, calls, signatures, signals, images, streams, etc. In addition, the strong involvement and role of mobile devices in our lives make them a source of enormous streams of data associated to peoples activities, relationships, and locations. Hence, the diversity of types of data are collected today (structured, semi-structured, unstructured). As a result, the challenges can be resumed to two main aspects: maintaining the quality of the data providers and standardizing the data format. The quality check of the data can be maintained by introducing adaptive middleware (Schantz et al. 2003) that can help in preserving the quality of service and the data via appropriate resource management binding and scheduling services and policies. Another solution is by integrating data quality lifecycle into the architecture design as illustrated in Scannapieco et al. (2004). Concerning the challenge of standardizing the format of data, it can be inspired from other concepts such as IoT-Lite

(Bermudez-Edo et al. 2017) by pioneering a data specification for data format.

Variability

The variability is about the stream data coming from different sources in different speeds and qualities. Hence, we have to face the challenge of handling the elasticity of resources in the need to connect, match, clean, and transform (Gandomi and Haider 2015). When it is about quality of the software data, it is manageable and can be controlled; however, when it is about the devices, it can be very heterogeneous since the user's behavior or the environment can easily influence the data (ur Rehman et al. 2017).

Veracity

The Mobile Big Data can contain data with inherited unreliability. The best example is social media (Zhang et al. 2016a), where we have to deal with emotional and opinion information, which can be very uncertain but important at the same time. This complexity is addressed simply by researching the use of analytic techniques (Gandomi and Haider 2015) in developing management of mining and detecting unreliable data and also by increasing security levels. Besides, Mobile Big Data involves the notion of trust in the interactions and sharing services or information such as mobile banking data (Lee and Chung 2009).

Value

The value of data depends on the outcome of data analytics on the data. Since, by using analytics methods on it, we get an idea about what the data can offer in terms of knowledge and insights, which leads to defining its utility and usefulness for making profits (LaValle et al. 2011). Moreover, the mobile data has a potential to generate considerable revenues using IoT infrastructure sensing as a service to solve many problems related to smart city concept, such as fleet management, transportation problems, healthcare, and public administration (Perera et al. 2014).

Conclusion

Emerging ubiquitous mobile services and applications have unveiled the Mobile Big Data era in which large volumes of data are derived from mobile Internet traffic. This data is ideal in supporting various personal and public services such as personal recommendation services, spatiotemporal event detection, social behavior analytics, network resource planning, and many more. This chapter discussed in detail the various sources that produced these large volumes of data and how the mobile data is managed in terms of data acquisition and processing. For data processing, approaches such as cloud-centric data processing and edge-based data processing are discussed in detail. While the state of the art of the Mobile Big Data is interesting and evolving, it still leaves significant scope for future work, which the chapter tried to address in terms of the six major characteristics of the big data – volume, velocity, variety, variability, veracity, and value.

Definitions

Multidimensional process analytics (MPA) augments business process analytics with the multidimensional perspective on the analysis data. The latter is typically event data that is produced during the execution of process instances. Classically, business process analytics “*is the family of methods and tools that can be applied to these events streams in order to support decision-making in organizations*” (zur Muehlen and Shapiro 2015). On top of just looking at the event streams, MPA enables their multidimensional representation and based on this the in-depth analysis of different process perspectives, e.g., activities and resources, as well as the comparison between different process execution variants or versions.

Overview

Generally, business process analytics (BPA) is concerned with the following tasks (zur Muehlen and Shapiro 2015):

- *Process Controlling* aims at the ex post analysis of event data stored from process instance executions.
- *Business Process Activity Monitoring* aims at monitoring process executions online, i.e., during execution, by providing information on, for example, critical events. Such information is presented in dashboards or by notifications such as alerts.
- *Process Intelligence* aims at finding unknown information from either real-world process event data or simulation data. Results can be suggestions for process optimization.

In lifting BPA to a multidimensional level, two main lines of existing work can be identified: (a) approaches routing in data warehousing (\mapsto *Process Warehousing (PWH)*) and (b) approaches routing in process mining/analysis (\mapsto *Multidimensional Process Mining (MPM)*). This is somehow obvious as BPA resides at the intersec-

tion of both worlds and a common challenge to both directions is the multidimensional modeling of process event data. However, differences in the analysis questions for PWH and MPM can be identified. Where PWH approaches reflect on the analysis of process data for different perspectives, MPM approaches do (also) consider the comparison of different process versions and variants, i.e., “*MPM does not discover a process model from a single event log, but multiple models from a set of sublogs*” (Vogelgesang et al. 2016a).

In summary, the key task of MPA is to model event data in a multidimensional fashion employing models and techniques from data warehousing in order to employ analysis techniques such as online analytical processing (OLAP) and data/process mining.

Key Research Findings

The first key task of MPA is the multidimensional modeling of process data. As common for the multidimensional analysis of data, e.g., in data warehouses (DWH), OLAP operations can then be applied to the multidimensional process database. The definition of the OLAP operations (second key task) depends then on the underlying data model. As the results of the multidimensional analysis can be complex, their adequate presentation constitutes the third key task. These three key tasks will be detailed in the following.

Multidimensional Data and Event Modeling

As motivated in section “[Overview](#),” there are two lines of data modeling, i.e., PWH inspired from data warehousing and MPM based on process logs. Figure 1a illustrates the basic idea of data modeling in PWH (top) and MPM (bottom) using a star schema. Star schemas along with snowflake schemas are the commonly used data models for relational data modeling in DWH (Chaudhuri and Dayal 1997). Roughly speaking, for both schemas, the analysis data is modeled as facts and stored in so-called fact tables. The facts can be analyzed along different dimensions that are represented at different granularity levels.

A commonly used example is dimension time with granularity levels day, month, and year.

For PWH, facts refer to performance measures of process elements, e.g., the cost of the process execution. Dimensions represent process perspectives that might influence the facts, most prominently time, resources, and behavior data.

Data modeling in MPM assumes a relation between cases (i.e., process executions) possessing attributes and being recorded on the basis of events. The attributes can be exploited as dimensions, for example, the age of a patient being classified into the age in years and into an age group at a more coarse-grained level. Also the events can be analyzed along dimensions, for example, the activity type. van der Aalst (2013) provides a multidimensional process cube; typical dimensions comprise time, case type, and event class. Figure 1b depicts an example of MPM data model (cf. Vogelgesang and Appelrath 2015).

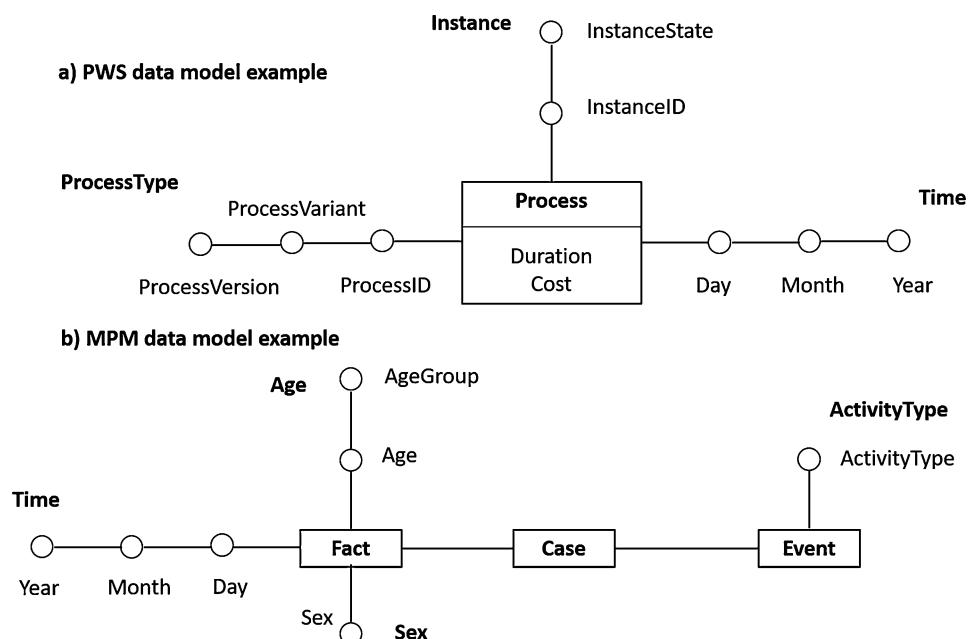

The differences in data modeling also lead to a difference in what the cells of the cubes for PWH and MPM contain. For PWH, the cells contain the numeric values for the facts such as cost,

duration, etc. For MPM the cells of the process cubes contain logs and the associated process models, respectively. In other words, from a log with a corresponding model, the combination of dimensions leads to a fragmentation of the logs into the cells. The example of a Dutch municipality in van der Aalst (2013) shows a sub log for a cell for a silver costumer (case type) for sales (event class) and for the year 2012.

Definition of OLAP Operations

Typically, OLAP operations operate along or across the dimensions of a data cube, for example, drilling down into the lower granularity or rolling up toward a higher granularity. Slicing and dicing enable the projection on dimensions and/or the selection of ranges of different dimensions.

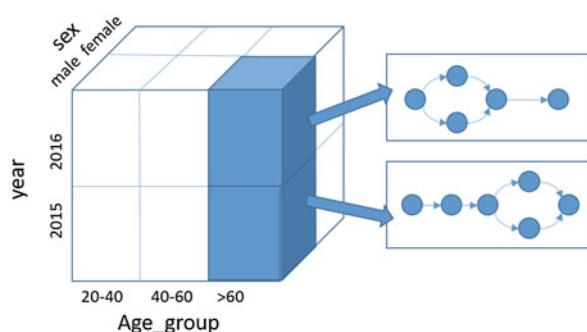

For PWH, in principle, the traditional OLAP operations can be applied as the logic of the cells and dimensions of PWH corresponds to the logic of DWH data cubes. Specifically, aggregation operations such as summing up or calculating the average over facts is possible if the facts refer to numeric facts related to business process

Multidimensional Process Analytics, Fig. 1 (a) Multidimensional data modeling in PWH, cf. Grossmann and Rinderle-Ma (2015) and (b) in MPM, cf. Vogelgesang and Appelrath (2015)

a) PWH view

Avg_duration		Chemo	Diabetes	AVG
2015	Running	8	10	9
	Completed	7	9	8
	AVG	7,5	9,5	8,5
2016	Running	8	9	8,5
	Completed	6	10	8
	AVG	7	9,5	8,25
AVG		7,25	9,5	8,375

b) MPM view

Multidimensional Process Analytics, Fig. 2 Results of applying OLAP operations on (a) PWH and (b) MPM. (The latter adapted from Cordes et al. 2014)

performance indicators, e.g., throughput. For the PWH schema in Fig. 1b, for example, one could roll up the average process duration to instance state (dimension instance) to year (dimension time) and to process versions (dimension process type). The view resulting from this roll up is depicted in Fig. 2a as a table structure. For instance, the average duration for completed instances of process-type diabetes was 9 in 2015.

Applying the OLAP operations in a traditional manner, however, is not possible for MPM as the cells of the process cubes do not contain facts as numeric values but logs and process models. Hence, a key finding in research is to define OLAP operations on logs and process models with specific challenge on finding appropriate aggregation functions (obviously, summing up logs and models is not possible).

Such OLAP operations for MPM are provided in Vogelgesang and Appelrath (2015). Here the user formulates OLAP queries which are translated into generic SQL queries that select event log attributes based on joins of the facts over the specified dimensions with filter conditions. It is also possible to apply aggregation on event basis based on the time stamps of the events.

Similarly, van der Aalst (2013) introduces the basis for OLAP operations on process cubes based on splitting or merging the logs in the cells. As a rule of thumb “[t]he case type and time window dimensions [...] are often used to merge or split a log vertically. The event class dimension is often used to merge or split a log horizontally”

(van der Aalst 2013). Splitting and merging serve as basis for defining OLAP operations roll up and drill down as well as slice and dice.

The results of applying OLAP operations are logs that can be mined for process models using existing process mining techniques (cf. van der Aalst 2016). Figure 2b shows the result of rolling up the process cube based on the schema in Fig. 1b. The highlighted cells contain the log data and the resulting models of the treatment processes for male patients beyond 60 for the years 2015 and 2016.

Visualization of Results

Figure 2 already indicates the different ways the results of multidimensional process analysis can be presented to analysts. While for PWH the results of OLAP operations can be conveyed based on, e.g., pivot tables or dashboards, the results of MPM are process models that can be displayed in a graphical way as typical for process mining techniques (e.g., as Petri nets or heuristic nets). What is more difficult is the presentation of differences between cells in the process cubes. However, such differences are usually of high interest to analysts to, for example, compare developments over time. For example, one would like to compare the treatment process executions for male patients beyond 60 years for 2016 with the corresponding model for 2015. Have there been any differences in how this patient group was treated? Contrary to comparing the values of

two cells as for PWH, comparing process models for differences is more difficult. There are general approaches for calculating differences between process models, e.g., Kriglstein et al. (2013), and approaches specific for comparing the results of MPM, cf. Cordes et al. (2014). In any case, the differences between the models are displayed using a difference graph that holds one of the models as basic version and depicts the difference to the other model using colors.

Examples of Application

Several applications of MPM to real-world event logs from different domains can be found. A selection comprises

Health Care

Hospital data was analyzed with PMCube (Vogelgesang and Appelrath 2015): several cubes with different combinations of dimensions were formed based on OLAP operations, for example, medical department and urgency or age and sex. In Vogelgesang et al. (2016a), the approach was combined with change logs (cf. e.g., Kaes and Rinderle-Ma 2015) in order to explore exceptional cases and situations where several of those were found, e.g., the “termination of anesthesia was initiated before the clearance of the surgeon” (Vogelgesang et al. 2016a).

Higher Education

Two case studies on MPM in higher education are available, i.e., applying PMCube on the HEP (higher education processes) data set (Vogelgesang et al. 2016a) and the Process Cubes approach on video lecture data from Eindhoven University of Technology (Bolt et al. 2015). The first case study data shows, for example, differences in conducting course processes when compared two 2 different years. In later courses, less exercises but more tutorials were provided. The second case study aims at defining analytic workflows for generating reports and statements about the lectures such as that student performance increases with watching the video. The

created reports and statements were evaluated with domain experts, i.e., lecturers.

Another case study on process data from Dutch Municipalities can be found in van der Aalst (2013).

Future Directions for Research

Although the approaches for PWH date back to the late 1990s, the approaches on MPM have just recently been developed, in the course of the advent and development of process mining. So the discipline of multidimensional process analytics still bears many open research questions which are shortly discussed in the following (based on van der Aalst (2013) and Vogelgesang et al. 2016a). The challenges hold specifically for MPM, and their coverage by existing literature is discussed in Vogelgesang et al. (2016a).

M

Performance

In general, OLAP operations on multidimensional data can become – depending on the data model – quite complex, e.g., if many join operations are required. This observation is also valid for OLAP operations on MPM data, where the operations might become even more complex as the underlying data, event logs, is more complex as for DWH and PWH data. Hence, the performance of conducting the OLAP operations plays a crucial role. OLAP query optimization in MPM is addressed by PMCube (Vogelgesang and Appelrath 2015). PMCube transforms OLAP queries into SQL patterns and hence pushes aggregation and filtering steps to the database. The subsequent comparison of several prototypical implementations for MPM on datasets of different complexity PMCs shows the best performance. Nonetheless, research on how to run OLAP operations for MPM efficiently can be extended in several directions, e.g., by looking at techniques from DWH research such as investigating query optimization, parallel processing, and index structures and using materialized views (Chaudhuri and Dayal 1997).

Presentation of Results and Interactivity

There are some approaches on visualizing the results of comparing cells in process cubes (cf. section “[Visualization of Results](#)”). Still the question remains on how to visualize differences between a higher number of cells, i.e., several process models as most existing approaches are restricted to visualizing the differences between two models, e.g., Kriglstein et al. (2013). The other research direction is to improve the interactivity of conducting multidimensional analysis on process data which is a crucial brick in explorative analysis. Interactivity mainly refers to the interaction with analysis results, i.e., process models. This mixes in with research on process visualization and process mining where interactivity has been identified as general challenge (van der Aalst et al. 2011). So the topic splits into providing general ways of interacting with process models but has specific challenges for MPA as the underlying data is calculated in a potentially complex manner and it hence can become expensive to recalculate results. Thus there is also an intersection with the challenge on performance (cf. section “[Performance](#)”). First approaches specific to MPM have been developed. Vogelgesang et al. (2016b), for example, introduce the concept of operation stacks in order to enable undo and redo of analysis steps. Research on interactivity is nonetheless open for extended interaction with process models and interaction in the context of the comparison of cells.

Changes in Data

Due to constant changes in applications and their environments, data is likely to be changed, i.e., new data is created, deleted, or updated. In order to keep analysis results up-to-date, the changes in the data have to be considered in the MPA. This issues has been researched well in DWH, specifically treated for updating materialized views (Chaudhuri and Dayal 1997). The core question here is how to update views by propagating the updates incrementally, instead of recalculating the views. As business process is constantly subject to change as well, the problem directly translates to MPA. For PWH being logically close to DWH, existing techniques for view updates

are likely to be applicable (although no specific statements on this were found). For MPM, where the problem of data change is referred to as concept drift (van der Aalst et al. 2011), updating materialized views is more challenging as the data and the OLAP operations to build the views are already more complex. Note that changes might not only affect the data within process cells but also attributes that form the dimensions such as weather data (van der Aalst 2013).

Conclusion

This list of future research directions is not complete and might also evolve with new insights into existing challenges. MPA is a relatively new research topic with ties to the more established research areas DWH and PWH. With new developments such as huge data volumes, streaming data, and distributed analysis of data, the above mentioned challenge will aggravate, and new challenges appear.

Definitions

RDF (<https://www.w3.org/RDF/>), the Resource Description Framework, represents a main ingredient and data representation format for Linked Data and the Semantic Web. It supports a generic graph-based data model and data representation format for describing things, including their relationships with other things. RDF is designed to flexibly model schema-free information which represents data objects as *triples* in the form (S, P, O) , where S represents a subject, P represents a predicate, and O represents an object. A triple indicates a relationship between S and O captured by P . Consequently, a collection of triples can be modeled as a directed graph where the graph vertices denote subjects and

objects, while graph edges are used to denote predicates. The SPARQL (<https://www.w3.org/TR/sparql11-overview/>) query language has been recommended by the W3C as the standard language for querying RDF data. A SPARQL query Q specifies a graph pattern P which is matched against an RDF graph G . The query matching process is performed via matching the variables in P with the elements of G such that the returned graph is contained in G (pattern matching). In practice, most RDF stores can be searched using queries that are composed of *triple patterns*. A triple pattern is much like a triple, except that S , P , and O can be replaced by variables. Similar to triples, triple patterns are modeled as directed graphs.

RDF has been gaining widespread momentum and usage in different domains such as the Semantic Web, Linked Data, Open Data, social networks, digital libraries, bioinformatics, or business intelligence. As an example of this trend, a growing number of ontologies and knowledge bases storing millions to billions of facts such as DBpedia, and Wikidata are now publicly available. With increasing sizes of RDF datasets, executing complex queries on a single node has turned to be impractical especially when the node's main memory is dwarfed by the volume of the dataset. Therefore, there was a crucial need for distributed systems with a high degree of parallelism that can satisfy the performance demands of complex SPARQL queries. Several distributed RDF processing systems have been introduced where the storage

and query processing of linked data are managed on multiple nodes. In general, distributed RDF systems are characterized by larger aggregate memory sizes and higher processing capacity. On the other hand, they might incur significant intermediate data shuffling when answering complex SPARQL queries that span multiple disjoint partitions. This entry gives an overview of various techniques and systems that have been *natively* designed and implemented from scratch to efficiently query large RDF datasets in distributed environments, i.e., native distributed RDF systems.

Overview

With increasing sizes of RDF datasets, executing complex queries on a single node has turned to be impractical especially when the node's main memory is dwarfed by the volume of the dataset. Therefore, there was a crucial need for distributed systems with a high-degree of parallelism that can satisfy the performance demands of complex SPARQL queries. Several distributed RDF processing systems have been introduced where the storage and query processing of linked data is managed on multiple nodes. Such distributed RDF systems are characterized by larger aggregate memory sizes and higher processing capacity. On the other hand, they might incur significant intermediate data shuffling when answering complex SPARQL queries that span multiple disjoint partitions. In this entry we give an overview of various techniques and systems for efficiently querying large RDF datasets in distributed environments.

Key Research Findings

To build an RDF data management system, the simplest approach is using relational databases to store the data, e.g., "*statement tables*" design pattern for storing RDF statements (Sakr and Al-Naymat 2010). From first few implementations, it shows that naive ways for using relational database as a black box show several shortcomings in terms of achieving the

performance and scalability of most use cases or datasets in reality. However, later generations of this kind significantly improve performance by designing more complicated table layouts associated with tailored indexing structures or even stored functions. Along with such strategies, alternative storage structures are proposed such as index permutations, property tables, vertical partitioning, graph-based storage, and binary storage (Sakr and Al-Naymat 2010). Among them, index permutations is pretty much the same with traditional statement tables but focuses on building faster access pattern by exhaustively indexing all possible patterns. The further modifications are exploiting data distribution of RDF graphs to partition the data in favor of collocation data items that retrieved together a query. Property tables and vertical partitioning are two approaches of this kind. Moving far away from traditional relational database design, graph-based storage and binary storage provide completely different storage structures with different focuses. The graph-based systems exploit the graph structure to build data structures that favor the graph exploration queries, e.g., subgraph matching. On the other hand, binary systems exploit the fast bitwise and compact bit/byte representations to be able to fit as much data into the main memory to achieve better performance and scale a bit better to certain dataset size. The single node systems remain limited by the computational power and memory capacities of a single machine. Therefore scaling the systems vertically in terms of adding a number of processing cores and adding more memory will soon hit its upper limits. To remedy such limitations of single node processing, the distributed processing infrastructure has been exploited. With the potential of a high degree of parallelism, a distributed system can satisfy the performance demands of complex SPARQL queries on very large RDF collections. The generic parallel processing platforms have their own shortcomings which motivated several systems to build their own underlying infrastructure to serve their requirements. The main research directions in these files focus on efficient partitioning RDF graph and distributed

query execution algorithms. Partitioning large graph data collections is a very challenging task; therefore many approaches have been developed to efficiently and effectively perform this operation. Some approaches suggest to partially duplicate the data in order to execute frequent queries entirely in parallel, without transferring intermediate results between nodes.

Examples of Systems

Several systems have been designed to handle RDF data and workloads in a distributed and scalable fashion. This section presents a selection of the most well-known approaches in this field. For example, Partout (Galárraga et al. 2014) is a distributed engine that relies on a workload-aware partitioning strategy for the RDF data by allowing queries to be executed over a minimum number of machines. Partout exploits a representative query load to collect information about frequently co-occurring sub-queries and for achieving optimized data partitioning and allocation of the data to multiple nodes. The architecture of Partout consists of a coordinator node and a cluster of n hosts that store the actual data. The coordinator node is responsible for distributing the RDF data among the host nodes, designing an efficient distributed query plan for a SPARQL query and initiating query evaluation. The coordinator does not have direct access to the actual data but instead utilizes global statistics of the RDF data, generated at partitioning time, for query planning. Each of the host nodes runs a centralized triple store, RDF-3X (Neumann and Weikum 2008). Queries are issued at the coordinator, which is responsible for generating a suitable query plan for the distributed query execution. The data is located at the hosts which are hosting the data partitions. Each host executes its part of the query over its local data and sends the results to the coordinator, which finally generates the query result. The global query optimization algorithm starts with a plan optimized with respect to the selectivity of the query predicates and then applies heuristics to obtain an efficient plan for the distributed setup. Each host relies on the

RDF-3X optimizer for optimizing its local query plan.

TriAD (Triple-Asynchronous-Distributed) (Gurajada et al. 2014) uses a main-memory and shared-nothing architecture which is based on an asynchronous message passing protocol. TriAD applies a classical master-slave architecture in which the slave nodes autonomously and asynchronously exchange messages to evaluate multiple join operations in parallel. Relying on asynchronous communication allows the sibling execution paths of a query plan to be processed in a freely multi-threaded fashion and only get merged (i.e., get synchronized) when the intermediate results of the entire execution paths are joined. TriAD employs six comprehensive combinations of indexing over the RDF elements. The indexes are maintained in a distributed main-memory data structure where each index is hash-partitioned according to its join key and locally sorted in lexicographic order. Therefore, TriAD can perform efficient, distributed merge joins over the hash-partitioned permutation lists. In addition, TriAD uses join-ahead pruning using an additional RDF summary graph. The join-ahead pruning is executed at the master node, in order to prune entire partitions of triples from the *SPO* lists that cannot contribute to the results of a given SPARQL query. TriAD uses a bottom-up dynamic programming mechanism for join-order enumeration and considers the locality of the index structures at the slave nodes, the data exchange cost of the intermediate results, and the option to execute sibling paths of the query plan in a multi-threaded fashion, in order to estimate the query execution plan with the cheapest cost.

The DREAM (Distributed RDF Engine with Adaptive Query Planner and Minimal Communication) system (Hammoud et al. 2015; Hasan et al. 2016) has been designed with the aim of avoiding partitioning RDF graphs and partitions SPARQL queries only, thus attempting to combine the advantages of the centralized and distributed RDF systems. DREAM stores a dataset intact at each cluster node and employs a query planner that partitions SPARQL queries. Specifically, the query planner transforms the query into a graph; decomposes this graph into sets of

subgraphs, each with a basic two-level tree structure; and maps each set to a separate machine. Afterward, all machines process their sets of subgraphs in parallel and coordinate with each other to return the final result. No intermediate data is shuffled and only minimal control messages and metadata are exchanged. To decide upon the number of sets (which dictates the number of machines) and their constituent subgraphs (i.e., the graph plan), the query planner enumerates various possibilities and selects a plan that results in the lowest network and disk costs for the graph. This is achieved through utilizing a cost model that relies on RDF graph statistics. Using the above approach, DREAM is able to select different numbers of machines for different query types, hence, rendering it adaptive.

Shi et al. (2016) present a distributed graph-based RDF store that leverages remote direct memory access (RDMA)-based graph exploration to provide highly concurrent and low-latency queries over large datasets. Shi et al. provide an RDMA-friendly distributed key/value store that provides differentiated encoding and fine-grained partitioning of graph data to reduce RDMA transfers. To support efficient scale-out, Shi et al. follow a graph-based design by storing RDF triples as a native graph and leverage graph exploration to handle queries. Shi et al. leverage full-history pruning to avoid the cost of expensive final join operations. Their system combines data migration for low latency and execution distribution for high throughput by leveraging the low latency and high throughput of one-sided RDMA operations. Consequently, it can avoid the costly centralized final join on the results aggregated from multiple machines. Shi et al. extend an RDF graph by introducing index vertices so that indexes are naturally parts of the graph. To partition and distribute data among multiple machines, they apply a differentiated partition schema to embrace both locality (for normal vertices) and parallelism (for index vertices) during query processing. Based on the observation that RDF queries only touch a small subset of graph data, the system further incorporates predicate-based finer-grained vertex decomposition and stores the decomposed graph

data into a refined, RDMA-friendly distributed hash table to reduce RDMA transfers. Depending on the selectivity and complexity of queries, the system decomposes a query into a sequence of sub-queries and handles multiple independent sub-queries simultaneously. For each sub-query, it adopts an RDMA communication-aware mechanism. For selective queries, it uses in-place execution that leverages one-sided RDMA read to fetch necessary data so that there is no need to move intermediate results. For nonselective queries, it uses one-sided RDMA WRITE to distribute the query processing to all related machines. To prevent large queries from blocking small queries when handling concurrent queries, Shi et al. provide a latency-centric work-stealing schema to dynamically oblige queries in straggling workers.

Cheng et al. (2015) present a hybrid method for processing RDF that combines similar-size and graph-based partitioning strategies. In this approach, similar-size partitioning is used for fast loading data, while graph-based partitioning is used to achieve efficient query processing. A two-tier index architecture is adopted. The first tier is a lightweight primary index which is used to maintain low loading times. The second tier is a series of dynamic, multilevel secondary indexes, computed during query execution, which is used to limit the inter-machine data transfer for subsequent operations for similar graph patterns. Additionally, this approach relies on a set of parallel mechanisms which combine the loading speed of similar-size partitioning with the execution speed of graph-based partitioning. For example, it uses fixed-length integer encoding for RDF terms and indexes that are based on hash tables to increase access speed. The indexing process does not use network communication in order to increase the loading speed. The local lightweight primary index is used to support very fast retrieval and avoid costly scans, while the secondary indexes are used to support nontrivial access patterns. The secondary indexes are built dynamically, as a by-product of query execution; thus they amortize costs of common expensive access patterns.

The DiploCloud system (Wylot et al. 2011; Wylot and Cudré-Mauroux 2016) has been

designed to use a hybrid storage structure co-locating semantically related data to minimize internode operations. The colocated data patterns are mined from both instance and schema levels. DiploCloud uses three main data structures: molecule clusters, template lists, and a molecule index. Molecule clusters extend property tables to form RDF subgraphs that group sets of related URIs in nested hash tables and to colocate data corresponding to a given resource. Template lists are used to store literals in lists, like in a columnar database system. Template lists allow to process long lists of literals efficiently; therefore, they are employed mainly for analytics and aggregate queries. The molecule index serves to index URIs based on the molecule cluster to which they belong. In the architecture of DiploCloud, the master node is composed of three main subcomponents: a key index encoding URIs into IDs, a partition manager, and a distributed query executor. The worker nodes of the system hold the partitioned data and its corresponding local indexes. The workers store three main data structures: a type index (grouping keys based on their types), local molecule clusters, and a molecule index. The worker nodes run sub-queries and send results to the master node. The data partitioner of DiploCloud relies on three molecule-based data partitioning techniques: (1) Scope-k Molecules that manually defines the size for all molecules, (2) manual partitioning where the system takes an input to manually define the shapes of molecules, (3) adaptive partitioning that starts with a default shape of molecules and adaptively increases or decreases the size of molecules based on the workload. Starlike queries are executed in parallel without any central coordination. For queries requiring distributed joins, DiploCloud picks one of the two execution strategies: (1) if the intermediate result set is small, DiploCloud ships everything to the master node that performs the join, and (2) if the intermediate result set is large, DiploCloud performs a distributed hash join.

The EAGRE (Zhang et al. 2013) system has been presented as an Entity-Aware Graph compREssion technique to encode RDF datasets

using key-value storage structures that preserve the structure and semantic information of RDF graphs. The main idea of this technique is to extract entities and entity classes from the original RDF in order to build a compressed RDF entity graph. The system adopts a graph partitioning mechanism that distributes RDF data across the worker nodes and designs an in-memory index structure to efficiently accelerate the evaluation of range and order-sensitive queries. In particular, the entity classes are partitioned on the computing nodes in a way that they preserve the structure locality of the original RDF graph. The evaluation process of a SPARQL query starts by identifying the entity classes using an in-memory index for the compressed RDF entity graph on a query engine. Then, the query is submitted to the worker nodes, which maintain RDF data, where the query coordinator on each worker participates in a voting process that decides the scheduling function of distributed I/Os. EAGRE uses a distributed I/O scheduling mechanism to reduce the cost of the disk scans and the total time for the query evaluation process. In practice, whenever some workers complete their local I/O operation, they exploit the scheduler to feed other workers with the gathered statistical information of the processed data.

SemStore (Wu et al. 2014) consists of the following main components: a data partitioner, a master node, and a number of computing nodes. The SemStore partitioner adopts a partitioning mechanism, Rooted Sub-Graph (RSG), that is designed to effectively localize all the queries in the shapes of a star, a chain, a tree, or a cycle that captures the most frequent SPARQL queries. The SemStore partitioner uses a k-means partitioning algorithm for assigning the highly correlated RSGs into the same machine. Each computing node builds local data indexes and statistics for its assigned subgraph and utilizes this information during local join processing and optimization. In addition, the data partitioner builds a global bitmap index over the vertices of the RDF graph and collects the global statistics. The master node is the SemStore component that receives the user query, builds the distributed query plan, and coordinates distributed data transfer between

the computing nodes. The computing nodes use TripleBit (Yuan et al. 2013) for local query evaluation.

Blazegraph (<https://www.blazegraph.com>) maintains three RDF indexes (SPA, POS, OSP) and leverages a B+Tree implementation. These indexes are dynamically partitioned into key-range shards that can be distributed between nodes in a cluster. Its scale-out architecture is based on multiple services. The shard locator service maps each key-range partition to a metadata record that allows to locate the partition. A transaction service coordinates locks to provide the isolation. A client service allows to execute distributed tasks. The query execution process starts with the translation of a SPARQL query to an abstract syntax tree. Then, the tree is rewritten to optimize the execution. Finally, it is translated to a physical query plan, vectorized, and submitted for execution.

Peng et al. (2016) propose a graph-based approach to evaluate SPARQL queries over a distributed RDF dataset. They adopt partial evaluation and assembly approach described by Jones et al. (1996). The method assumes that RDF data is partitioned among multiple machines in a cluster and it divides the query execution into two steps. First, each node partially evaluates the query with the data that it owns and builds a collection of intermediate results, i.e., partial matches. Second, the partial matches are joined either in centralized or distributed manner. To compute the partial matches, the authors employ their previous work on a centralized RDF query engine, gStore (Zou et al. 2014). The method builds the results step-by-step until no more matches can be found or the entire query is satisfied. Since the data is fragmented among many machines, the algorithm terminates when the query is satisfied up to the limits of the local data. In order to combine the partial matches, the authors first propose a centralized algorithm where all intermediate results are sent to one machine that performs an iterative join process. The second algorithm proposed by Peng et al. combines the partial matches in a distributed manner. By using bulk synchronous parallel model (Valiant 1990).

Chameleon-db (Aluc et al. 2013) has been proposed as a workload-aware RDF data management system that automatically and periodically adjusts its layout of the RDF database with the aim of optimizing the query execution time and auto-tuning its performance. Such adjustment is done in a way that enables partitions to be concurrently updated without the need of stopping the query processing. Similar to the previous approach, RDF data and SPARQL queries are represented as graphs, and queries are evaluated using a subgraph matching algorithm. However, the previous approach evaluates the queries over the entire RDF graph; chameleon-db partitions the RDF graph and prunes out the irrelevant partitions during query evaluation by using partition indexes. The main goal of the chameleon-db partitioning strategy is to carefully identify the graph partitions that truly contribute to the final results in order to minimize the number of irrelevant intermediate results for final joins. To prune the irrelevant partitions, chameleon-db uses an incremental indexing technique that uses a decision tree to keep track of which segments are relevant to which queries.

Wang et al. (2016) built on the system described by Peng et al. (2016) and proposed a distributed method to evaluate regular path queries (<https://www.w3.org/TR/sparql11-property-paths/>), i.e., queries over an RDF graph that retrieve resources connected by a sequence of predicates. The authors use partial evaluation to parallelize the execution within multiple nodes containing partitioned RDF triples. First, every node finds the property paths within its local data. Second, every node finds the possible connection with the previously computed paths and triples distributed among other machines. In order to compute the possible connections, the presented system maintains two special indexes pointing to directly connect resources on other machines. Then, all partial answers are grouped in parallel based on three types of partial answer. Finally, all grouped partial answers are sent to a coordinating node that performs joins to generate the final results.

AdHash (Harbi et al. 2015; Al-Harbi et al. 2016) is another distributed in-memory RDF

engine which initially applies lightweight hash partitioning that distributes the RDF triples by hashing on their subjects. AdHash attempts to improve the query execution times by increasing the number of join operations that can be executed in parallel without data communication through utilizing hash-based locality. In particular, the join patterns on subjects included in a query can be processed in parallel. The locality-aware query optimizer exploits this property to build a query evaluation plan that reduces the size of intermediate results transferred among the worker nodes. In addition, AdHash continuously monitors the data access patterns of the executed workload and dynamically adapts to the query workload by incrementally redistributing and replicating the frequently partitions of the graphs. The main goal for the adaptive dynamic strategy of AdHash is to effectively minimize or eliminate the data communication cost for future queries. Therefore, hot patterns are redistributed and potentially replicated to allow future workloads which contain them to be evaluated in parallel by all worker nodes without any data transfer. To efficiently manage the replication process, AdHash specifies a budget constraint and uses an eviction policy for the redistributed patterns. As a result, AdHash attempts to overcome the disadvantages of static partitioning schemes and dynamically reacts with changing workloads. The locality-aware query planner of AdHash uses the global statistics and the pattern index to decide if a query, in whole or partially, can be processed without communication. Queries that can be fully answered without communication are planned and executed by each worker independently. For queries that require communication, the planner exploits the hash-based data locality and the query structure to find a plan that minimizes communication and the number of distributed joins.

Potter et al. (2016) propose a distributed algorithm to answer queries over a partitioned RDF graph. The algorithm dynamically decides when and how to exchange data between the machines, i.e., it exchange data only when it is needed. The algorithm adapts the index-nested loop join, and at each stage it decides if the next stage should

be further executed on the same machine or if it should be moved/forked to another server. Specifically, after reordering the triple patterns from the query, each server tries to recursively find RDF triples which match the pattern. Each stage of the nested join loop, which corresponds to a triple pattern, takes as an input a triple pattern and the partial answers of the previous stages. Before evaluating a triple pattern with bindings from previous partial answers, the server verifies if there is another server in the cluster that has RDF triples which can contribute to the query execution. If there is a machine that can contribute to the query evaluation, it receives a message with the current partial answer, i.e., the answer including all previous stages of the query execution. The new machine can then continue the forked query evaluation with the data located on this machine. The presented variant of the index-nested loop join algorithm dynamically jumps to the relevant servers when it is required by the query execution process based on the query itself and the data partitioning. The servers exchange the messages asynchronously without static synchronization in the query plan.

Network Big Data Security Issues

Niranjan K. Ray, Biswaranjan Acharya, and Anil Kumar Swain

Kalinga Institute of Industrial Technology (KIIT), Deemed to be University, Bhubaneswar, India

Definitions

- Mobile ad hoc network (MANET): It is a type of wireless networks which is most suitable for environment where establishing other types of networks are neither possible nor advisable. A node in MANETs performs the role of both host as well as router.

- Cloud computing: It is a type of Internet-based computing platform, where different services such as storage, database, integration, security, and management are delivered to computers and devices through the internet. It stores and maintains the data in a cloud data center. Cloud center usually supports more numbers of users, applications, and data.
- Internet of things (IoT): It is the collection of different things (physical gadgets, vehicles, home machines, etc.) inserted with hardware, programming, sensors, and actuators. It can be acknowledged in three standards: web situated (middleware), things arranged (sensors), and semantic-arranged (information).

Introduction

Today a wide range of wireless products are available in the market. They are omnipresent and are influencing the society in many ways. Their applications are ranging from Bluetooth (IEEE 802.15.1), cellular data services (3G/4G), wireless fidelity (IEEE 802.11), Zigbee (IEEE 802.15.4), WiMax (IEEE 802.16), etc. Basically, these technologies are available in different forms such as mobile notebook/tablets and laptops. Most of the wireless networks such as wireless LAN and cellular networks are infrastructure based. They require base station or access point to operate. However, few networks such as MANETs do not require any preestablished infrastructure to operate. Infrastructure-less networks can be deployed anywhere with minimal cost and effort. Other than this there are also many other types of networks present to overcome some of the major challenges faced by the traditional wireless networks. These networks are software-defined networks (SDN), wireless mesh network, and Internet of things (IoT). All these networks are the backbone of many applications such as smart home, smart healthcare, smart city, etc. (Mohanty et al. 2016; Lacink and Ristve 2017; Sundaravadivel et al. 2018). With the increase in the networking applications, there is an increase in data transmission and processing.

This leads to use of big data applications and tools. Networking for big data is still a huge challenging area for researchers. There are many problems that need to be addressed properly such as information retrieval in big data, data storage management for big data, network optimization for big data, network security and privacy issues in big data, and so on. This chapter discusses some security aspects of networking technology used in field in big data applications.

Security Aspects in Networking

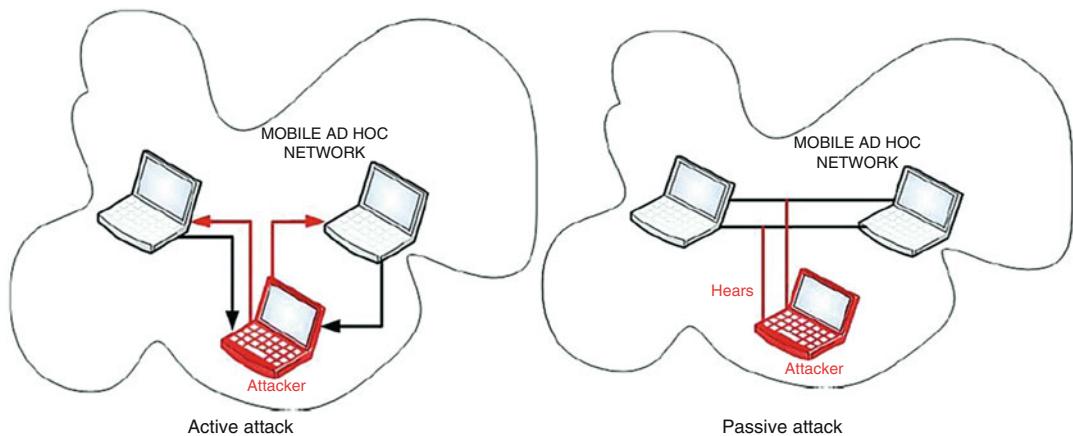

In this section few security mechanisms for different networking applications are discussed briefly.

Security in MANET

Security always remains an important concern in MANET due to its vulnerable characteristics and behavior. Attackers target to attack across all layers of protocol stack. It is observed that different mechanisms are used for this Joshi (2011) and Obi (2004). In Shi-Chang et al. (2010), the security architecture is divided into five layers such as (i) infrastructure layer, (ii) communication security layer, (iii) routing security layer, and (v) application security layer. Specially network layer is severely affected by attackers. Network layer attack in MANETs can be divided into two main categories: (i) active attack and (ii) passive attack. Active attacks are targeted to prevent services from working properly or shut them down completely. Intrusion prevention measures like encryption and authentication can prevent nodes from disrupting traffic. Passive attacks are typically more severe attacks; it is also known as internal attacks. In this attack, a malicious node affects the route discovery process by changing the content of the discovered route. It can also invalidate the route cache of other nodes by advertising incorrect paths. The active and passive attacks are shown in Fig. 1.

Some of the active attacks and their prevention mechanisms are discussed here briefly:

Sleep Deprivation Attack: It is a type of denial-of-service (DoS) attack. In this approach an

Network Big Data Security Issues, Fig. 1 Active and passive attacks in MANETs

attacker tries to interact with a legitimate node to feel that the attacker is a legitimate user, but the main purpose of the attacker is to keep the victim node from entering into the sleep mode. A malicious node forwards a route request (RREQ) packet to all its neighboring node with an address which is not valid in that network.

Black Hole Attack: The intruder responds back RREQ with a packet having large sequence number. It means it has the fresh route to the destination node. By doing this the intruder becomes part of many routes. This way it acts as a relay node in many paths and drops the packet instead of forwarding. Causing serious degradation of throughput.

Gray Hole Attack: It is a type of black hole attack, but it is more difficult to detect than the black hole attack. It operates in two phases: (i) malicious node advertises itself as having a valid route to a destination node, and (ii) the node drops the intercepted packets with a certain probability. The major difference is that in black hole attack, the intruder drops every packet received by the node. However, in gray hole attack, the intruder might drop packet selectively.

Worm Hole Attack: In this approach an attacker tunnels the RREQ directly to the destination node. It prevents any other route from being discovered. The tunnel can be created by means of a high-quality wireless link. After

building a wormhole link, the attacker is able to receive all the packets and forwards them to the other malicious node through the wormhole link.

Sybil Attack: In this approach an attacker creates a new identity, discarding the previously created one. A malicious node tries to gain more resources, information, access, etc. than what a single node deserves in a network.

One solution to overcome sleep deprivation attack (Yi et al. 2009) is neighbor supervision. The neighbor node maintains a priority queue of incoming RREQs and reduces the probability of processing RREQs from a node if a high number of incoming RREQs are received from that node. Few active attacks are discussed in Abdelhaq et al. (2011). On the prevention side, various key and trust management schemes have been developed to prevent external attacks from outsiders, and various secure MANET routing protocols have been proposed to prevent internal attacks originated from within the MANET system (Zhang and Lee 2005).

Intrusion Detection in MANETs

An intrusion detection system (IDS) is a defense system that detects hostile activities in a network. It then tries to prevent many activities that may compromise system security. Intrusion prevention techniques alone may not be sufficient in MANETs. As the system becomes more complex, there are also more weaknesses, which

lead to more security problems. The prevention part may involve issuing alerts as well as taking direct preventive measures such as blocking a suspected connection. Firewalls are the first line of defense; IDSs come into the picture only after an intrusion has occurred and a node has been compromised. IDS can be classified as (i) host based or (ii) network based. In network-based approaches, capture and analyze packets from network traffic in host-based approaches take the help of operating system in its analysis. Few intrusion detection techniques for MANETs are discussed below here.

Stand-Alone Intrusion Detection Systems: In this approach a node independently makes the decision based on the information collected by it to determine the intrusion. It is suitable in the network where nodes are not capable of running an IDS or have an IDS installed in it.

Distributed and Cooperative Intrusion Detection Systems: Node in the network participates in intrusion detection. In this approach, an IDS agent runs at each node. The role of IDS agent is to detect and collect local events and data to identify possible intrusion. The IDS agent also cooperatively participates in global intrusion detection action.

Security in Cloud Computing

Cloud computing is one of the emerging technology in the recent times which has varieties of applications at different fields. In this section security requirements and some security techniques for cloud computing are discussed.

Security Requirements in Cloud Computing

- Authentication: It is a basic requirement to provide security. It identifies the users according to verifying their username and password.
- Authorization: It ensures referential integrity of a task in cloud computing. This process exerts control and privileges over different ongoing process or task.
- Confidentiality: It gives more security to cloud computing and allows only an authorized person to access the data. In cloud computing, this process controls organization's data across the multiple distributed databases. It is employed in public cloud because public

cloud has many numbers of users and it is open for all users. It allows various protocols to be imposed in different layers of cloud applications.

- Integrity: It means the information of a user data cannot be modified by the environment. It assured that information cannot be tampered at multiple distributed databases in different places.
- Non-repudiation: It gives security against false denial of involvement of a communication. Non-repudiation applies the traditional e-commerce security protocols and token provisioning to data transmission within cloud applications such as digital signatures, timestamps, and confirmation receipts.

Security Issues in Cloud Computing

• Software security issues: Software security plays a vital role in computer system at present times. Security measures might be hard because usually software has thousands or millions lines of code. In case of real-time system, fully reliable software is needed to handle the critical situations. A business organization stores their important files and data into digital files in high-value price of information. Here the company revenues in the stake. By software faults, the SaaS providers are to ensure about no data leakage. In spite of being in a more tightly managed environment, software is no more secure simply by virtue of being in a virtualized environment.

- Virtual machine security: Virtualization is a key element of a cloud. Virtualization has a major task – it ensures different instances running in the same physical machine. Without much difficulty virtualization can be cloned and smoothly moved between physical servers. This advantage of VM makes it difficult to achieve and maintain consistent security. At any point of time, it is very hard to maintain the table of VM auditable record of the security. Due to its flexibility, it has wide adoption in the industry. IaaS providers in their business put trust and confidence on quick deployments of VM on top of VMMs. A multi-tenant and virtualized approach gives

profit by cloud providers' perceptive, but it increases the collocation attack surface. Virtualization software contains bugs that allow virtualized code to break loose to some extent. Managing images, monitoring virtual machines, and virtual machine mobility are the issues related on virtualization.

- Internet and services security issues: Cloud infrastructures are composed by the hardware, where data is stored and processed. It is also composed by the path, where it is transmitted. A large number of data packets are transmitted from source to destination by so many numbers of third-party devices and links in a cloud scenario. The transmission medium is the Internet. Some known issues are IP spoofing, port scanning, packet sniffing, malware, and social engineering.
- Network security issues: Network security issue is another key issue in cloud computing applications. Each network is affected by some security threats. Different types of attacks are associated with the networks such as DNS attacks, sniffer attacks, etc. In order to convince the information security and data integrity, Hypertext Transfer Protocol Secure (HTTPS) and Secure Shell (SSH) are the most common acceptance.
- Access security issues: Authentication is a technique which gives security to the data, email, and other accounts of the customer. By combination of username and password, it gives protection. This technique is used in cloud. It is also very much required to deploy security policies to address the issues such as authentication and authorization requirements. For specific access conditions, SaaS service providers' application must be customized and configurable.
- Trust security issues: Trust is one of the security aspects of cloud computing. Cloud providers must trust customers to access their cloud in an honest manner. There are some trust assets that are needed when adding stakeholders in the cloud. Trust is not always established at both customer's and providers' mind. Only trust cannot provide comfort to a customer. Some additional features are needed

to include in order to increase customer's confidence. Trust management is not only a factor in cloud computing, but also it applies in other distributed systems and peer-to-peer (P2P) and sensor networks.

5G Security

The emerging technological concept of the 5G network is promising to fulfill the growing desires of wireless communication. 5G will provide many benefits, such as enhanced speed, lower latency, and better efficiency. However, due to increased numbers of devices and a use of virtualization and cloud, it will equate to many more security threats. At the side of growing speed of transmission, wide variety of customers, reliability, and coverage of the cell network, safety is an issue of key significance that requires careful consideration. The security in 5G basically focuses on the following:

- (i) Prevent threats by using firewalls to protect the network and using access control to minimize user-based risk.
- (ii) Stop and fix advanced malware by behavior-based checks on endpoints.
- (iii) Detect anomalies by using packet capture, big data, and machine learning to identify threats not spotted by basic filters.
- (iv) Incorporate DNS intelligence by monitoring DNS activity and protect against any malicious activities.
- (v) Make threat intelligence paramount by understanding the malicious efforts of hackers.

New security issues beginning in the innovations to be conveyed in 5G were examined to take suitable countermeasures for the future network.

There are numerous advancements proposed in literature that offer arrangements for the 5G systems, e.g., physical layer security, monstrous MIMO, incorporated SDN engineering, etc. (Hidano et al. 2015). There are crucial issues in the 5G where remote transmissions are inalienably helpless against security breaks and among different advancements. The three most encouraging ones are talked about: heterogenous

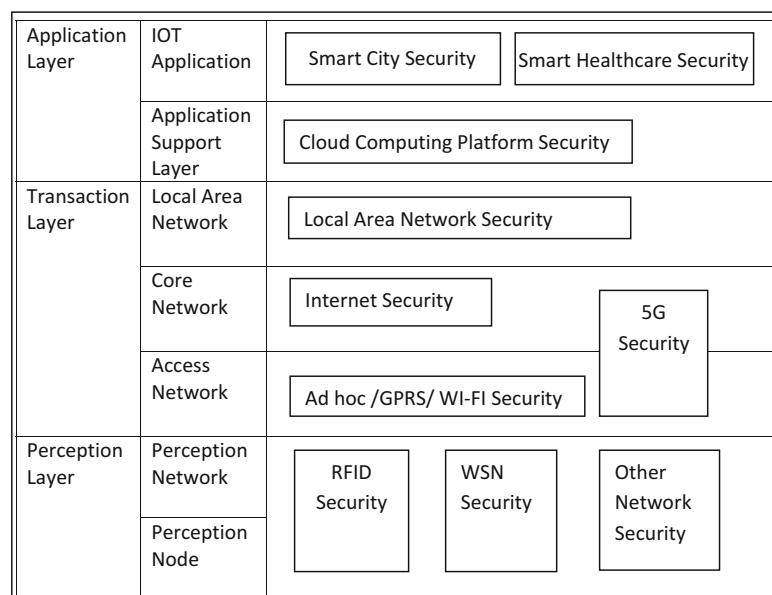

systems, huge numerous information various yield, and millimeter wave (Yang et al. 2015). On the premise of the key standards of every innovation, it recognized the rich open doors and the exceptional difficulties that security architects must handle. Such a recognizable proof is required to conclusively propel the comprehension of future physical layer security. Critical advances will be the illumination of the security prerequisites; the audit of existing security models, specifically the LTE security engineering; and lastly the choice of the 5G safety efforts in tight systems administration with the plan of the general 5G organize design (Schneider and Horn 2015). Physical layer security of applying non-orthogonal various access (NOMA) in huge-scale systems is researched (Qin et al. 2016). A new physical layer paradigm for secure key exchange between the legitimate communication parties in the presence of a passive eavesdropper (Mazin et al. 2017). Another work exhibited agent cases of potential dangers and assaults against the primary parts of the up and coming 5G correspondence frameworks with a specific end goal to explain the future security issues and difficulties in the up and coming 5G period. Especially, it concentrated

on cases of potential dangers and assaults for the accompanying 5G framework parts: the UE, the entrance organizes the versatile administrator's center system and the outer IP systems (Mantas et al. 2015).

Security in IoT

IoT is the collection of different real-world things connected by Internet. It can be acknowledged in three standards: web situated (middleware), things arranged (sensors), and semantic-arranged (information). The association of physical things to the Internet makes it conceivable to get to remote sensor information and to control the physical world from a separation. The functionality of IoT can be expressed in three layers: (i) application layer, (ii) transportation layer, and (iii) perception layer. Application layer security can be achieved by implementing security features in storage servers. Few such work is reported in Sicari et al. (2016), Matharu et al. (2014), Weber (2010), and Nguyen et al. (2015). Transport layer security can be implemented through access network and core network and perception layer security through perception node and network. Functionality and security level at each layer is shown in Fig. 2.

Network Big Data Security Issues, Fig. 2
Security architecture in IoT

Conclusion and Future Direction

Security is considered to be a very big issue in networking. In this chapter we have discussed few security aspects in MANETs, cloud computing, 5G, and IoT application areas. Numerous methods have been proposed in literature to make network more secured. However, as the requirement is changing rapidly and many new applications, protocols, and devices are involved with the network, security will remain the key concern for new technology and applications.

²Federal Institute of Education Science and Technology Sul-Rio Grandense (IFSUL), Charqueadas, Brazil

Introduction

Currently, a huge amount of data has been created from several distributed sources. In this scenario,

a new problem has emerged: how to develop and deploy infrastructures (i.e., storage, network, processing) that are scalable and elastic enough to handle this massive amount of data in a suitable way. The big data concept is related to the capacity of such infrastructures to cope with this enormous amount of data along with quality of service (QoS) metrics that include performance, timeliness, and availability (Assunção et al. 2015).

Scalability is the capacity to enhance the infrastructure by increasing the number of computational resources at the same pace that the quantity of data to be processed grows. It means that the infrastructure must be flexible enough to grow based on the demand for computational resources in order to provide high-quality services (Rodrigues et al. 2016).

To deliver big data demands, the whole infrastructure must be elastic as well. In other words, the infrastructure must grow in quantity of computing resources in order to handle the amount of data that arrives to be processed and reduce such amount of resources when they are not needed. On the one hand, such increase in amount of resources at the infrastructure is necessary to keep quality of service metrics. On the other side, the reduction of resources is necessary to reduce costs when they are no longer necessary.

From the above, big data computing is a complex concept that is dependent on computational resources delivered in a scalable and elastic way. In this context, network resources play a key role in enabling quick and sustainable communications expansion while ensuring that applications are linked to mission-critical data transaction and content environments (Borovick and Villars 2012). This paper presents a definition of network-level support for big data computing along with some important technologies employed to provide support for big data environments and applications.

N

Definitions

A network supporting big data is composed of both links inside data centers (i.e., internal links or internal connections) and links across

the WAN (i.e., external links or external connections). Network-level support for big data computing enables communication among nodes playing a vital role in allowing fast and sustainable exchange of an enormous amount of data (i.e., raw data, analyzed data) as well as ensuring that these nodes are linked to essential systems and applications.

The network infrastructure that could be physical or virtual must be designed to be scalable, elastic, and resilient in order to optimize performance due to the characteristics of big data environments. Thus, the network infrastructure must enable full link utilization by deploying multiple paths allowing the nodes to pick the most efficient route up and in this way offering adequate levels of performance.

Overview

The concept of big data demands that a massive amount of data is processed, generating information in real time. In order to support such processing power regarding response time, large-scale environments must offer some features, such as scalability, availability, and fault tolerance. Such features necessarily pass through a reliable network level to handle all data flows among the processor nodes.

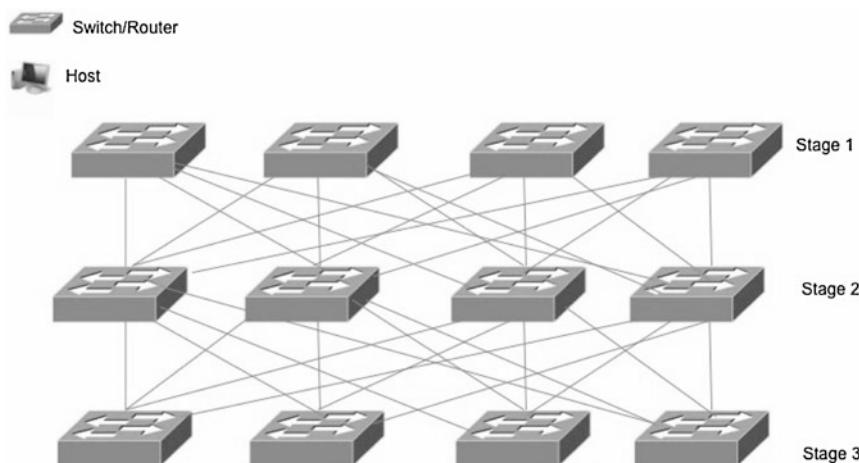

First, this section presents the physical substrate of the network, which consists of the communication devices and channels currently used in large-scale environments that support big data applications. Next, this section presents the software layer that comprises of technologies that make the network flexible enough to fit the application needs. Finally, this section is concluded with a current scenario of convergence between all the network capabilities discussed.

Physical Network Substrate

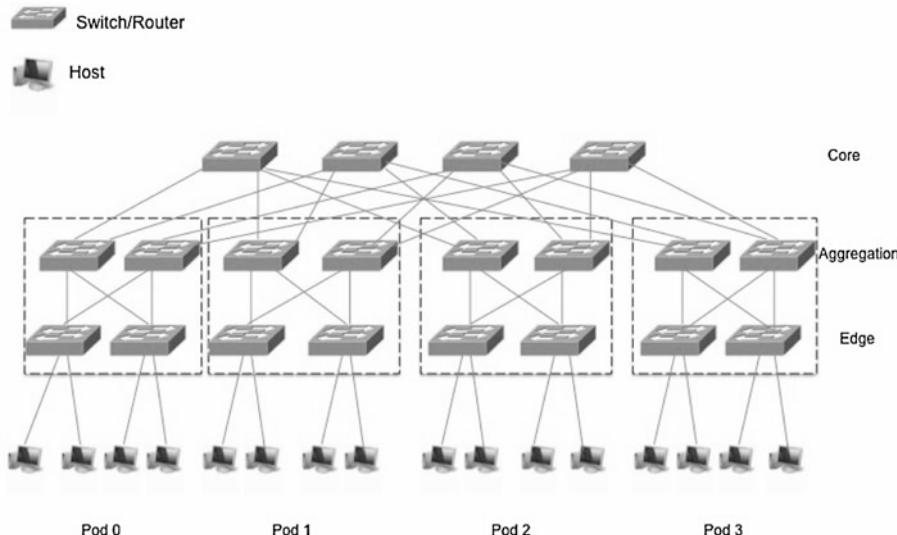

Data centers have become a useful communication infrastructure to support big data. Currently, there are some different ways to deploy a network topology to support big data, but the vast majority are structures based on trees, which includes Clos topology and fat-tree topologies (Al-Fares et al. 2008; Bari et al. 2013; Guo and Yang 2015).

Clos topology is built up from multiple stages of switches as depicted in Fig. 1, which is an example of a Clos topology composed of three stages. This topology is easy to understand, and each switch in a particular stage is connected to all switches in the next stage providing an extensive diversity of paths for data communication.

According to the literature, fat-tree topology is a particular sort of Clos topology that has its structure based on a tree as presented in Fig. 2. Fat-tree topology is built of k-port switches that

Network-Level Support for Big Data Computing, Fig. 1 Clos topology

Network-Level Support for Big Data Computing, Fig. 2 Fat-tree topology ($k = 4$)

contain k pods. Each pod has two levels of $k/2$ switches, namely, aggregation and edge. Each of the $(k/2)$ core switches has one port connected to each of k pods. The i -th port of any core switch is connected to pod i so that consecutive ports in the aggregation level of each pod switch are connected to core switches on $k/2$ strides. Each edge switch is directly connected to $k/2$ end hosts. Each of the remaining $k/2$ ports of an edge switch is connected to $k/2$ ports of an aggregation switch.

Although the physical network substrate is implemented not to be changed, it supports flexibility in many ways. Link aggregation (Seifert 2000) at the network-level consists of a technology that provides means for traffic to be forwarded in parallel through available channels, where each device may dynamically aggregate the corresponding ports into an aggregation port which shows up as a single, logical, high bandwidth port or interface to other processes executing on the device. Currently, it allows link aggregation from two to eight physical channels into a single virtual channel aiming to increase the bandwidth and, as a consequence, increasing performance.

Nowadays, data centers have taken advantage of network devices that provide support to link aggregation. Figure 3 presents the physical con-

nnections of a modern data center network in which the communicating hosts (a) are connected to edge devices (b). Such devices are connected to the network core (c) by multiple channels.

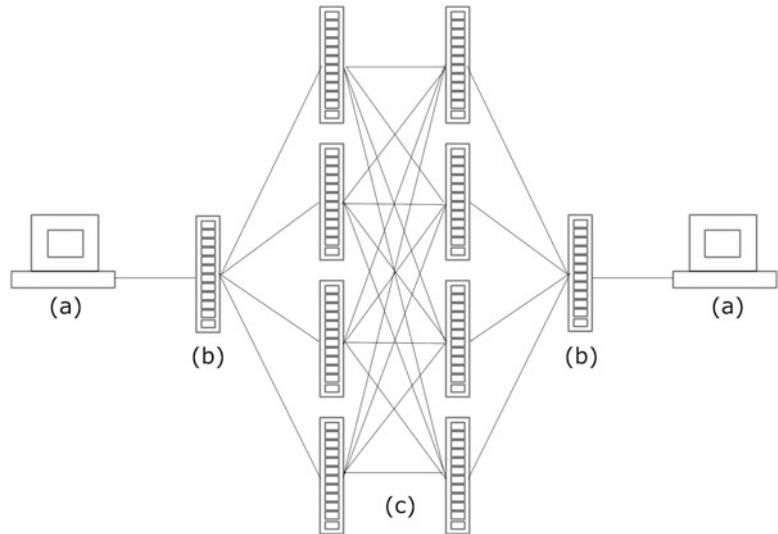

The devices composing the core are interconnected via multiple channels as well. Multiple connections between edge devices and core devices are usually a way to enable routing and high availability. Besides, several protocols have used this technology to support link aggregation. Furthermore, it is important to mention that in case of failure of one of the redundant links, frames may be forwarded to and from the remaining links of the aggregation port transparently to the process executing on the devices.

In this scenario, each network equipment manufacturer has developed its own layer 2 technology (i.e., multi-link trunking) aiming to provide support to link aggregation protocols. In this way, protocols at layer 3 which include virtual concatenation (VCAT) and link aggregation control protocol (LACP) can be developed to enhance both link aggregation and port aggregation (Berggreen and Litjens 2006).

Although this option to use link aggregation is offered to a plethora of data centers, it is not largely utilized because of the enormous traffic on the network, which increases the problem

Network-Level Support for Big Data Computing

Fig. 3 Multi-link network data center substrate

of packet collisions and network loops. Aiming to overcome such limitations, it becomes necessary the use of a technology that manages the aggregation and disaggregation of links with a wide vision of the packet flows. In this context, two innovative technologies have emerged: network function virtualization (NFV) and software-defined networking (SDN).

Logical Network Layer

For a long time, network infrastructures had been limited by physical substrate choices such as equipment and topology. In such environments, the higher level the infrastructure, the more difficult it would be to implement any change. It remained true until the emergence of virtualization. The virtualization layer has provided flexibility over the physical substrates as it allows virtual overlay networks to be maintained, and data streams can be managed independently and in separate paths. Today's network environments use a variety of virtualization models, ranging from traditional virtualization layers such as Xen (Barham et al. 2003) to lightning virtualization layers such as Containers (Xavier et al. 2013) and Unikernels (Xavier et al. 2016), each one being chosen due to its capabilities, such as resource isolation, performance, and security, among others.

Based on this new idea, specialized appliances were replaced by virtual machines, in order to speed up the deployment of network services. As a consequence, dedicated appliances were replaced by virtual machines, with the goal of speeding up the deployment of network services to meet the growth of data centers. This new concept is known as network function virtualization (NFV) (Mijumbi et al. 2016), and it allows network services to be started and stopped according to demand. Therefore, NFV services provide the ability to tune and modify network resources in real time, delivering customized customer experiences. It makes the infrastructure flexible enough to evolve at the same pace as the applications and their related services.

One technology that has been developed side by side, but independently from NFV, is software-defined networking (SDN) (Lemeshko and Vavenko 2017). It is a technology that offers dynamicity, manageability, and adaptive computer networking to big data environments. It is currently one of the most promising technologies for handling the high bandwidth requirements and the dynamic nature of big data applications, making networks more flexible and efficient.

In SDN, the network control is programmable directly by administrators, enabling support to key functions that include configuration, management, and protection. In this way, SDN

optimizes the use of network resources in a quick and efficient manner. Additionally, such a programmable network provides support to administrators to dynamically adjust the flow of data traffic through the network to meet the demands of change since all network intelligence is logically centralized in software-based controllers that have a global view of the network.

It is important to mention as well that, in SDN, the data plane is separated from the control plane, thus enabling a new operational method that is different from the traditional computer network. Figure 4 depicts such separation between data plane and control plane showing their interaction through an orchestrator. Traditional computer networks have proposed that each device has the data plane and the control plane. On the other side, SDN has proposed to separate both the control plane and the data plane. The control plane is centralized in the SDN controller, and the data plane is kept on the network device.

The control plane (Zhao et al. 2017) is responsible for understanding how the packets have been routed, in other words, what is the best route to forwarding the data flow and how to better assemble the routing table, whereas the data plane is responsible for routing packets based on simple rules, which is associated with each entry in the routing table of the network device.

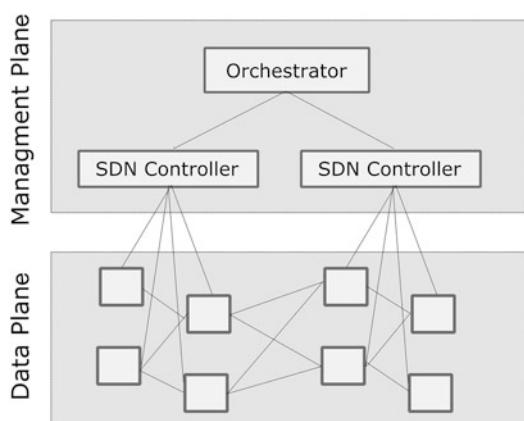

One important characteristic that makes SDN a technology viable to the needs of big data applications is that all packet forwarding requests are made from the hosts to the SDN controller. Thus, the controller knows in advance which path these packets will use to traffic, and so it can expand the channels of that path at runtime before sending the devices the route to be established. Such characteristic is significant when dealing with a huge amount of data usually forwarded in big data environments.

Finally, SDN controllers can respond to requests from network devices and reconfigure them quickly if compared to traditional infrastructures, with the advantage of adapting to network growth transparently. Thus, it provides an efficient method to improve performance as well.

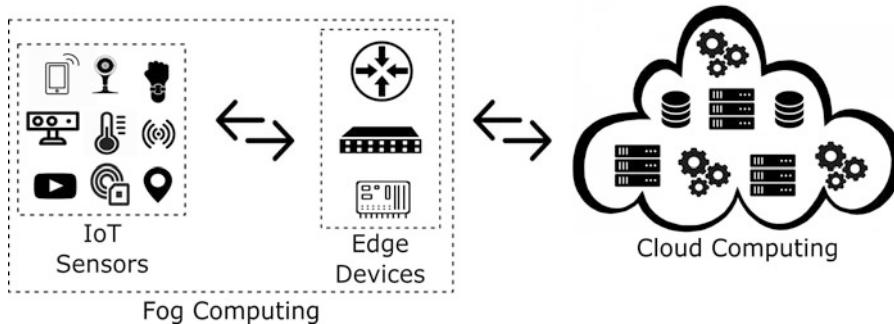

Network Convergence

In big data environments, cloud providers offer data analysis and integration services in the form of an Analytics-as-a-Service (AaaS) (Lomotey and Deters 2014). The exponential increase in a number of sensor-generating data to be processed by such services boosted the advent of the Internet-of-Things (IoT) (Dlamini and Johnston 2016). To meet this growing demand in the amount of data to be transmitted between the customer and the cloud, it would be necessary to increase the capacity of the communication channels. However, the increase in this type of infrastructure is expensive. For a time, techniques similar to offloading (Gao et al. 2017) tried to be a palliative to solve the limitations of latency in the data transfer.

Currently, edge computing (Klas 2017) is a low-cost change in infrastructure that addresses such limitations because it brings cloud services closer to the customer and offer embedded devices with relative processing power. From the above, there is a new emerging trend toward the integration of IoT, cloud computing, and edge devices that is known as fog computing (Yousefpour et al. 2017). Therefore, such new paradigm is defined as an architecture that extends computational capacity and cloud storage to network

Network-Level Support for Big Data Computing, Fig. 4 SDN architecture plane

Network-Level Support for Big Data Computing, Fig. 5 The composition of fog computing and its relation with cloud computing

access layers, allowing data to be analyzed and transformed into information or actions more quickly.

Although some authors treat fog and edge computing as synonyms, there is a difference between these two approaches as to where intelligence is located and the power of processing. Figure 5 illustrates such a difference within a large-scale computing environment, where edge computing brings processing power and communication capabilities to programmable devices located at the edge of the network, such as devices that once played only gateways. It draws closer to the consumer a significant processing power and network, providing quality of service and reducing point of failure. Fog computing extends cloud power by encompassing IoT and edge computing devices in an environment of distributed and scalable services, supported by processor nodes, networking, and storage.

Therefore, fog computing has emerged based on several different technologies such as sensor networks, ubiquitous computing, pervasive computing, grids, and cloud computing. It is also thankful for the spread of customizable low-cost hardware with a variety of modules to allow exchange of information of these platforms with other devices. While this promotes a high adaptability to many environments and contexts, it is weakened by the lack of standardization in communication. In particular, networks that serve as a communication channel between these devices have not been developed specifically for

this type of scenario. Therefore, fog has used existing technologies, and these do not take into account the characteristics of the sensors, for example, concerning about energy waste.

Examples of Network-Level Application for Big Data Processing

Among the applications that provide environments at the network infrastructure level for big data processing, Containers are the ones that cause the most reliability. Containers (Xavier et al. 2016) consist of lightweight virtual machines, which, unlike traditional virtual machines, perform similarly to applications running directly on the operating system. It is because instead of virtualization being managed by an additional layer called hypervisor, Containers are managed directly by the kernel.

This type of virtualization is standard in large-scale environments such as Mesos (Delvalle et al. 2016), Docker (Dirk 2014), and YARN (Vavilapalli et al. 2013). Scalable applications such as Hadoop (Mallika and Selvamuthukumaran 2017) and MPI (Subramoni et al. 2017) can be used for the Containers features, such as elasticity and resource isolation. In this way, big data applications can grow over need-based resources, isolated from one another through virtual network channels. From the service provider's point of view, Containers provide a fast deployment option of the infrastructure tools needed to process big data applications.

Security is another critical topic (Barona and Anita 2017). Many data centers that support private clouds at peak times do not have sufficient resources to meet the demands to be processed while maintaining quality of service for big data applications. In this case, service providers allocate a slice of resources in public clouds. This mechanism, called hybrid clouds, and some security issues must be taken into account, based on the importance of the data that travels out of the private environment of the service provider. In order to maintain control over these issues, some techniques already used at the network level are applied, such as the virtual private network (VPN) and encryption (Mary and Amalarethinam 2017).

Future Directions for Research

Based on the themes presented, some significant research directions may be pointed out.

- The network level consists of consolidated and old technologies. Research on the physical substrate will require a lot of effort with a minimal gain. Searches should be directed to software layers that can modify flows without changing the physical substrate. NFV and SDN can contribute to the attendance of several metrics, such as performance, security, and availability, among others.
- New approaches for virtualization are emerging, but they are still immature to be used in production environments, but that in a short time may replace Containers as a de facto standard in support of big data applications, such as Unikernels.
- Allocating network resources intelligently is a crucial point for improving the performance of big data applications. Some big data programming models such as Hadoop (Mallika and Selvamuthukumaran 2017) exchange data between processors that support map and reduce processes. Therefore, it is interesting that such processes are allocated to nearby nodes in the network. Also, increasing the bandwidth be-

tween such nodes dynamically also becomes an interesting capacity to the network.

- Undeniably, the most massive volume of data currently generated comes from IoT devices. The traffic and analysis of this data depend on open environments that do not limit such growth. Therefore, a concept that is not new but is more current than ever consists of network neutrality (Garrett et al. 2017). Technically, this concept means that any data that travels over the network must be treated in the same way and be transferred at the same speed. With the exponential growth of mobile devices, network neutrality is becoming increasingly difficult. But much more than a technical concept, there is a political and financial motivation in the sense that certain service providers could privilege data from some types of devices or equipment brands to the detriment of others.

Definitions

NoSQL (Not Only SQL) is a new generation of high-performance database systems that have been designed to deal with the increasing scaling requirement of modern Web-scale applications. In particular, the new NoSQL systems had a number of design features in common:

- The ability to horizontally scale out through-put over many servers.
- A simple call level interface or protocol.
- Supporting weaker consistency models in contrast to ACID guaranteed properties for transactions in most traditional RDBMS. These models are usually referred to as *BASE* models (*Basically Available, Soft state, Eventually consistent*) (Pritchett 2008).
- Efficient use of distributed indexes and RAM for data storage.
- The ability to dynamically define new attributes or data schema.

These design features are made in order to achieve the following system goals (Sakr 2014; Zhao et al. 2014):

- *Availability*: They must always be accessible even on the situations of having a network failure or a whole datacenter that went of-flne.
- *Scalability*: They must be able to support very large databases with very high request rates at very low latency.

• *Elasticity*: They must be able to satisfy changing application requirements in both directions (scaling up or scaling down). Moreover, the system must be able to gracefully respond to these changing requirements and quickly recover its steady state (Sakr et al. 2011b; Sakr and Liu 2013).

• *Load balancing*: They must be able to automatically move load between servers so that most of the hardware resources are effectively utilized and to avoid any resource overloading situations.

• *Fault tolerance*: They must be able to deal with the situation that the rarest hardware problems go from being freak events to eventualities. While hardware failure is still a serious concern, this concern needs to be addressed at the architectural level of the database, rather than requiring developers, administrators, and operations staff to build their own redundant solutions.

• *Ability to run in a heterogeneous environment*: On scaling out environment, there is a strong trend toward increasing the number of nodes that participate in query execution. It is nearly impossible to get homogeneous performance across hundreds or thousands of compute nodes. Part failures that do not cause complete node failure but result in degraded hardware performance become more common at scale. Hence, the system should be designed to run in a heterogeneous environment and must take appropriate measures to prevent performance degradation that are due to parallel processing on distributed nodes.

N

Overview

For decades, relational database management systems (e.g., MySQL, PostgreSQL, SQL Server, Oracle) have been considered as the *one-size-fits-all* solution for data storage and retrieval. They have matured after extensive research and development efforts and very successfully created a large market and solutions in different business domains. However,

ever-increasing need for scalability and new application requirements have created new challenges for traditional RDBMS. Therefore, there has been some dissatisfaction with this *one-size-fits-all* approach in some Web-scale applications (Stonebraker 2008). The *CAP* theorem (Brewer 2000) has shown that a distributed database system can only choose at most two out of three properties: *Consistency*, *Availability*, and *tolerance to Partitions*. Therefore, most of these systems decide to compromise the strict consistency requirement. In particular, they apply a relaxed consistency policy called *eventual consistency* (Vogels 2008) which guarantees that if no new updates are made to a replicated object, eventually all accesses will return the last updated value (Bermbach et al. 2013). If no failures occur, the maximum size of the *inconsistency window* can be determined based on factors such as communication delays, the load on the system, and the number of replicas involved in the replication scheme.

Google has introduced one of the early systems leading the wave of NoSQL systems by presenting *Bigtable* as a distributed storage system for managing structured data that is designed to scale to a very large size (petabytes of data) across thousands of commodity servers (Chang et al. 2008a). Bigtable has been used by many Google products and projects including Google search engine, Google Finance, Orkut, Google Docs, and Google Earth. Bigtable does not support a full relational data model. However, it provides clients with a simple data model that supports dynamic control over data layout and format. In particular, a Bigtable is a sparse, distributed, persistent multidimensional sorted map. The map is indexed by a row key, column key, and a timestamp. Each value in the map is an uninterpreted array of bytes. Thus, clients usually need to serialize various forms of structured and semi-structured data into these strings. A concrete example that reflects some of the main design decisions of Bigtable is the scenario of storing a copy of a large collection of web pages into a single table. At the physical level, Bigtable uses the distributed Google File System

(GFS) (Ghemawat et al. 2003) to store log and data files. The Dynamo system (DeCandia et al. 2007) is another leading system that has been introduced by Amazon as a highly available and scalable distributed key-/value-based datastore. Dynamo is used to manage the state of services that have very high reliability requirements and need tight control over the trade-offs between availability, consistency, cost-effectiveness, and performance. Dynamo provided a simple primary-key-only interface and relied on a query model that uses simple read and write operations to a data item that is uniquely identified by a key. State is stored as binary objects (blobs) identified by unique keys. No operations span multiple data items. Dynamo's partitioning scheme relies on a variant of consistent hashing mechanism (Karger et al. 1997) to distribute the load across multiple storage hosts.

Following the main concepts of *Google Bigtable* and *Amazon Dynamo*, several systems have been implemented (<http://NoSQL-database.org/>). In general, these systems can be broadly classified into the following categories (Cattell 2011; Sakr et al. 2011a):

- *Key-value stores*: These systems use the simplest data model which is a collection of objects where each object has a unique key and a set of attribute/value pairs.
- *Document stores*: These systems have the data models that consist of objects with a variable number of attributes with a possibility of having nested objects.
- *Extensible record stores*: They provide variable-width tables (column families) that can be partitioned vertically and horizontally across multiple nodes.

Examples of Systems

Key-Value Stores

Key-value stores use a simple data model, in which data are considered as a set key-value pairs, in which keys are unique IDs for each data and also work as indexes during accessing the data. Values are attributes or objects which contain the actual information of data. There-

fore, these systems are called key-value stores. The data in key-value stores can be accessed using simple interfaces such as insert, delete, and search by key. Normally, secondary keys and indexes are not supported. In addition, these systems also provide persistence mechanism as well as replication, locking, sorting, and other features. For example, **Redis** (Zawodny 2009) is an open-source key-value store system written in C. It supports a fairly rich data model for stored values. Values can be lists, sets, and structures in addition to basic types (Integer, String, Double, and Boolean). Apart from ordinary operations such as reading and writing, Redis also provides a few atomic modifier such as increment of a numeric value by one, adding an element to a list, etc. Redis mainly stores data in memory, which ensures high performance. To provide persistence, data snapshots and modification operations are written out to disk for failure tolerance. Redis can scale out by distributing data (normally achieved at client side) among multiple Redis servers and providing asynchronous data replication through master-slaves.

Memcached (Fitzpatrick 2004) is the first generation of key-value stores initially working as cache for web servers then being developed as a memory-based key-value store system. Memcached has been enhanced to support features such as high availability, dynamic growth, and backup. The original design of Memcached does not support persistence and replication. However, its follow-up variation **Membrain** and **Membase** does include these features which make them more like storage systems. **DynamoDB** (Sivasubramanian 2012) is a NoSQL store service provided by Amazon. Dynamo supports a much more flexible data model especially for key-value stores. Data in Dynamo are stored as tables, each of which has a unique primary ID for accessing. Each table can have a set for attributes which are schema free and scalar types and sets are supported. Data in Dynamo can be manipulated by searching, inserting, and deletion based on the primary keys. In addition, conditional operation, atomic modification, and search by non-key attributes are also supported (yet inefficient), which makes it also closer to that of a docu-

ment store. Dynamo provides a fast and scalable architecture where sharding and replication are automatically performed. In addition, Dynamo provides support for both eventually consistency and strong consistency for reads while strong consistency degrades the performance. Project **Voldemort** (<http://www.project-voldemort.com/>) has been contributed by LinkedIn. It provides multi-version concurrency control (MVCC) for updates.

Document Stores

Document stores provide a more complex data structure and richer capabilities than key-value systems. In document stores, the unit of data is called a document which is actually an object that can contain an arbitrary set of fields, values, and even nested objects and arrays. Document stores normally do not have predefined schemas for data and support search and indexing by document fields and attributes. Unlike key-value stores, they generally support secondary indexes, nested objects, and lists. Additionally, some of them can even support queries with constraints, aggregations, sorting, and evaluations. For example, **MongoDB** (<https://www.mongodb.com/>) is an open-source project developed in C++ and supported by the company 10gen. MongoDB provides its data model based on JSON documents and maintained as BSON (a compact and binary representation of JSON). Each document in MongoDB has a unique identifier which can be automatically generated by the server or manually created by users. A document contains an arbitrary set of fields which can be either arrays or embedded documents. MongoDB is schema free and even documents in the same collection can have completely different fields. Documents in MongoDB are manipulated based on the JSON representation using search, insertion, deletion, and modification operations. Users can find or query documents by writing them as expressions of constraints of fields. In addition, complex operations such as sorting, iteration, and projecting are supported. Moreover, users can perform MapReduce-like program and aggregation paradigms on documents, which makes it possible to execute more complicated analytic

queries and programs. Documents can be completely replaced, and any parts of their fields can also be manipulated and replaced. Indexes of one or more fields in a collection are supported to speed up the searching queries. In addition, MongoDB scales up by distributing documents of a collection among nodes based on a sharding key. Replication between master and slaves with different consistency models depends on whether reading from secondary nodes is allowed and how many nodes are required to reach a confirmation.

CouchDB (<http://couchdb.apache.org/>) is an Apache open-source project written in Erlang. It is a distributed document-based store that manipulates JSON documents. CouchDB is schema free; documents are organized as collections. Each document contains a unique identifier and a set of fields which can be scalar fields, arrays, and embedded documents. Queries on CouchDB documents are called views which are MapReduce-based JavaScript functions specifying the matching constraints and aggregation logics. These functions are structured into so-called designed documents for execution. For these views, B-Tree-based indexes are supported and updated during modifications. CouchDB also supports optimistic locks based on MVCC (multi-version concurrency control) Bernstein and Goodman (1981) which enables CouchDB to be lock-free during reading operations. In addition, every modification is immediately written down to the disk and old versions of data are also saved. CouchDB scales by asynchronous replication, in which both master-slave and master-master replication are supported. Each client is guaranteed to see a consistent state of the database; however, different clients may see different states (as strengthened eventually consistency). Amazon provides Simple Storage Service (S3) (<https://aws.amazon.com/s3/>) as an online public storage web service that provides infinite store for objects of variable sizes. In S3, an object is simply a byte container which is identified by a URI. Clients can read and update S3 objects remotely using a simple web service (SOAP- or REST-based) interface.

Extensible Record Stores

Extensible record stores (also called column stores) are initially motivated by Google's Bigtable project (Chang et al. 2008b). In the system, data are considered as tables with rows and column families in which both rows and columns can be split over multiple nodes. Due to this flexible and loosely coupled data model, these systems support both horizontal and vertical partitioning for the scalability purposes. In addition, correlated fields/columns (named as column families) are located on the same partition to facilitate query performance. Normally column families are predefined before creating a data table. However, this is not a big limitation as new columns and fields can always be dynamically added to the existing tables. For example, HBase (George 2011) is an Apache open-source project and is developed in Java based on the principles of Google's Bigtable. HBase is built on the Apache Hadoop Framework and Apache ZooKeeper (Hunt et al. 2010) to provide a column-store database. As HBase is inherited from Bigtable, they share a lot of features in both data model and architecture. However, HBase is built on HDFS (Hadoop Distributed File System) instead of GFS, and it uses ZooKeeper for cluster coordination compared with using Chubby in Bigtable. HBase puts updates in the memory and periodically writes them to disk. Row operations are atomic with the support of row-level transactions. Partitions and distributions are transparent to users, and there is no client-side hashing like some of the other NoSQL systems. HBase provides multiple master nodes to tackle the problem of single-point failure of the master node. Compared with Bigtable, HBase does not have location groups but only that of column families. In addition, HBase does not support secondary indexing; therefore, queries can only be performed based on primary keys or by fully scanning the table. Nevertheless, additional indexes can be manually created using extra tables.

Hypertable (<http://hypertable.org/>) project is designed to achieve a high performance, scalable, distributed storage and processing system for

structured and unstructured data. It is designed to manage the storage and processing of information on a large cluster of commodity servers, providing resilience to machine and component failures. Like HBase, Hypertable also runs over HDFS to leverage the automatic data replication and fault tolerance that it provides. In Hypertable, data is represented in the system as a multidimensional table of information. The Hypertable systems provide a low-level API and Hypertable Query Language (HQL) that allows to create, modify, and query the underlying tables. The data in a table can be transformed and organized at high speed by performing computations in parallel, pushing them to where the data is physically stored.

Cassandra (Lakshman and Malik 2010) is an open-source NoSQL database initially developed by Facebook in Java. It combines the ideas of both Bigtable and Dynamo and it is now open sourced under the Apache license.

Cassandra shares the majority of the features as other extensible record stores (column stores) in both data model and functionality. It has column groups and updates are cached in the memory first then flushed to disk. However, there still some differences:

- Cassandra have columns which are the minimum unit for storage and super columns which contains a set of columns to provide additional nestedness.
- Cassandra is fully decentralized of which every node in the cluster is considered equal and performs identical functions. In Cassandra, a leader is selected based on the gossip protocol, failures are detected by using the phi accrual algorithm, and scalability is achieved by consistent hashing. All the process that have been mentioned before, leader selection, failure detection, and recovery, are performed automatically.
- Cassandra only supports the eventually consistency model. It provides quorum reads to ensure clients get the latest data from majority of the replicas. Writes in Cassandra are atomic within a column family, and some

extent of versioning and conflict resolution are supported.

Definitions

- Data stream algorithms process a continuous stream of data with only a limited possibility to store past records.
- Online machine learning covers methods that update their models after observing a new event and can immediately serve predictions based on the updated model.

Overview

In this chapter, we overview the main online learning methods for classification and regression. We highlight the most important ideas, including linear models, gradient descent, and tree based methods. This chapter is based on the concepts introduced in the “Overview of Online Machine Learning in Big Data Streams” chapter of this Encyclopedia. Additional topics are covered in the chapters “Reinforcement Learning, Unsupervised Methods, and Concept Drift in Stream Learning,” and “Recommender Systems over Data Streams”.

Introduction

Classification and regression are the most widely used machine learning tools, with the goal to predict the unknown label of a data instance based on its attributes or variables. The label is discrete for classification and continuous for regression. Classification and regression in batch settings are well established, with several textbooks available in data mining (Pang-Ning et al. 2006) and machine learning (Friedman et al. 2001).

Classification by online machine learning is summarized in one of the earliest overviews of the field (Widmer and Kubat 1996). The principal task is to learn a concept incrementally by processing labeled training examples one at a time. After each data instance, we can update the model, after which the instance is discarded. The requirements for **machine learning over fast data streams** are summarized in the “► [Overview of Online Machine Learning in Big](#)

[Data Streams](#)” chapter of this Handbook: The algorithms should (1) work from data streams with only a limited possibility to store past data, (2) adapt their models to potential concept drift in the data, and (3) operate in a multi-server distributed computational environment.

For classification and regression over streaming data, the first two of the requirements play a key role. By the first requirement, data is transient, since it does not fit in main memory; hence algorithms that iterate over the entire data multiple times are ruled out. By the second requirement, we cannot assume that the examples are independent, identically distributed, and generated from a stationary distribution; hence different predictions by different models have to be applied and evaluated at different times. Special modeling tools are required to meet the two challenges, and known evaluation and comparison methods are not convenient yet (Gama et al. 2009).

An important, and perhaps the oldest, application of online learning is single-trial EEG classification, in which the system learns from the online feedback of the experimental subjects (Obermaier et al. 2001). These early experiments differ from the approach in this section in that the performance was only measured at the end of the experiments, and no systematic analysis of the classifier performance in time was conducted.

This section is organized as follows: First, we describe the difficulties and possibilities of evaluating online learning methods in section “[Evaluation](#).“ We cover the most important online classification and regression methods in the remaining sections. We discuss the main linear models in section “[Linear Models](#),“ tree-based methods in section “[Decision and Regression Trees](#),“ classifier ensembles in section “[Ensemble Methods](#),“ Bayes models in section “[Bayes Models](#),“ and finally, neural networks in section “[Neural Networks](#).“ Other methods such as **nearest neighbor** (Law and Zaniolo 2005) are known as well. Our list of online classification methods is not comprehensive; for an extended list, see the recent survey (Gaber et al. 2007).

In this chapter, we build on several surveys for online machine learning in general (Gaber et al.

2007; Bifet et al. 2011; Shalev-Shwartz et al. 2012; Fontenla-Romero et al. 2013; Gaber et al. 2014) and subfields (Widmer and Kubat 1996; Tsymbal 2004; Cheng et al. 2008; Mahdiraji 2009; Quionero-Candela et al. 2009; Kavitha and Punithavalli 2010; Žliobaite et al. 2012; Aggarwal 2013; Silva et al. 2013; Gama et al. 2014). As for other areas of machine learning, we refer to the chapters “► Reinforcement Learning, Unsupervised Methods, and Concept Drift in Stream Learning” and “► Recommender Systems over Data Streams” in this Handbook.

Evaluation

In an infinite data stream, data available for training and testing is potentially infinite. Hence hold-out methods for selecting an independent test set seem viable at first glance and are used in a large number of online machine learning research results. However, for online evaluation, we have no control over the order in which the data is processed, and the order is not independent of the data distribution. Since the distribution generating examples and the decision models evolve over time, cross-validation and other sampling strategies are not applicable (Gama et al. 2009).

Most studies of online learning determine overall loss as a sum of losses experienced by individual training examples. Based on this so-called predictive sequential, abbreviated as **prequential** method (Dawid 1984), we define **online training and evaluation** in the following steps:

1. Based on the next unlabeled instance in the stream, we cast a prediction.
2. As soon as the true label of this instance becomes available, we assess the prediction error.
3. We update the model with the most recently observed error calculated by comparing the predicted and the true labels before proceeding with the next item of the data stream.

Prequential error is known to be a pessimistic estimator, since it may be strongly influenced

by the initial part of the sequence, when only a few examples have been processed, and the model quality is low. The effect of the beginning of the stream can be mitigated, for example, by forgetting mechanisms (Gama et al. 2009, 2013).

A further issue in online evaluation is that in reality, labels may arrive with delay (Žliobaite et al. 2012). The majority of adaptive learning algorithms require true labels to be available immediately after casting the prediction. If true labels are delayed, we have to join two streams with time delay, one for the variables and one for the labels, which can make the implementation of the prequential evaluation scheme computationally challenging.

Error metrics that can be defined for individual data points can be applied for prequential evaluation. For example, the definition of mean squared error (MSE), a popular metric for regression, is

$$MSE = \frac{1}{N} \sum_{i=1}^N (\hat{y}_i - y_i)^2, \quad (1)$$

where y_i is the actual and \hat{y}_i is the predicted class label for data point i and N is the current size of the data stream. Accuracy and error rate can be computed by a similar averaging formula.

For certain common metrics such as precision, recall, and true- and false-positive rates, the definition will involve the changing size of the set of positive, negative, or all instances, which makes the metrics difficult to interpret in a very long stream of inhomogeneous data. Although one definition of the area under the receiver operating characteristics curve (AUC) (Fogarty et al. 2005) is based on true- and false-positive rates, its online interpretation is described in Zhao et al. (2011).

Linear Models

Linear models in online machine learning date back to the perceptron algorithm (Rosenblatt 1958). The **perceptron learning** algorithm learns label y of d -dimensional input vector x as a linear combination of the coordinates,

$$\hat{y} = \mathbf{w} \cdot \mathbf{x}. \quad (2)$$

The prediction mechanism is based on an n -dimensional hyperplane of direction \mathbf{w} , which divides the instance space into two half-spaces. The margin of an example, $y \cdot \mathbf{w} \cdot \mathbf{x}$, is a signed value proportional to the distance between the instance and the hyperplane. If the margin is positive, the instance is correctly classified; otherwise, it is incorrectly classified.

The perceptron can be trained by gradient descent for hinge loss as target function. If labels y take the values ± 1 and prediction \hat{y} is defined by Eq. (2), hinge loss is equal to

$$\ell(\mathbf{w}; (\mathbf{x}, y)) = \begin{cases} 0 & \text{if } y \cdot \hat{y} \geq 1; \\ 1 - y \cdot \hat{y} & \text{otherwise,} \end{cases} \quad (3)$$

from which the gradient can be computed as follows: If prediction \hat{y} has the correct sign, and its absolute value is at least 1, that is, hinge loss is 0, then there is no change; the algorithm is passive. Otherwise, the gradient for \mathbf{w} is $-\mathbf{x} \cdot \hat{y}$, and the update rule for learning rate η is

$$\mathbf{w} \leftarrow \mathbf{w} + \eta \cdot \mathbf{x} \cdot \hat{y} \quad \text{if } y \cdot \hat{y} < 1. \quad (4)$$

The online gradient descent algorithm simply applies the above step to training examples in order (Langford et al. 2009). By contrast, the batch gradient descent algorithm reads the input multiple times and usually repeatedly optimizes coefficients for the same instance. Batch gradient descent can be emulated by an online algorithm: We go through training examples one by one in an online fashion and repeat multiple times over the training data (Cesa-Bianchi and Gentile 2008).

Based on the general idea of perceptron learning, several online linear models have been proposed; for a detailed overview, see Fontenla-Romero et al. (2013). The **Passive-Aggressive (PA) classifier** (Crammer et al. 2006) is a popular online linear model that works well in practice, for example, applied as the Gmail spam filter (Aberdeen et al. 2010). The main goal of the PA algorithm is to improve the convergence properties of the perceptron algorithm, the simplest

numerical optimization procedure. Several improved online optimization procedures were proposed prior to PA: Kivinen and Warmuth (1997) give an overview of numerous earlier additive and multiplicative online algorithms, all of which are solvable by gradient descent (Li and Long 2002; Gentile 2001; Crammer and Singer 2003; Kivinen et al. 2004). Based on the experiments in Crammer and Singer (2003) and Crammer et al. (2006), the Passive-Aggressive algorithm outperforms most of the earlier online linear classification methods. Perceptron learning and most of its successors apply both to classification and regression; in other words, the range of the actual label y can be both binary and continuous.

The PA algorithm solves a constrained optimization problem: We would like the new classifier to remain as close as possible to the current one while achieving at least a unit margin on the most recent example. We use the Euclidean distance of the classifiers, $\|\mathbf{w} - \mathbf{w}'\|^2$. PA optimizes for hinge loss, with the goal to keep the distance minimal and the value of the margin at least 1, that is, to solve the optimization problem

$$\mathbf{w} \leftarrow \operatorname{argmin}_{\mathbf{w}'} \|\mathbf{w} - \mathbf{w}'\|^2 \text{ s.t. } \ell(\mathbf{w}; (\mathbf{x}, y)) = 0. \quad (5)$$

The algorithm is passive if loss is 0, and otherwise aggressive, since it enforces zero loss. As shown in Crammer et al. (2006), the solution of the optimization problem yields the update rule

$$\mathbf{w} \leftarrow \mathbf{w} + \ell(\mathbf{w}; (\mathbf{x}, y)) \cdot y \cdot \mathbf{x} / \|\mathbf{x}\|^2. \quad (6)$$

In Crammer et al. (2006), variants of PA are described that introduce a slack variable $\xi \geq 0$ in Eq. (5) such that the margin must stay below ξ . Adding constant times ξ or ξ^2 to the minimization target in Eq. (5) leads to similar optimization problems. In the same paper, multi-class, cost-sensitive, and regression variants are described as well.

Although the class of linear predictors may seem restrictive, the pioneering work of Vapnik (1998) and colleagues demonstrates that by using kernels one can employ highly nonlinear

predictors as well. The **support vector machine (SVM)** learns an optimal separating hyperplane \mathbf{w}^* in a certain high-dimensional mapped space defined by the mapping $\varphi(\mathbf{x})$ over training vectors \mathbf{x} . Like with perceptron learning, the prediction has the form $\hat{y} = \mathbf{w}^* \cdot \varphi(\mathbf{x})$; however, \mathbf{w}^* may be of very high dimensionality.

Potential problems of the very high-dimensional mapped space are eliminated by the **kernel trick**. In the optimization procedure, \mathbf{w}^* turns out to be the combination of the so-called support vectors, the subset SV of training instances \mathbf{x}_i for $i \in SV$ that maximize the margin. We can obtain the parameters

$$\mathbf{w}^* = \sum_{i \in SV} \alpha_i y_i \varphi(\mathbf{x}_i), \quad (7)$$

where y_i are the labels and α_i can be found by maximizing the margin. By Eq. (7), we can reduce the prediction to computing inner products in the mapped space:

$$\mathbf{w}^* \cdot \varphi(\mathbf{x}) = \sum_{i \in SV} \alpha_i y_i \varphi(\mathbf{x}_i) \cdot \varphi(\mathbf{x}), \quad (8)$$

The main goal of online SVM is to maintain a set of support vectors and corresponding multipliers within the limits of available memory. Whenever an online SVM learner decides to add new support vectors, others need to be discarded first, and α_i need to be updated.

To decide which support vector to discard, the definition of the span and the S-span of the support vectors defined by Vapnik and Chapelle (2000) can be used. The span of a support vector is the minimum distance of the vector from a certain set defined by all others. The S-span of a set of support vectors is the maximum span among them.

An online SVM method to update the set of support vectors from the data stream is proposed in Agarwal et al. (2008), namely, maintaining a set of support vectors and multipliers that fit into the memory limit. For a misclassified new instance, the algorithm measures the S-span of all possible ways of replacing one old support vector with the new instance and selects the best

one. Multipliers are updated by the incremental learning procedure of Cauwenberghs and Poggio (2000).

Several other, similar online SVM optimization methods are known, for example Crammer and Singer (2003), Crammer et al. (2004), Bordes and Bottou (2005), and Bordes et al. (2005). Online learning algorithms were also suggested as fast alternatives to SVM in Freund and Schapire (1999), based on the online algorithm for calculating the maximum margin linear model of Frie et al. (1998). Online gradient descent optimizers for linear models often work with kernels as well Kivinen et al. (2004).

Decision and Regression Trees

In a decision or regression tree, each internal node corresponds to a test on an attribute, while leaves contain predictors for classification or regression. To build a tree, decision tree induction algorithms iterate through each attribute and compute an information theoretic function such as entropy or Gini index for classification and variance for regression (Pang-Ning et al. 2006).

Online tree induction algorithms face the difficulty that the recursive tree construction steps cannot read past data. After a split decision is made, batch algorithms partition all data into child nodes and compute the required information theoretic function of the attributes separately in each child node. Online algorithms cannot partition past data; instead, they take advantage of the potentially infinite data and use fresh instances only in the newly created nodes.

Another problem with online tree construction is that a split decision has to be made at a certain point in time, without seeing future data. A popular solution is to use the Hoeffding criterion for a statistical guarantee that the selected split is optimal for future data as well. In the so-called Hoeffding tree or very fast decision tree (VFDT) (Domingos and Hulten 2000), attribute information theoretic functions are maintained over the stream. If the Hoeffding criterion is met, a split decision is made, and the attribute statistics over the new child nodes are computed based on

the new data from the stream. Similar methods for regression trees are described in Alberg et al. (2012) and Ikonomovska et al. (2015). For online vertical parallel distributed Hoeffding trees, see Kourtellis et al. (2016).

One problem in decision tree construction on streaming data is the cost of maintaining attribute statistics for many-valued attributes. For such attributes, a low granularity histogram has to be maintained. In Jin and Agrawal (2003), a method is described that partitions the range of a numerical attribute into intervals and uses statistical tests to prune these intervals.

Another difficulty is caused by nonstationary data, since each new child node is processed based on a new portion of data from the stream. Decision trees over evolving streams are considered in Bifet and Gavaldà (2009), Bifet (2010), and Bifet et al. (2017). We give an overview of general methods for nonstationary data in the chapter “► Reinforcement Learning, Unsupervised Methods, and Concept Drift in Stream Learning” of this Handbook.

Ensemble Methods

Ensemble methods build multiple, potentially different models on potentially different subsets of instances and attributes (Pang-Ning et al. 2006). The simplest example is **bagging** where several base models are trained based on samples with replacement. Sampling with replacement can be simulated online (Oza 2005; Bifet et al. 2010). A special ensemble technique, the online random forest algorithm, is described in Denil et al. (2013).

A highly successful ensemble technique is **boosting**, in which we generate a sequence of base models by incorporating the prediction error of the previous models when constructing the next. For example, in AdaBoost, an algorithm designed for online learning in its first description (Freund and Schapire 1995), the next classifier is trained by weighting instances based on the function of the error of previous classifiers. In gradient boosting (Chen and Guestrin 2012), the

next model is trained on the residual, that is, the difference of the training label and the continuous predicted label of the previous classifiers.

For online boosting, the difference compared to batch boosting is that the performance of a base model cannot be observed on the entire training set, only on the examples seen earlier. Like with online decision tree induction, decisions need to be taken based only on part of the training data. Various online boosting algorithms are described in Oza (2005), Chen et al. (2012), and Beygelzimer et al. (2015), based on the ideas of parallel boosting via approximation Fan et al. (1999), Palit and Reddy (2012), and Lazarevic and Obradovic (2002). For gradient boosted trees (Chen and Guestrin 2012), a recent, most successful classification method, the online version, is described in Vasiloudis et al. (2017).

Bayes Models

Bayesian networks were one of the earliest applications for online learning (Friedman and Goldszmidt 1997), with the first methods mostly using mini-batch updates (Buntine 1991). Bayesian learning methods maintain conditional probability tables $P(\mathbf{x}|y)$ by counting, where \mathbf{x} is a feature vector and y is its label. Considering the conditional probability tables and the class distribution as priors, the predicted class of an instance will be the one that maximizes the posterior probability computed by the Bayes rule (Pang-Ning et al. 2006).

The simplest, naive Bayes model makes the “naive” assumption that each input variable is conditionally independent given the class label (Duda et al. 2012). While this model works surprisingly well (Domingos and Pazzani 1997), a weaker assumption is needed in Bayesian networks (Pearl 2014), in which we represent each variable with a node in a directed acyclic graph. Rather than assuming independence naively, we assume that each variable is conditionally independent given its parents in the graph.

For online learning, it is easy to update the conditional probabilities both for naive Bayes and for Bayesian networks (Friedman and Goldszmidt 1997), provided that they fit into internal memory. Methods for updating the network structure online are described, for example, in Friedman and Goldszmidt (1997) and Chen et al. (2001).

Neural Networks

Neural networks and deep learning have shown great promise in many practical applications ranging from speech recognition (Hinton et al. 2012) and visual object recognition (Krizhevsky et al. 2012) to text processing (Collobert and Weston 2008). One of the earliest applications of online trained neural networks is EEG classification (Haselsteiner and Pfurtscheller 2000).

Gradient descent is perhaps the most commonly used optimization procedure for training neural networks (LeCun et al. 1998), which naturally leads to online learning algorithms (Juang and Lin 1998) as well. The traditional formulation of gradient descent is impractical for very large neural networks. A scalable online distributed version, Downpour SGD (Dean et al. 2012), uses asynchronous parameter updates in conjunction with a parameter server described in the chapter “► [Overview of Online Machine Learning in Big Data Streams](#)” of this Handbook.

²Department of Computer Science, Stanford University, Stanford, CA, USA

Synonyms

Incremental learning; Online machine learning on streams; Stream learning

Definitions

- Data stream algorithms process a continuous stream of data with only a limited possibility to store past records.
- Online machine learning covers methods that update their models after observing a new event and can immediately serve predictions based on the updated model.

Overview

In this chapter, we investigate online learning based recommender algorithms that can efficiently handle nonstationary datasets. We show that online learning for recommendation is rather usual than the exceptional task: For example, if no user history is available, we have to build a user model on the fly, based on the interactions in the live user session.

To the best of our knowledge, this is the first survey with a comprehensive overview of the ideas for recommendation over streaming data and their implementation in various distributed data stream processing systems.

The chapter is based on the notions of online learning, as introduced in the chapter “Overview of Online Machine Learning in Big Data Streams” of this Encyclopedia.

Introduction

Big data analytics promise to deliver valuable business insights. However, this is difficult to realize using today’s state-of-the-art technologies, given the flood of data generated from various sources. A few years ago, the term **fast data** (Lam et al. 2012) arose to capture the idea that **streams** of data are generated at very high rates and that these need to be analyzed quickly in order to arrive at actionable intelligence.

Fast data can flood from network measurements, call records, web page visits, sensor readings, and so on (Bifet et al. 2011). The fact that such data arrives continuously in multiple, rapid, time-varying, possibly

unpredictable, and unbounded streams appears to yield some fundamentally new research problems. Examples of such applications include financial applications (Zhu and Shasha 2002), network monitoring (Babu and Widom 2001; Abadi et al. 2003), security, sensor networks (De Francisci Morales et al. 2016), Twitter analysis (Bifet and Frank 2010), and more (Fontenla-Romero et al. 2013).

Traditional data processing assumes that data is available for multiple access, even if in some cases it resides on disk and can only be processed in larger chunks. In this case, we say that the data is **at rest**, and we can perform **batch processing**. Database systems, for example, store large collections of data and allow users to initiate queries and transactions.

Fast data or **data in motion** is closely connected to and in certain cases used as a synonym of the **data stream** computational model (Muthukrishnan et al. 2005). In this model, data arrives continuously in a potentially infinite stream that has to be processed by a resource-constrained system. The main restriction is that the main memory is small and can contain only a small portion of the stream; hence most of the data has to be immediately discarded after processing.

In one of the earliest papers that describe a system for data stream processing (Abadi et al. 2003), the needs of monitoring applications are described. The tasks relevant for monitoring applications differ from conventional processing of data at rest in that the software system must process and react to continuous input from multiple sources. The authors introduce the data active, human passive model, in which the system permanently processes data to provide alerts for humans.

Several surveys for online machine learning in general (Gaber et al. 2007, 2014; Bifet et al. 2011; Shalev-Shwartz et al. 2012; Fontenla-Romero et al. 2013) and subfields (Widmer and Kubat 1996; Tsymbal 2004; Cheng et al. 2008; Mahdiraji 2009; Quionero-Candela et al. 2009; Kavitha and Punithavalli 2010; Žliobaite et al. 2012; Aggarwal 2013; Silva et al. 2013; Gama et al. 2014) have appeared recently. Our survey

is different, first of all, in that we focus on three aspects: the data stream computational model, the adaptive methods for handling concept drift, and the distributed software architecture solutions for streaming. We also elaborate on systems for machine learning by distributed data stream processing. In particular, we explore the idea of using parameter servers.

In this chapter, we give an overview of distributed software architectures for online machine learning. The handbook contains three related chapters that describe specific areas of online machine learning. Online classification and regression is explained in “[Online Machine Learning Algorithms Over Data Streams](#),” recommendation in “[Recommender Systems Over Data Streams](#),” and finally additional topics in “[Reinforcement Learning, Unsupervised Methods, and Concept Drift in Stream Learning](#).”

Requirements for Machine Learning Over Fast Data Streams

Needs and opportunities for **machine learning over fast data streams** are stimulated by a rapidly growing number of industrial, transactional, sensor, and other applications (Žliobaite et al. 2012). The concept of online machine learning is summarized in one of the earliest overviews of the field (Widmer and Kubat 1996). In the data stream computational model, only a small portion of the data can be kept available for immediate analysis (Henzinger et al. 1998). This has both algorithmic and statistical consequences for machine learning: Suboptimal decisions on earlier parts of the data may be difficult to unwind and, if needed, require low memory sampling and summarization procedures. For data streaming applications, incremental or online learning fits best.

Requirement 1 Online learning updates its model after each data instance without access to all past data; hence the constraints of the data streaming computational model apply.

Data streaming is not just a technical restriction on machine learning: Fast data is

not just about processing power but also about fast semantics. Large databases available for mining today have been gathered over months or years, and the underlying processes generating them have changed during this time, sometimes radically (Hulten et al. 2001). In data analysis tasks, fundamental properties of the data may change quickly, which makes gradual manual model adjustment procedures inefficient and even infeasible (Žliobaite et al. 2012). Traditional, batch learners build static models from finite, static, identically distributed data sets. By contrast, stream learners need to build models that evolve over time. Processing will strongly depend on the order of examples generated from a continuous, nonstationary flow of data. Modeling is hence affected by potential concept drifts or changes in distribution (Gama et al. 2013).

Requirement 2 Adaptive machine learning models are needed to handle concept drift.

As an additional consequence of Requirement 2, adaptive learning also affects the way evaluation is performed. Potentially in every unit of time, the system may return predictions from different models, and we may receive too few predictions from a particular model to evaluate by traditional metrics. Instead, we have to define error measures that we can minimize in a feedback system: Predictions are made for a stream of objects one by one, and the correct answer is received immediately afterward. A discrepancy between the prediction and the observed value serves as feedback, which may immediately trigger modifications to the model (Widmer and Kubat 1996).

Finally, the third important aspect for online learning from big data is algorithmic. In order to cope with the volume of the data, processing has to be distributed. Clusters of machines are hard to manage, and hardware failure must be mitigated in the case of an application running on thousands of servers. Map-Reduce (Dean and Ghemawat 2008) was the first programming abstraction designed to manage the cluster, provide fault tolerance, and ease software development and

debugging. While Map-Reduce is designed for batch processing, distributed data stream processing needs other solutions, such as communication between processing elements (Neumeyer et al. 2010) via an interconnection topology (Toshniwal et al. 2014). For an outlook, mostly batch distributed data mining solutions are surveyed in Fan and Bifet (2013).

Requirement 3 Online learning from big data has to be implemented in a distributed stream processing architecture.

Data-intensive applications often work in the data stream computational model (Babcock et al. 2002), in which the data is transient: Some or all of the input data is not available for random access from disk or memory. The data elements in the stream arrive online and can be read at most once; in case of a failure, it is possible that the data elements cannot be read at all. The system has no control over the order in which data elements arrive to be processed either within a data stream or across data streams.

The strongest constraint for processing data streams is the fact that once an element from a data stream has been processed, it has to be discarded or archived. Only selected past data elements can be accessed by storing them in memory, which is typically small relative to the size of the data streams. Many of the usual data processing operations would need random access to the data (Babcock et al. 2002): For example, only a subset of SQL queries can be served from the data stream. As surveyed in Muthukrishnan et al. (2005), data stream algorithms can tackle this constraint by a variety of strategies, including adaptive sampling in sliding windows, selecting representative distinct elements, and summarizing data in low memory data structures, also known as sketches or synopses.

When designing online machine learning algorithms, we have to take several algorithmic and statistical considerations into account. The first problem we face is the restrictions of the computational model. As we cannot store all the input, we cannot unwind a decision made on past data. For example, we can use statistical tests to choose from competing hypotheses (Domingos

and Hulten 2000), which give theoretical guarantees in the case of identically distributed data.

A second problem with real stream learning tasks is that data typically changes over time, for example, due to concept drifts (Widmer and Kubat 1996). For changing distributions, we can even use the streaming computational model to our advantage: By permanent training, we can adapt to concept drift by overwriting model parameters based on insights from fresh data and thus forgetting the old distribution (Frigó et al. 2017). Possible means of concept drift adaptation, however, will depend on the task, the data, and the choice of the algorithm (Widmer and Kubat 1996; Klinkenberg and Joachims 2000).

In this chapter, we give a brief overview of how different, mostly open source, software projects manage machine learning tasks over streaming data. We note that very active, ongoing research in the field may make parts of our description obsolete very quickly. First, in section “[Data Stream Processing Engines](#),” we provide a summary of the most important distributed data stream processing engines with active development at the time of writing. Next, in section “[Taxonomy of Machine Learning Tools](#),” we give a taxonomy of the possible machine learning solutions with respect to support from streaming data and distributed processing. Since operation on shared-nothing distributed architectures is a key requirement for big data processing solutions, we discuss the main machine learning parallelization strategies in section “[Parallel Learning and the Parameter Server](#).“ One particularly popular solution, the parameter server is also described in more detail. Finally, in section “[Stream Learning Libraries](#),” we list functionalities of stream learning libraries as of the time of writing.

Data Stream Processing Engines

Distributed stream learning libraries are usually either part of **data stream processing engines (DSPEs)** or built on top of them through interfaces. For a better understanding of the software architecture, we give an overview of DSPEs next.

Since the emergence of early systems such as Aurora (Abadi et al. 2003; Arasu et al. 2003), several DSPEs have been developed. For a survey of DSPEs, see Ranjan (2014). The main focus of the most recent evolving DSPEs is to provide simplicity, scalability, stateful processing, and fault tolerance with fast recovery. In terms of simplicity, the most important goal is to overcome the need to integrate the DSPE with a batch processing engine as in the so-called lambda architecture described, among other places, in Marz and Warren (2015) and Kiran et al. (2015).

In this section, we focus on Apache Spark (Zaharia et al. 2010) and Apache Flink (Carbone et al. 2015), since at the time of writing, these DSPEs have the most active development for learning from streams. Other systems usually provide machine learning functionalities by interfacing with SparkML, a Spark-based machine learning library, or SAMOA (Morales and Bifet 2015), a stream learning library designed to work as a layer on top of general DSPEs. We list the functionality of these systems in section “[Stream Learning Libraries](#).”

Without attempting to be exhaustive, we list some other main DSPEs. Note that this field is very active, and several systems with large impact on both DSPEs and stream learning have already stopped development. For example, several active projects have borrowed concepts from the **S4 project** (Neumeyer et al. 2010), which retired in 2014. Proprietary systems are summarized in Gualtieri et al. (2013); it appears to be the case that commercial developers as of yet have no special focus on data stream processing; hence our main goal is to give an overview of the open source solutions.

Storm (Toshniwal et al. 2014) relies on the concept of the connection topology of the processing elements. The topology is allowed to contain cycles; however, in case of a failure with cycles, neither the exactly-once nor the at-least-once processing condition can be enforced. **Samza** (Noghabi et al. 2017) provides a design for fast recovery after failures independent of the state size. As a new advantage, stateful streaming systems have the possibility to emulate batch operation; hence the need for the lambda

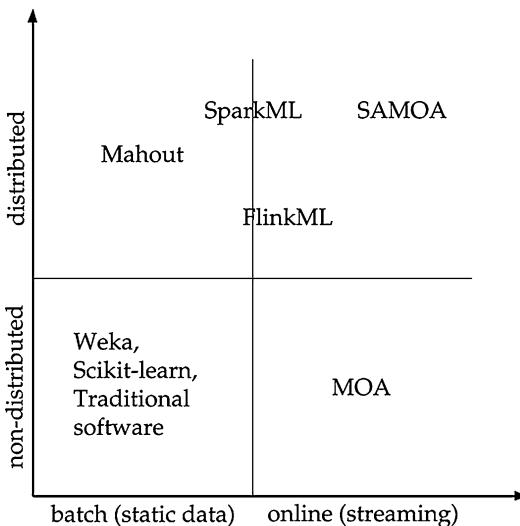

architecture can be eliminated. **Beam** (Akidau et al. 2015), based on the Google Cloud dataflow model (Chambers et al. 2010; Akidau et al. 2013, 2015), focuses on event time windows to process out-of-order data. Beam can be connected to the deep learning framework TensorFlow (Dean et al. 2012) for batch machine learning. Finally, while most of the above systems are distributed, we mention Esper (Bernhardt and Vasseur 2007) as a prominent single machine, in-memory DSPE.

One DSPE in the focus of this article, **Spark** (Zaharia et al. 2010) treats stream processing as a sequence of small batch computations. Records in the stream are collected into micro-batches (by time), and a short-lived batch job is scheduled to process each micro-batch. The advantage of this approach is its intuitive transition from batch to streaming with straightforward fault tolerance and interaction with batch programs. The main disadvantage is higher latency due to the inherent scheduling overhead for the micro-batch.

Another DSPE of our choice, **Flink** (Carbone et al. 2015) provides consistent managed state with exactly-once guarantees while achieving high throughput and low latency, serving both batch and streaming tasks. Flink handles the stream event by event in a true streaming fashion through the underlying streaming (dataflow) runtime model. While this provides more fine-grained access to the stream, it does not come with a throughput overhead due to various runtime optimizations such as buffering of output records. The advantages are very low processing latency and a natural stateful computational model. The disadvantages are that fault tolerance and load balancing are more challenging to implement. Flink is primarily for stream processing. Flink batch tasks can be expressed by using loops in stream processing, as we will see in the next section.

Taxonomy of Machine Learning Tools

In this article, we survey online machine learning tools for big data. Our main focus are models, architectures, and software libraries that process

Online Machine Learning in Big Data Streams: Overview, Fig. 1 Taxonomy of machine learning tools

streaming data over distributed, shared-nothing architectures. As shown in Fig. 1, the two key distinguishing features of machine learning tools are whether they are distributed and whether they are based on static or streaming data.

As the least restrictive of the four quadrants in Fig. 1, **batch non-distributed** tools can implement any method from the other quadrants. If scale permits, data streams can first be stored and then analyzed at rest, and distributed processing steps can be unfolded to run sequentially on a single-processor system. Traditional machine learning tools, for example, R, Weka, and scikit-learn, fall into this quadrant.

Distributed batch machine learning systems (Fan and Bifet 2013) typically implement algorithms by using the Map-Reduce principle (Dean and Ghemawat 2008). Perhaps the best-known system is Mahout (Owen et al. 2011) built on top of Hadoop (White 2010), but a very rich variety of solutions exists in this field. GraphLab (Low et al. 2012), withdrawn from the market in 2016, was another mostly batch tool that has also influenced online systems.

Online learning solutions cover algorithms that immediately build models after seeing a relatively small portion of the data. By this require-

ment, we face the difficulty of not necessarily being able to undo a suboptimal decision made in an earlier stage, based on data that is no longer available for the algorithm.

The first library for online machine learning, MOA (Bifet et al. 2010) collects a variety of models suitable for training online, most of which we describe in the “[Online Machine Learning Algorithms Over Data Streams](#)” chapter of this handbook. Based on MOA concepts, SAMOA (Morales and Bifet 2015) is a distributed framework – a special purpose DSPE – and library that provides distributed implementation for most MOA algorithms. Online learning recommender systems, both distributed and nondistributed, are also described in Pálovics et al. (2017). Another recent nondistributed online learning tool is described in Bifet et al. (2017).

For a **distributed online learning** software architecture, the underlying system needs to be a DSPE. In addition to SAMOA, which can be considered a DSPE itself, most DSPEs of the previous section can be used for distributed online learning. For example, Flink, Samza, and Storm implement interfaces to use SAMOA libraries. On the other hand, a DSPE can also implement batch machine learning algorithms: For example, the machine learning library SparkML is mostly batch and FlinkML is partly batch.

Combined batch and online machine learning solutions are of high practical relevance. We can train our model batch based on a precompiled sample and then apply prediction for a live data stream. DSPE solutions are progressing in this area. One recent result, Clipper is a low-latency online prediction system (Crankshaw et al. 2017) with a model abstraction layer that makes it easy to serve pre-trained models based on a large variety of machine learning frameworks.

Another batch approach to learning from time-changing data is to repeatedly apply a traditional learner to a sliding window of examples: As new examples arrive, they are inserted into the beginning of the window. Next, a corresponding number of examples are removed from the end of the window, and the learner is reapplied, as in early research on concept drift in learning

from continuous data (Widmer and Kubat 1996; Hulten et al. 2001). Finally, as a combination with online learning methods, the batch-trained model can be incrementally updated by a streaming algorithm (Frigó et al. 2017).

Parallel Learning and the Parameter Server

In order to design distributed modeling algorithms, we have to elaborate on parallelization strategies. **Horizontal** or **data parallel** systems partition the training data and build separate models on subsets that may eventually get merged. Such a solution is applied, for example, for training XGBoost trees (Chen et al. 2016). This approach, however, will typically depend on the partitioning and lead to heuristic or approximate solutions.

Vertical parallel or model parallel training

solutions partition across attributes in the same data point, rather than partitioning the training data coming from the stream. Each training point is split into its constituting attributes, and each attribute is sent to a different processing element. For example, for linear models trained by gradient descent, coefficients can be stored and updated by accessing a distributed store (Li et al. 2014a). As another example, the fitness of attributes for a split in a decision tree construction can be computed in parallel (Morales and Bifet 2015). Further examples such as TensorFlow (Dean et al. 2012), Petuum (Xing et al. 2015), and MXNet (Chen et al. 2015) are also capable of model parallel training. The drawback is that in order to achieve good performance, there must be sufficient inherent parallelism in the modeling approach.

The **parameter server** introduced in Smola and Narayananurthy (2010) is a popular way to implement model parallel training, with several variants developed (Ho et al. 2013; Li et al. 2013, 2014a,b), including an application for deep learning (Dean et al. 2012). The main idea is to simplify the development of distributed machine learning applications by allowing access to shared parameters as key–value pairs. As shown

in Fig. 2, the compute elements are split into two subsets: Parameters are distributed across a group of **server nodes**, while data processing and computation are performed at **worker nodes**. Any node can both push out its local parameters and pull parameters from remote nodes. Parallel tasks are typically asynchronous, but the algorithm designer can be flexible in choosing a consistency model.

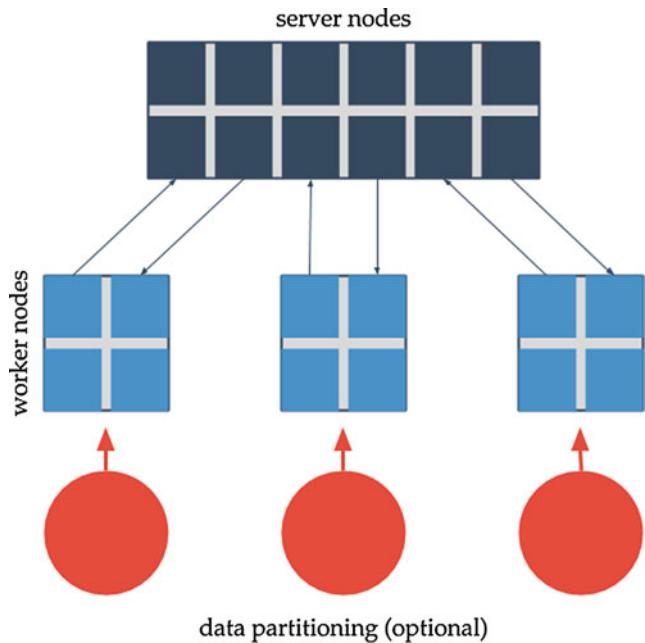

Various parameter server systems are summarized best in Li et al. (2014a). The first generation (Smola and Narayananurthy 2010) uses distributed key-value stores such as Memcached (Fitzpatrick 2004) to store the parameters. More recent solutions (Dean et al. 2012; Li et al. 2013) implement specific parameter access interfaces. For example, as the first step toward a general platform, (Ho et al. 2013) design a table-based interface for stale synchronous operation, which they use to implement a wide variety of applications.

Most results (Smola and Narayananurthy 2010; Ho et al. 2013; Li et al. 2014a) describe parameter servers for variants of regression as well as unsupervised modeling by latent Dirichlet allocation. Another popular use is classification by deep neural networks (Dean et al. 2012; Li et al. 2013). An implementation for Multiple Additive Regression Trees is given in Zhou et al. (2017).

Recommendation algorithms can also be implemented by the parameter server principle. Batch implementations of asynchronous distributed stochastic gradient descent recommender algorithms are given in Ho et al. (2013) and Schelter et al. (2014). A recent comparison of distributed recommenders, including an online one based on a Flink parameter server, is given in Pálovics et al. (2017).

The parameter server idea fits the data stream as well as the batch computational models. For example, if it suffices to read the data only once and in input order for gradient descent, a batch parameter server such as in Li et al. (2014a) immediately yields a streaming algorithm. Yet, most applications are for batch modeling only (Smola and Narayananurthy 2010; Ho et al. 2013; Li et al. 2014a; Schelter et al. 2014; Zhou et al.

Online Machine Learning in Big Data Streams: Overview,
Fig. 2 The parameter server architecture for distributed machine learning

2017). As examples of parameter servers for online learning, applications for reinforcement learning can be found in Nair et al. (2015) and for recommenders in Pálovics et al. (2017).

Stream Learning Libraries

We provide an overview of the present machine learning functionalities of the main open source engines. Note that all these engines are under active development with a very large number of components already available as research prototypes or pull requests. For this reason, we only want to give a representative overview of the main components.

MOA and SAMOA

SAMOA (Morales and Bifet 2015), a distributed online learning library, is based on the concepts of MOA (Bifet et al. 2010), a single machine library. SAMOA provides model parallel implementations of specific algorithms by using the concepts of Storm (Toshniwal et al. 2014): Processing elements are connected in a loop-free topology, which connects the various pieces of user code. SAMOA can run on top of a DSPE

with a flexible interface connection. SAMOA connectors are implemented for all active DSPEs in section “Data Stream Processing Engines.”

For classification, SAMOA (De Francisci Morales 2013; Morales and Bifet 2015) provides the Vertical Hoeffding Tree (VHT), a distributed version of a streaming decision tree (Domingos and Hulten 2000). For clustering, it includes an algorithm based on CluStream (Aggarwal et al. 2003). The library also includes meta-algorithms such as bagging and boosting.

Apache Spark

Spark has a very rich set of batch machine learning functionalities, including linear, tree, support vector machine, and neural network models for classification and regression, ensemble methods as well as explicit and implicit alternating least squares for recommender systems, and many more listed at <https://spark.apache.org/mllib/>. However, the only streaming algorithm in Spark MLLib is a linear model with ongoing work regarding online recommender and latent Dirichlet allocation prototypes. Spark has no SAMOA connector yet.

Spark has several parameter server implementations, most of which are batch only. We men-

tion two projects with recent activity. Glint is a parameter server-based latent Dirichlet allocation implementation, which is described in Jagerman et al. (2017). Angel is a general parameter server (Jiang et al. 2017) that has implementations for logistic regression, SVM, matrix factorization, latent Dirichlet allocation, and more. Angel supports synchronous, asynchronous, and stale synchronous processing (Jiang et al. 2017).

Apache Flink

Flink has a loosely integrated set of machine learning components, most of which are collected at <https://github.com/FlinkML>. In addition to the SAMOA connector at <https://github.com/apache/incubator-samoa/tree/master/samoa-flink>, Flink has a true streaming parameter server implementation at <https://github.com/FlinkML/flink-parameter-server>, which includes a Passive Aggressive classifier and gradient descent matrix factorization. Finally, Flink can serve online predictions by models trained on any system supporting the PMML standard (Grossman et al. 2002), using the JPMMML library at <https://github.com/FlinkML/flink-jpmmml>.

In Flink, the parameter server is implemented as part of the data stream API at <https://github.com/FlinkML/flink-parameter-server>. Since the communication between workers and servers is two-way, the implementation involves loops in stream processing. As mentioned in section “[Data Stream Processing Engines](#),” exactly-once processing and fault tolerance are conceptually difficult, and implementation is not yet complete as of the time of writing (Carbone et al. 2017).

Conclusions

In this chapter, we provided an overview of the general requirements for online machine learning. Some algorithms are described in more details in three more chapters of this handbook, including “[Online Machine Learning Algorithms Over Data Streams](#)”; “[Reinforcement Learning, Unsupervised Methods, and Concept Drift in Stream Learning](#)”; and “[Recommender Systems Over Data Streams](#)”.

This article is a reference material and not a survey. We do not attempt to be comprehensive in describing all existing methods and solutions; rather, we give pointers to the most important resources in the field. All related subfields, online algorithms, online learning, and distributed data processing are hugely dominant in current research and development with conceptually new research results and software components emerging at the time of writing. In this article, we refer to several survey results, both for distributed data processing and for online machine learning.

Ontologies for Big Data

Eva Blomqvist
Linköping University, Linköping, Sweden

Synonyms

Classically, in AI, ontologies were considered a form of knowledge representation and frequently

denoted knowledge models. More recent near-synonyms include the term *vocabulary*, which is usually used for expressive ontologies on the Web that are used as vocabularies for online datasets. Even more recently the term *knowledge graph* has gained increased popularity. It can be viewed as a more general term, since a knowledge graph does not necessarily have to be an ontology; however, most ontologies could be considered to be knowledge graphs.

Overview

This chapter introduces the concept of ontology, in the context of computer science and in particular Big Data. First, some terminology is introduced and the concept is defined. Further, some background and history of ontologies in computer science is presented. Next, common representation formats and standards are introduced, followed by a discussion on methods for constructing, finding, and reusing ontologies. The chapter is concluded by discussing the contribution of ontologies to Big Data solutions, as well as current research challenges for ontologies.

Definitions

An ontology in the computer science field can be defined as “a set of representational primitives with which to model a domain of knowledge or discourse” (Gruber 2009), where such primitives include concepts (or classes) and relations (attributes, properties, or other relations between entities). It is also commonly described as a formal specification of a shared conceptualization. Where a conceptualization is an abstract representation of some actual phenomenon or state of affairs, e.g., the concept of cat is usually understood by everyone, that conceptualization is a different thing from the actual cats that exist in the world that are probably not even aware of being grouped under that abstract concept. Formal means that it should be represented in some machine interpretable language with well-defined semantics, most commonly a logic-based

language that facilitate some logical reasoning over the models. Specification refers to that it contains definitions, perhaps in the form of logical axioms, of the concepts it is comprised of. Finally, shared means that it should usually not represent only the viewpoint of a single individual, but rather be shared among users and/or system instances within some domain and/or for some specific task.

Background and Origin

The term ontology originates in ancient Greek, where *on* (genitive *ontos*) is the verb “being” and *logia* (originally derived from *logos*) is the term for “science” or “study” ([Nationalencyklopedien](#)). Ontology as a term could thereby be interpreted as “the study of being,” and since the seventeenth century, the term *ontology* has been used to denote the field of metaphysics devoted to the study of the nature of being (Simons [2009](#)). In more recent times, the term ontology has been adopted by the computer science field and now denotes a formal structure that explicitly specifies the concepts existing within some domain or related to a specific application. In contrast to the original meaning, ontologies are today often used in a less prescriptive way, i.e., ontologies in computer science do not primarily deal with the inner “true” nature of reality; instead they are a means of *describing* a domain specifically tailored for a task at hand, i.e., to be used as a knowledge representation within some computer system.

Even in the field of computer science, there are however numerous definitions of the term ontology in the literature, still today existing in parallel. Apart from the one referenced above, in the definitions section, among the most commonly used definitions we find:

- “An ontology is an explicit specification of a conceptualization.”(Gruber [1993](#))
- “An ontology is a formal, explicit specification of a shared conceptualization.” (Studer et al. [1998](#))
- “An ontology is a logical theory accounting for the intended meaning of a formal vocab-

ulary, i.e., its ontological commitment to a particular conceptualization of the world. The intended models of a logical language using such a vocabulary are constrained by its ontological commitment. An ontology indirectly reflects this commitment by approximating these intended models.” (Guarino [1998](#))

An ontology corresponds to a specific *domain* of knowledge, it has a scope and is thereby focused on describing a certain domain (although sometimes the domain can be very broad, and sometimes as narrow as a single software application). The domain can be an industry domain, an enterprise, a research field or any other imaginable restricted set of knowledge, whether abstract, concrete or even imagined or envisioned. Additionally the ontology is constructed with a certain *usage* in mind, this usage target sets additional restrictions on the content and structure of the ontology. An ontology may, for example, be used to classify instances, check consistency, or answer queries, but on the other hand, there may be different kinds of uses, like communicating and sharing precise definitions of terms within a community of human practitioners. The nature or the intended use sets requirements on the content and structure of the ontology.

Formally, an ontology that is represented in a logical language is simply a set of logical axioms expressed in that language. However, in practice, it is often useful to think about an ontology as consisting of a set of basic building blocks. The most basic building blocks of an ontology are its concepts, also commonly denoted *classes*. There is no consensus around the definition of what an ontology concept really is, but generally a concept can be seen as having three parts (according to Cimiano [2006](#)):

- an intentional definition,
- an extension,
- a set of lexical realizations.

Where the intentional definition is a definition or description of the meaning of the concept, sometimes this is simply represented as a natural language description of the concept but could

also be the logical axioms involving the concept. The extension contains the instances of the concept, the set of members of this category of entities, and the set of objects that exemplify the notion represented by the concept. The set of lexical realizations is a set of terms that may be used to represent the concept, e.g., both the terms “packet” and “parcel” may be used to represent the conceptual notion of a package in some ontology. Sometimes a lexical realization is also called a label of the concept, the concept may thereby have a set of alternative labels, and the labels may very well be from different languages.

Another basic element is the relation. A relation is some kind of association that exists between two or more instances, although in most cases ontology representation languages restrict this to modelling only binary relations. In general a relation can be viewed as a tuple of instances, but the properties of the relation should be described in the ontology. One such description can be some lexical realizations of the relation, i.e., relation labels, and possibly a set of axioms determining the semantic interpretation of the relation. For example, the special type of relation usually denoted subsumption, taxonomical relation, or “subclass of” has several lexical realizations, such as “subsumption,” “subclass-of,” and “is_a.” This type of relation additionally comes with some specific semantics, for example, the relation is commonly defined to be transitive, and its domain and range can usually be any concept in an ontology. For specific types of relations, such as the “subclass-of,” that are predefined in many ontology representation languages, these semantics are inherent in the semantics of the logical language, but for other relations, they need to be specified explicitly in the ontology, if needed for some reasoning task.

Ontologies can also be classified from the point of view of their level or generality, as described by Guarino (1998). Top-level ontologies describe general concepts like space and time, which are most often independent of application domains and specific problems. These ontologies can be shared by large communities. Examples of top-level ontologies include DOLCE (<http://www.loa.istc.cnr.it/old/DOLCE.html>)

and its more popular ultra-light version DUL (http://ontologydesignpatterns.org/wiki/Ontology:DOLCE+DnS_Ultralite), SUMO (<http://www.adampease.org/OP/>), BFO (<http://ontology.buffalo.edu/bfo/>), and CYC (<http://www.cyc.com/>). Domain ontologies describe a vocabulary of a specific domain and are sometimes specializations of top-level ontologies. Task ontologies in turn describe the vocabulary of a generic task or activity and may also be specializations of top-level ontologies. Finally, an application ontology is a specialization of a domain ontology adapted for a specific application or task.

Another classical distinction was the separation between the ontology and its knowledge base or in logical terms between the TBox and the ABox. While earlier this was a clear distinction, today, and in particular on the Web, this distinction has been blurred. Today ontology and knowledge base is used almost interchangeably, and an ontology can many times be comprised of both concepts and instances, i.e., both TBox and ABox. Instead the distinction is made between ontologies and datasets, where ontologies are seen as the schemas that describe the content of the dataset, but where this schema can also contain sets of instances. An example of such a case would be an ontology that models a set of codes used in the data as instances of an ontology concept. In this case, the codes and the description of their intended meaning is seen as part of the ontology, regardless if they are modelled as individuals or classes. The codes are then referenced and used in the dataset.

Ontology Representation and Reasoning

Many different logical formalisms exist for representing and reasoning with ontologies, each one having its own benefits and drawbacks. The choice of representation should be made based on the requirements of the ontology, but additionally things like standardization and tool availability may influence such a decision. In the early days of ontology engineering, two different traditions

co-existed; while some people preferred frame-style logics that are more closely related to traditional information modelling, others preferred to use description logics (DL) related formalisms. However, with the emergence of the Semantic Web community in the early 1900s, and the W3C standards emerging from that, the predominant formalism is now DLs, and most commonly the W3C recommendation OWL (Web Ontology Language) (OWL Working Group 2012). Nevertheless, other languages (and OWL extensions) for specific purposes, such as temporal reasoning, fuzzy, or probabilistic reasoning, have also emerged but are much less common in practical applications.

The Resource Description Framework (RDF) (RDF Working Group 2014) is another W3C recommendation, for representing data and metadata about resources on the Web, or, for instance, to represent the data associated with an OWL ontology. The RDF model is based on triples, consisting of a subject, a predicate, and an object. This is how we can talk about resources in RDF, i.e., state facts, through expressing triples connecting the resource to other resources or literals, i.e., forming an RDF graph. URIs are used to identify resources; hence, this is a Web-targeted formalism, but which can equally well be used in other settings. RDF has several serializations, e.g., both an XML syntax (Gandon et al. 2014) and several more human readable formats, such as turtle (Beckett et al. 2014), into which also OWL ontologies can be serialized.

RDF Schema (RDFS) (Brickley et al. 2014) is an extension of RDF for defining schemas to be used by RDF data. With RDFS one can build a simple ontology, for example, defining named classes (concepts) using `rdfs:Class` and a taxonomy of classes using `rdfs:subClassof`. OWL builds on RDF(S) in the sense that it extends the RDFS syntax with further features but additionally restricts RDFS to make automated reasoning feasible. Both OWL and RDFS can syntactically be represented as an RDF graph.

For performing automated reasoning over OWL ontologies, a number of inference engines exist, where one list is maintained by the

W3C (2016). Many triple stores, i.e., database management systems tailored for storing and serving RDF data, also include inference engines supporting subsets of the OWL language. Due to its DL roots and its focus on the open Web, OWL has however a number of specific features that have been criticized throughout the years. This includes, for instance, the open-world assumption, which makes the OWL semantics unintuitive to many people more familiar with traditional relational databases or information modelling and which makes it complex and sometimes unfeasible to perform constraint checking over data. Therefore, a W3C working group recently published a new recommendation, the RDF Shapes Constraints Language (SHACL) (Knublauch and Kontokostas 2017). The language is intended for describing RDF data, as well as checking constraints over those data, i.e., an area that is poorly covered by the OWL language. Although it can be debated if SHACL should be considered an ontology language or not, it is nevertheless certainly an important complement to OWL when describing and reasoning over data.

Ontology Engineering and Reuse

Methodologies for creating ontologies have existed as long as ontologies have been used in the context of AI. Traditionally, such methodologies were based on knowledge engineers performing some kind of knowledge acquisition directly from domain experts and then formalizing this knowledge into an ontology. Most early methods were “manual” in the sense that they did not rely on any tool support or automated processes. In the 1990s and 2000s, there were many attempts at drawing from software engineering in order to somewhat formalize and structure such methodologies. Examples of commonly referenced ontology engineering methodologies include METHONTOLOGY (Fernández et al. 1997), ontology development 101 (Noy and McGuinness 2001), the method for developing enterprise ontologies by Grüniger and Fox (1995) (also the first to introduce the notion of

competency questions as ontology requirements), and the NeOn family of methods (Suárez-Figueroa et al. 2012). More recent methodologies commonly focus on an agile process, such as eXtreme Design (Blomqvist et al. 2016), or on the iterative evolution of ontologies, such as DILIGENT (Pinto et al. 2009).

For building ontologies, several tools have been proposed during the past decades (see also the list by W3C 2016); however, today two tool suites could be viewed as the most popular and widely used; the Protégé tool suite (including both the desktop version and the online collaborative WebProtégé environment) and TopBraid Composer as part of TopQuadrant's suite of tools. While the latter is commercial and provides many features and components also related to managing and transforming RDF data, the former is open source and targeted entirely at OWL ontologies, but with a large user community and many interesting tool plugins.

Another popular approach is, rather than building an ontology by hand, to try to derive ontologies from other resources. There is a large body of work on deriving ontologies from other structured sources, such as XML schemas, relational databases, tables and CSV-files, etc. Other approaches try to derive ontologies automatically from unstructured sources, such as natural language texts, so-called ontology learning. Although many approaches have been proposed, there is still a gap in terms of building a suitable ontology for a set of requirements out of such resources; hence, such learned ontologies are only suitable for certain tasks and will usually produce quite shallow and logically inexpressive ontologies, i.e., rather lists of terms or simple taxonomies than expressive OWL models.

There are many best practices available when constructing and publishing ontologies. Some have emerged in the form of Ontology Design Patterns (Hitzler et al. 2016), while others are included in documents describing how to publish and manage your Web data (Dodds and Davis 2012) and W3C guideline documents (Kendall et al. 2008) or as part of the language recommendations themselves.

When reusing existing large ontologies, a common task is also to align two or more ontologies. Ontology matching and alignment (Euzenat and Shvaiko 2013) is the task of finding correspondences, e.g., overlap or relations, between the ontologies. A number of automated approaches have been proposed for this task, but in the end, it is usually recognized that a human expert needs to be involved to validate the produced alignment, check for problems, and repair issues found.

Commonly Used Vocabularies

As mentioned earlier, for a very specific use case, it is rare to find one ontology or a set of ontologies, that completely cover all the requirements. Nevertheless, there are some standard ontologies that are frequently reused and extended, which are worth mentioning. The W3C has in recent years chosen to recommend a set of vocabularies for data on the Web. This set includes:

- The RDF data cube vocabulary (<https://www.w3.org/TR/vocab-data-cube/>) – intended for representing multi-dimensional data on the web using RDF, such as large statistical datasets.
- The Prov-O (<https://www.w3.org/TR/prov-o/>) – intended for representing provenance about data on the Web.
- The data catalogue vocabulary DCAT (<https://www.w3.org/TR/vocab-dcat/>) – intended for representing metadata about a dataset or catalogue.
- The organization ontology (<https://www.w3.org/TR/vocab-org/>) – intended as a common vocabulary for publishing data about organizations.
- The time ontology (<https://www.w3.org/TR/owl-time/>) – intended for expressing temporal concepts in a standardized manner.
- The Semantic Sensor Network ontology (SSN) (<https://www.w3.org/TR/vocab-ssn/>) – intended for representing information about sensor data and IoT systems, such as data about observations and the sensors that made the observations.

In addition, the standardization organization OGC has also published a standard for representing and querying geographical data on the Web, GeoSPARQL (<http://www.opengeospatial.org/standards/geospqrql>), which includes a vocabulary for representing geographical features and their attributes.

Apart from standard vocabularies, there are also numerous well-known ontologies, such as the top-level (upper) ontologies mentioned earlier, as well as specific reference ontologies in various domains, such as Snomed-CT (<https://www.snomed.org/snomed-ct>) and the Gene ontology (<http://www.geneontology.org/>) in the medical field. A collection of such vocabularies, with references to their usage, can be found at the Linked Open Vocabularies site (<http://lov.okfn.org/dataset/lov/>). However, there are also domain specific catalogues available, such as BioPortal for the biomedical domain (<https://bioportal.bioontology.org/>).

Ontology Usage for Big Data

Ontologies can be used for many tasks. While, in the earlier days of AI, ontologies were often used in isolation, providing the logical machinery for some reasoning task that was central to the application, such as an expert system, today most ontologies are used in combination with large datasets and potentially other classes of methods, such as natural language processing (NLP) or machine learning (ML) approaches. A few of the tasks for which ontologies can be applied include:

- Data integration – acting as a unifying model for representing and linking diverse datasets.
- Data access – acting as vocabularies for understanding and querying datasets, regardless whether those datasets are integrated and stored in one place or queries are simply translated and distributed to the original data sources, as well as allowing for graph traversal to explore and analyze the datasets.
- Semantic search – providing the opportunity to refine or expand a keyword query in a structured manner or translating a search query into a structured query over a dataset.

- Data analysis, cleaning, and constraint checking – providing logical axioms for performing data analysis, allowing analytical queries, or checking quality or other constraints over data.
- Reasoning for deriving new information – providing logical axioms for deriving relevant conclusions from the available data.
- Semantic similarity computations – allowing for computing the similarity between individual data (or ontology) elements, as well as sets of elements representing, for instance, the attributes of an entity.
- Ontology-based information extraction – supporting the extraction of new structured information from natural language text, for populating its knowledge base or another dataset.
- Integration with ML approaches – ontologies can, for instance, be used as a structure of the potential input features of a ML method or provide the output structure, e.g., classes, to which some input is automatically classified.

When working with diverse data sources on the Web, there are two main directions of approaches for integrating data, i.e., usually depending on whether data will be transformed into a common format, loaded and stored in a central storage, or if data is to still be kept in distributed storage facilities and only accessed through a common interface. In the former case, a common pattern is to create (or reuse) a shared unifying ontology (or several ontologies), into which all the data to be loaded is mapped and then transformed into a common format, such as RDF. Data can then be stored and retrieved from a single storage and queried by referring to the unifying ontology (or ontologies). However, when considering big data, this will rarely be a feasible approach, i.e., to load all the data into the same storage (even if a distributed one). Another approach is then to instead simply map relevant parts of the schemas or data models of the original data sources into the common unifying ontology (or ontologies) and to use these

mappings for generating queries to the original data sources, based on any query or reasoning task expressed over the unifying ontology (or ontologies). Approaches in this direction can today be found under the label ontology-based data access (OBDA). Several mapping languages exist, for instance, between relational models and ontologies, such as the R2RML (a W3C recommendation) (Das et al. 2012). However, this is still an area of active research, especially when it comes to efficiency of query distribution and execution over diverse sources.

Apart from this, ontologies are already used in large-scale settings on the Web under the term *knowledge graphs*. The most prominent example of this, and the application that popularized the term knowledge graph, is of course the Google knowledge graph (Singhal 2012). The Google knowledge graph is an ontology coupled with a large dataset, used to interpret queries and enrich returned results in the Google search engine. The Google knowledge graph contains a general-purpose ontology, intended to cover all possible domains of interest, but clearly focused on common entity categories, such as persons, organizations, places, events, etc. When such a category of interest is discovered from a search query, Google is able to use the knowledge graph to “understand” what kind of answers the user is looking for, and reply in a more precise manner, rather than a simple list of pages with snippets. For instance, when searching for a famous person on Google, the result usually contains an additional small table with data about that person, next to the usual hit list with pages. This is generated based on the knowledge graph. Following the example of Google, recently many other large companies have tried a similar path, creating their own knowledge graphs, such as Facebook’s experiments with their Graph Search (Olanoff et al. 2013), Microsoft’s entity engine (Lardinois 2014), and lately developing enterprise knowledge graphs at Siemens (Fishkin 2018). Even before Google announced their knowledge graph, IBM had already used similar approaches, combined with advanced NLP techniques, in their success with IBM Watson (<https://www.ibm.com/watson/index.html>), the

Jeopardy-winning general-purpose question answering system.

Research Challenges

Current research challenges, regarding ontologies, include finding the balance between carefully engineered knowledge representations, such as an ontology, and other kinds of models, for instance, learned through machine learning methods. While ontologies are transparent and can easily provide explanations for a derived conclusion, it is often not feasible to create a detailed model of the complete domain and task by hand, and it may not even be the case that the knowledge exists at design time. Rather, some parts of it may need to be discovered from incoming data or user interactions and modified as the system runs. This is nowadays recognized as one of the main research integration challenges in AI, i.e., to integrate the knowledge representation and reasoning approach with state-of-the-art machine learning methods in order to take advantage of both.

A related problem is the challenge of coverage and fit of ontologies that exist today. Despite many ontologies being published and shared today, it is still rare to find an existing ontology that perfectly fits your needs. Usually it needs to be combined with other ontologies or extended with specifics of your use case. Hence, despite the fact that many ontologies exist, one has to expect that a certain amount of extension is usually needed in order to use an ontology or that parts of several ontologies are needed to annotate a dataset. Therefore, there is still a lot of ongoing research regarding the tasks of finding, evaluating, and reusing ontologies, as well as aligning several ontologies into an ontology network. Additionally, the challenge of updating ontologies, e.g., through ontology evolution, is also an ongoing research topic.

In particular when using ontologies for big data applications, the issue of scale, i.e., both volume and velocity, is an important aspect. Although some ontologies are potentially too expressive to be used for large-scale inferencing,

there are both subsets of the OWL language where efficient reasoning methods exist and methods for performing incremental reasoning or stream reasoning using windows over data, which can make OWL ontologies applicable in large-scale settings. However, this challenge is still a topic of research as well.

Nevertheless, regardless of the actual representation formalisms, ontologies in the form of knowledge graphs have already proven their usefulness and applicability in big data settings, such as operating a search engine over the entire Web in the case of Google.

Optimizing Geo-Distributed Streaming Analytics

Abhishek Chandra¹, Benjamin Heintz¹, and Ramesh Sitaraman²

¹University of Minnesota, Minneapolis, MN, USA

²University of Massachusetts, Amherst, MA, USA

Overview

Data analytics is undergoing a revolution: the volume and velocity of data sources are increasing rapidly. Across a number of application domains from web, social, and energy analytics to scientific computing, large quantities of data are generated continuously in the form of posts, tweets, logs, sensor readings, and more. A modern analytics service must provide real-time analysis of these data streams to extract meaningful and timely information. As a result, there has been a growing interest in streaming analytics with recent development of several distributed analytics platforms (Apache Storm 2015; Boykin et al. 2014; Zaharia et al. 2013).

In many streaming analytics domains, inputs originate from diverse sources including users, devices, and sensors located around the globe. As a result, the distributed infrastructure of a typical analytics service (e.g., Google Analytics, Akamai Media Analytics, etc.) has a hub-and-spoke model. Data sources send streams of data to nearby “edge” servers. These geographically distributed edge servers send data to a central location that can process the data further, store summaries, and present those summaries in visual form to users of the analytics service. While the central hub is typically located in a well-provisioned data center, resources may be limited at the edge locations. In particular, the available WAN bandwidth between the edges and the center is limited.

A traditional approach to analytics processing is the *centralized model* where no processing is performed at the edges and all the data is sent to a dedicated centralized location. This approach is generally suboptimal, because it strains the scarce WAN bandwidth available between the edges and the center, leading to delayed results. Further, it fails to make use of the available compute and storage resources at the edge. An alternative is a *decentralized approach* (Rabkin et al. 2014) that utilizes the edge for much of the processing in order to minimize WAN traffic. However, neither approach is optimal for modern analytics requirements. Instead, analytics processing must utilize *both* edge and central resources in a carefully coordinated manner in order to achieve the stringent requirements of an analytics service in terms of network traffic, user-perceived delay, as well as accuracy of results.

A crucial question for a geo-distributed analytics system is how best to utilize resources at both the edges and the center in order to deliver timely results. In particular, optimizing geo-distributed streaming analytics requires an analytics system to determine how much computation to perform at the edges and how much to leave for the center (i.e., *where* to compute), as well as *when* to send partial results from edges to the center. These questions must be addressed in the context of the trade-off between multiple metrics: cost (e.g.,

WAN traffic), timeliness (e.g., latency), and data quality (e.g., result accuracy).

Key Research Findings

Recent work (Heintz et al. 2015, 2016a, 2017) has addressed the problem of optimizing geo-distributed streaming analytics by analyzing these trade-offs in the context of *windowed grouped aggregation*, an important primitive in any stream analytics system. This work systematically analyzes these trade-offs both in the context of exact computation (where all data must be completely processed) and approximate computation (where some error can be tolerated).

Abstractions for grouped aggregation are provided in most data analytics frameworks, for example, as the Reduce operation in MapReduce or Group By in SQL and LINQ. A useful variant in stream computing is *windowed* grouped aggregation, where each group is further broken down into finite time windows before being summarized. Windowed grouped aggregation is one of the most frequently used primitives in an analytics service and underlies queries that aggregate a metric of interest over a time window. Example queries that utilize windowed grouped aggregation include computing content popularity for a web analytics application or the average network load distribution for a network monitoring application.

Exact Computation

Recent work (Heintz et al. 2015, 2017) focuses on designing algorithms for performing windowed grouped aggregation in order to optimize the two key metrics of any geo-distributed streaming analytics service: *WAN traffic* and *staleness* (the delay in getting the result for a time window). The aggregation algorithm runs on each edge, aggregating the records in the input stream and sending (partial) aggregates to the center over the WAN. The scheduling problem is to determine when to send which aggregates to the center.

This work examines baseline approaches such as pure streaming, a centralized approach where all data is immediately sent from edge to center without any edge processing, and pure batching, a decentralized approach where all data during a time window is aggregated at the edge, with only the aggregated results being sent to the center at the end of the window. It shows that such approaches do not jointly optimize traffic and staleness and, hence, are suboptimal. It presents a family of *optimal offline algorithms* that *jointly minimize* both staleness and traffic. One offline optimal algorithm is the *eager optimal algorithm* that eagerly flushes updates for each distinct key immediately after the final arrival to that key within a window. Another offline optimal algorithm is the *lazy optimal algorithm* which schedules its updates to start at the last possible time that would still enable it to flush all its updates with an optimal staleness. There is a family of optimal algorithms whose schedules consist of update times that lie between those for the eager and lazy algorithm for each key.

Using these offline optimal algorithms as a foundation, practical online aggregation algorithms are developed that emulate the offline optimal algorithms. The key insight here is that windowed grouped aggregation can be modeled as a *caching problem* where the cache size varies over time. This insight allows the decomposition of the scheduling problem into two subproblems: determining the (dynamic) *cache size* and defining a *cache eviction policy*. While the first subproblem can be solved by using insights gained from the optimal offline algorithms, the second subproblem lends itself to using the vast prior work on cache replacement policies (Podlipnig et al. 2003). To overcome potential problems with pure emulation of either the eager or the lazy offline optimal algorithms in practice, a *hybrid algorithm* is proposed that computes cache size as a linear combination of eager and lazy cache sizes. Concretely, a hybrid algorithm with a *laziness parameter* α – denoted by $\text{hybrid}(\alpha)$ – estimates the cache size $c(t)$ at time t as:

$$c(t) = \alpha \cdot c_l(t) + (1 - \alpha) \cdot c_e(t),$$

where $c_l(t)$ and $c_e(t)$ are the lazy and eager cache size estimates, respectively. By selecting an appropriate value for α , the hybrid algorithm can achieve the desired trade-off between traffic and staleness.

The practicality of these algorithms is demonstrated through an implementation in Apache Storm (2015), deployed on the PlanetLab (2015) testbed. The experiments are driven by workloads derived from anonymized traces of a popular web analytics service offered by Akamai (Nygren et al. 2010), a large content delivery network. The results of the experiments show that the proposed online hybrid aggregation algorithms simultaneously achieve traffic close to optimal while reducing staleness significantly compared to baseline algorithms such as batching. Further, these algorithms are robust to a variety of system configurations (number of edges), stream arrival rates, and query types.

Approximate Computation

In a geo-distributed setting, due to constrained WAN bandwidth, it is not always feasible to produce exact results in a timely manner. In such cases, applications must either sacrifice timeliness by allowing delayed – i.e., late – results or sacrifice accuracy by tolerating some error in the results. This is a fundamental trade-off: it is not always feasible to compute exact results with bounded staleness (Rabkin et al. 2014). Further, many real-world applications can tolerate some staleness or inaccuracy in their final results.

Recent work (Heintz et al. 2016a) has studied the *staleness-error trade-off* for windowed grouped aggregation in geo-distributed streaming analytics, recognizing that applications have diverse requirements: some may tolerate higher staleness in order to achieve lower error and vice versa. As in the exact computation scenario, the aggregation algorithm runs on each edge, partially aggregating the input data and sending results to the center over the WAN. In this case, the scheduling problem is to determine when, and if, aggregates need to be sent to the center. Aggregation algorithms are devised to solve *two complementary problems*: minimize staleness un-

der an error constraint and minimize error under a staleness constraint.

This work first designs theoretically optimal offline algorithms to solve each of these problems and then develops practical online algorithms based on the intuition derived from the offline optimal algorithms. The optimal offline algorithms allow minimizing staleness (resp., error) under an error (resp., staleness) constraint. Intuitively, the error-bound problem is solved by transmitting only the aggregates that are essential to meet the error constraint. For the staleness-bound problem, error is minimized by prioritizing keys for transmission, based on their potential error (if not sent), while fully utilizing the available network bandwidth.

Using these offline algorithms as references, practical online algorithms are designed to efficiently trade off staleness and error. These practical algorithms are based on the key insight of representing grouped aggregation at the edge as a *two-part cache*. This formulation generalizes the caching-based framework for exact windowed grouped aggregation (Heintz et al. 2015) by introducing cache *partitioning* and cache *eviction* policies to identify which partial results must be sent and which ones can be discarded.

The practicality and efficacy of these algorithms is demonstrated through both trace-driven simulations and implementation in Apache Storm (2015), deployed on a PlanetLab (Peterson et al. 2003) testbed. Using workloads derived from traces of a popular web analytics service offered by Akamai (Nygren et al. 2010), experiments show that the proposed algorithms reduce staleness and error significantly compared to a practical aggregation algorithm that effectively combines batching with streaming using random sampling. The proposed techniques apply across a diverse set of aggregates, from distributive and algebraic aggregates (Gray et al. 1997) such as Sum and Max to sketch-based approximation of holistic aggregates such as unique count (via sketch data structures such as HyperLogLog Flajolet et al. 2007). Further, they can handle diverse network bandwidth and workload conditions and are adaptive to variable network conditions.

Related Work

Numerous stream computing systems (Akidau et al. 2013; Chandrasekaran et al. 2003; Kulkarni et al. 2015; Qian et al. 2013; Zaharia et al. 2013; Apache Flink 2016; Chen et al. 2016) have been proposed in recent years. The Google Dataflow model (Akidau et al. 2015) and the Apache Beam project (2016) have presented a unified abstraction for computing over both bounded and unbounded datasets. These systems provide many useful ideas for new analytics systems to build upon, but they are primarily designed for tightly coupled computing environments such as clusters and data centers and do not fully consider the challenges in a geo-distributed environment.

Wide-area computing has received increased research attention in recent years, due in part to the widening gap between data processing and communication costs. Much of this attention has been paid to batch computing (Pu et al. 2015; Vulimiri et al. 2015a,b; Heintz et al. 2016b). Relatively little work on streaming computation has focused on wide-area deployments or associated questions such as where to place computation. Pietzuch et al. (2006) optimize operator placement in geo-distributed settings to balance between system-level bandwidth usage and latency. Hwang et al. (2008) rely on replication across the wide area in order to achieve fault tolerance and reduce straggler effects.

JetStream (Rabkin et al. 2014) considers wide-area streaming computation and addresses the tension between timeliness and accuracy, focusing at a higher level on the appropriate abstractions for navigating this trade-off. Meanwhile BlinkDB (Agarwal et al. 2013) provides mechanisms to trade accuracy and response time, though it does not focus on processing streaming data. Das et al. (2014) consider trade-offs between throughput and latency in Spark Streaming, but they focus on exact computation and consider only a uniform batching interval for the entire stream.

Aggregation is a key operator in analytics, and grouped aggregation is supported by many

data-parallel programming models (Boykin et al. 2014; Gray et al. 1997; Yu et al. 2009). Larson et al. (2002) explore the benefits of performing partial aggregation prior to a join operation. While they also recognize similarities to caching, they consider only a simple fixed-size cache. In sensor networks, aggregation is often performed over a hierarchical topology to improve energy efficiency and network longevity (Madden et al. 2002; Rajagopalan and Varshney 2006). Amur et al. (2013) study grouped aggregation, focusing on the design and implementation of efficient data structures for batch and streaming computation, though they do not consider staleness, a key performance metric in a geo-distributed setting.

Future Directions for Research

As more and more data is generated by sensors and IoT devices near the edges, research on optimizing geo-distributed streaming analytics can be taken into several directions. One area of research would be to optimize streaming analytics for a heterogeneous, geo-distributed computational environment. This could include edge devices and computing resources, in-networking processing elements, as well as centralized data centers. These elements can differ in their computing, storage, and networking capabilities, and their interactions can lead to interesting resource provisioning and scheduling issues. Another area of research is to achieve desired cost-latency-accuracy trade-offs in streaming analytics by utilizing alternate approaches such as sampling, sketching, as well as compression. For instance, sketching techniques can allow trading off accuracy for latency, and compression techniques can help minimize WAN bandwidth usage. Optimizing different types of queries and multi-query optimization is another area of future research. While multi-query optimization in traditional database systems has focused on minimizing execution time and memory usage, the metrics of interest in a geo-distributed streaming analytics settings are different and will result in new research issues.

Orchestration Tools for Big Data

Saurabh Garg¹, Siqi Wang¹, and Rajiv Ranjan²

¹School of Engineering and ICT, University of Tasmania, Hobart, TAS, Australia

²School of Computing Science, Newcastle University, Newcastleupon Tyne, UK

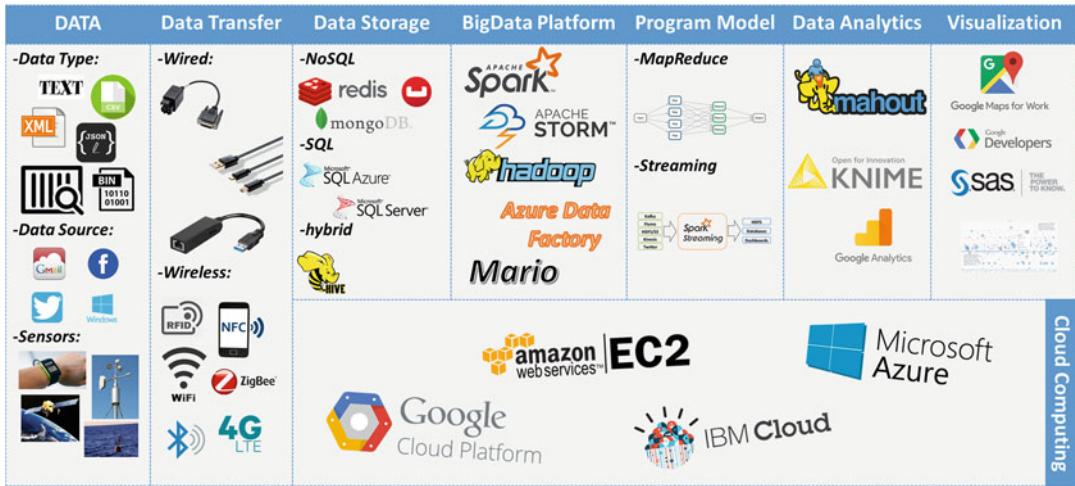

Introduction

With increasing digitization of data and advancement of storage and communication technologies, we are generating quintillion bytes of data every day (Goloboff 1999). According to recent studies, this data collected will become as much as 40 yottabytes by 2020 (Chen et al. 2016). Every second more than 500 millions of tweet messages are posted on Twitter-like social media site. Square Kilometer Array (SKA) radio telescopes can transmit a massive 155.7 terabytes per second. This data explosion is called *big data* that refers to such large quantity of data that it cannot be efficiently handled by traditional data architectures. According to NIST (Grady et al. 2014), big data is characterized by four properties, namely, volume (size of the dataset), variety (data from multiple repositories, domains, or types), velocity (rate of data ingestion), and variability (change in data characteristics). This big data paradigm has brought both opportunities and challenges. Leaders from different organizations such as commercial, academic, and government strongly believe that access to this amount of data is going to revolutionize businesses, scientific research, and government policies.

Big data management and processing is also a challenging task even though it has been partially mitigated by recent advancement in the development of fast processors. However, regardless of how increased CPU speeds are, it cannot surpass the data volumes that are being generated today and will be in future (Kim et al. 2016). To address these issues, there has been a great increase recently in different technologies to sup-

port processing and generating insights from big data. These technologies address different challenges in different stages of data life cycle (Kim et al. 2016) which consist of data collection (includes communication and storage), preparation (involves data cleaning, integration, and organization), analysis (involves extraction of information and knowledge from the data), and action (involves using this knowledge to drive decision-making). Figure 1 shows examples of such technologies such as fast communication technologies (e.g., 5G for mobile data (Chen and Zhao 2014)), data storage (e.g., NoSql databases such as MongoDb (Chodorow 2013), HDFS (Karun and Chitharanjan 2013)), big data platforms (e.g., Hadoop (Vavilapalli et al. 2013) and Spark (Zaharia et al. 2016)), analytics libraries (e.g., Mahout), visualization (e.g., Google Charts), and processing infrastructure (cloud computing).

Based on these technologies, several decision-making applications such as disaster management and intrusion detection can be designed. However, the challenge is how to integrate these technologies in a way that it achieves the objective of users in terms of performance and quality of the solution. This issue or challenge is part of *big data orchestration* process. Big data orchestration process manages whole life cycle of data from collection to insights for the end user. However, user's goals are generally expressed in terms of performance objectives and vary from application to application. For instance, for disaster management applications such as flood modeling, time is a critical performance measure; similarly for some applications such as credit card transaction analysis, a user may want every transaction needs to be processed within a given deadline. For medical data analysis, accuracy of recommendations is the most crucial part. Moreover, data injected might also dynamically vary in generation rate or inherent characteristics, or underline computing infrastructure might fail or degrade in performance. Therefore, big data orchestrator needs to select and configure appropriate tools for each operation, integrate and deploy them to achieve end user goals considering uncertainties

Orchestration Tools for Big Data, Fig. 1 Technologies in big data life cycle

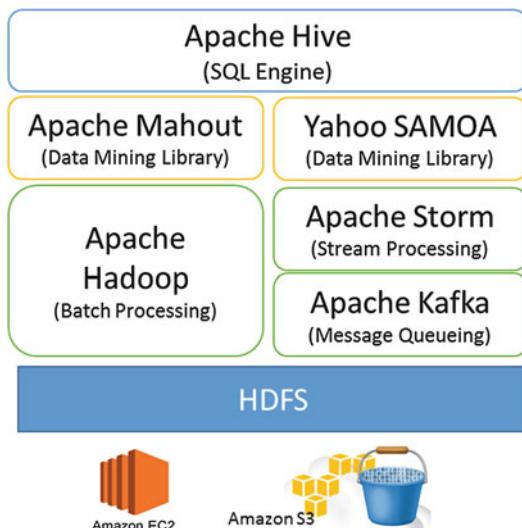

at different levels of big data processing stack. In this chapter, we will discuss in detail big data orchestrator process and its requirements to fulfill users' requirements. We will discuss also the tools and technologies available for enabling orchestration of big data applications. Then we conclude by describing the open challenges.

BigData Orchestration Operations and Challenges

An orchestration platform integrates different tools and technologies for different stages of big data analysis (Ranjan et al. 2017). Figure 1 shows these big data tools in different stages of data starting from data ingestion to visualization of insights. Orchestration platform will select appropriate ones and deploy the whole solution on different cloud infrastructures involving initiating different virtual machines and configuring different services. The orchestration engine configures these tools keeping in consideration end user's specified quality of service (QoS) requirements. It will also establish relationship (data flows) between different tools and services. The orchestration platform also needs to monitor the deployed application's performance and make runtime changes as needed to fulfill QoS requirements. In summary,

there are four key orchestration operations for managing a big data application. To understand these operations and their requirements, let us take an example of flood monitoring and prediction application. This application needs processing of historical and real-time data; thus multiple and heterogeneous big data technologies are required as specified in Fig. 2. The application combines stream data in free text format from Twitter and flood simulation data stored over Amazon S3. In the application, HDFS can be used to store the output from batch (e.g., Hadoop (Karun and Chitharanjan 2013)) and stream processing (e.g., Apache Storm (van der Veen et al. 2015)) platforms. The analytical part of the application can be build using different programming models and libraries such as Mahout. Apache Hive (Huai et al. 2014) can be used to extract insights from database and send these in the form of alerts to the users.

- 1. Big Data Tools Selection:** This is the first stage of orchestration platform where it needs to analyze user's QoS requirements and select appropriate tools. There are several options for each stage of data processing for required solution functionality. The orchestration has to select in a way that different tools (Apache Hadoop, Storm, Spark, Mahout, Hive, MongoDB) from different stages are

Orchestration Tools for Big Data, Fig. 2 Flood monitoring and prediction application

inter-operable and compatible with cloud resources (CPU, storage, network) in addition to user's QoS requirements such as target budget of solution and availability. The hard challenge is to optimally and automatically select tools, hardware, and their configurations such that anticipated QoS constraints (e.g., minimizing event detection delay, minimizing data processing cost) are met while optimizing performance of big data software stack (e.g., minimizing response time for Apache Hadoop) and of cloud resources (maximizing utilization). For example, in Fig. 2, there is a need to optimally select configurations of Apache Hadoop (number of map tasks, number of reduce tasks, map slots per CPU, reduce slots for CPU, max RAM per slot) and Amazon CPU resource (<http://aws.amazon.com/ec2/instance-types>) configurations (I/O capacity, RAM, CPU speed, local storage, cost) driven by application-level performance SLA constraints (analyze 100 GB of Tweets in 10 min subject to maximum budget of \$100). The space of possible configurations for big data processing tools and cloud resource is very large, so computing an optimal solution is NP-complete and therefore intractable given current technology. We need algorithms that

can analyze existing cloud resources and big data processing tools for automatic optimal configuration selection decisions. Minimally, the orchestration platform should provide support for an administration to make these decisions.

2. Big Data Application Deployment (Both Design Time and Runtime): This operation involves instantiating big data tools on selected cloud services with communication protocols and big data database solutions. During deployment, variation in the requirements of each big data software needs to be taken in account. For some big data workloads (high-volume batch processing of historical Tweets by Hadoop in Fig. 2), storage requirements dominate, while for others (transactional query processing by Apache Hive in Fig. 2), computational requirements dominate, and for still others (real-time Twitter stream processing by Apache Storm in Fig. 2), communication requirements dominate. To deploy big data stack on cloud resources which is a multitenancy environment, orchestration systems should deploy the solution in such a way that there will be minimized interference from other application solutions.

3. Monitoring Big Data Application Solution (Runtime): To guarantee QoS requirements, monitoring is a must for making sure each and every tool that is part of the solution is running at optimal performance level. Monitoring QoS objectives of a big data application solution involves regular collection of performance statistics from different deployed big data tools for each stage of data processing cycle and cloud virtual machines. Each stage may have different performance metric for evaluation. For example, at user level or application level, event detection delays and response time are the most important factors, while throughput and latency are important for message queueing systems (e.g., Apache Kafka) and stream processing systems such as Apache Storm. Read/write latency and throughput are important measure for performance of HDFS. Availability, utilization,

and processing speed are essential measure for CPU resources. The challenge in monitoring other than defining the exact performance measure for individual software tools in the solution is integration of them to have unified view of performance for the end user.

4. **Runtime Management:** Based on monitoring data, a big data orchestrator may need to detect the deviation in performance behavior of application and initiate corrective action (adjusting configurations) in a manner that it does not disrupt the availability of solution's output to the end user. An example of corrective action may be to adjust cloud computing resources by adding more number of virtual machines for improving throughput and reduce processing delays. The challenge here comes from unpredictable behavior of ingested data and underline cloud computing resources. As variability is one of the characteristics of big data, it is clear that we cannot expect same data flow rate all the time. If data flow rate is higher, then more computing and storage resources are required. If data flow rate is lower, then hardware resource needs to be minimized; otherwise it will lead to wastage of monetary cost for underutilized resources. The hard challenge in making such adjustment is in computing exact adjustment to make in different parts of software and hardware stack. This requires also accurate prediction models for data flow rates and hardware performance.

Technologies for Big Data Orchestration

In recent years, there are several orchestration tools that have been developed which facilitate orchestration operation to different capacities. In this section we will discuss important orchestration tools. The comparison of these tools is given in Table 1.

Apache YARN

Apache YARN (Vavilapalli et al. 2013) is an open-source resource management technology deployed on Hadoop clusters. YARN supports

allocation of resources for a variety of applications. It runs two daemons, which handle two different tasks: job tracking and progress monitoring. These two daemons are called the resource manager and the application manager, respectively. The resource manager allocates resources to various applications, and the application manager monitors the execution of the process. YARN offers significant advantages in scalability, efficiency, and flexibility compared to the classic MapReduce engine in the first edition of Hadoop; when a user submits an application, an instance of a lightweight process called the ApplicationMaster is started to coordinate the execution of all tasks within the application. This includes monitoring tasks, restarting failed tasks, speculatively running slow tasks, and calculating total values of application counters. In the YARN architecture, a global ResourceManager runs as a master daemon, usually on a dedicated machine, that arbitrates the available cluster resources among various competing applications. The ResourceManager tracks how many live nodes and resources are available on the cluster and coordinates what applications submitted by users should get these resources and when.

Apache Mesos

Mesos (Kakadia 2015) is an open-source software originally developed at the University of California at Berkeley. It sits between the application layer and the operating system and makes it easier to deploy and manage applications in large-scale clustered environments more efficiently. Mesos utilizes the modern kernel features in Linux to provide isolation for CPU, memory, I/O, file systems, rack locations, and so on. The important feature of Mesos is that it can integrate several heterogeneous resources and provide easy access to application frameworks. Mesos introduces a distributed two-level scheduling mechanism. Mesos decides how much resources to provide for each big data framework, and the framework determines which resources to accept and which calculations to run on it; it does not set up a large number of server clusters for different parts of the application, but rather

Orchestration Tools for Big Data, Table 1 Comparison of orchestration tools

	Selection	Deployment	Monitoring	Runtime management (reactive)	Runtime management (predictive)
Apache YARN	Manual	Deploys the application on cluster. No resource contention detection or handling	Progress of application execution	Yes (changes in resource consumption and fault tolerance)	Yes
Apache Mesos	Manual	Resource offers are created by Mesos based on specified resource sharing policy such as fair share. No resource contention detection or handling	Monitor failures and resource usage	Fault tolerance	No
AWS Lambda	Automatic	Deploy virtual machines, storage, network, and then applications (written in Java, Node.js, C#, and Python)	Hardware level and software level using CloudWatch	Fault tolerance, scaling of resources	Information not available
MROrchestrator	Automatic	NA	Monitor resource-level bottleneck	Yes (adjust resources based on requirements)	Task's execution time estimation and resource utilization
Azure data factory	Workflow creation interface for users	Deploy the data processing pipeline and cloud resources	Monitor the data flows	Yes, reactive approach by adjusting the resources according to data flow	No
Beygelzimer et al	Automatic	No information available	No information available	Tackle a real-time ectopic beat detection problem in healthcare	No

can share a different part of the resources that can run the different parts of the application without interfering with each other. Mesos also enables dynamically allocation of resources to application frameworks. With the help of Mesos' Docker executor, Mesos can run and manage Docker containers with the Chronos and Marathon frameworks. Docker containers provide a consistent, compact, and flexible way to package applications. Using Docker to implement applications on Mesos provides a truly resilient, efficient, and consistent platform for providing a range of applications in the field or in the cloud. Mesos consists of a master process that manages slave daemons running on each cluster node and frameworks that run tasks on these slaves. The master implements fine-grained

sharing across frameworks using resource offers. Each resource offer is a list of free resources on multiple slaves. When the master node decides to give some resource offers from slaves to application frameworks, they decide whether to accept those resources. The master decides how many resources to offer to each framework according to a given organizational policy, such as fair sharing or strict priority.

Amazon Lambda

AWS Lambda (<https://aws.amazon.com/lambda/details/>) is a serverless compute service that allows the execution of code that is written in Node.js, Python, C#, and Java to be executed in response to events and automatically adjust the underlying compute resources. This service

allows integration with other AWS services and can provide high scalability, performance, and security. AWS Lambda can automatically run code in response to multiple events, such as HTTP requests via Amazon API Gateway, modifications to objects in Amazon S3 buckets, table updates in Amazon DynamoDB, and state transitions in AWS Step Functions. Amazon Lambda selects the appropriate highly available compute infrastructure and performs all the administration needed for its maintenance including automatic scaling, provision, deployment of security patch, monitoring, and logging. Amazon Lambda uses Amazon CloudWatch (<https://aws.amazon.com/cloudwatch/>) to monitor hosted applications which can be used to collect and track metrics, collect and monitor log files, set alerts, and automatically react to changes in your AWS resources.

MROrchestrator

MROrchestrator (Sharma et al. 2012) is a software layer that assumes or requires no changes to the Hadoop framework, making it a simple, flexible, portable, and platform generic design architecture. It provides fine-grained, dynamic, and coordinated allocation of resource to MapReduce jobs in Hadoop. Based on the runtime resource profiles of tasks, MROrchestrator builds online resource estimation models for on-demand allocations; MROrchestrator is complementary to the contemporary resource scheduling managers like Mesos and Next Generation MapReduce (NGM).

Azure Data Factory

Big data requires service that can orchestrate and operationalize processes to refine these enormous stores of raw data into actionable business insights. Azure Data Factory (Klein 2017) is a managed cloud service that's built for these complex hybrid extract-transform-load (ETL), extract-load-transform (ELT), and data integration projects. It is a cloud-based data integration service that allows data-driven workflows in the cloud to be used to coordinate and automate data movement and data

conversion. Using Azure Data Factory, you can create and plan data-driven workflows (called pipelines) that can get data from different data stores. It can process and convert data by using computational services such as Azure HDInsight Hadoop, Spark, Azure Data Lake Analytics, and Azure machines. In addition, you can publish output data to data storage such as Azure SQL data warehouses for business intelligence (BI) applications. Ultimately, through the Azure data plan, raw data can be organized into meaningful data storage and data lakes to achieve better business decisions.

Azure Data Factory itself does not store any data. It lets you create data-driven workflows to orchestrate the movement of data between supported data stores and the processing of data using compute services in other regions or in an on-premises environment. Azure Data Factory has built-in support for pipeline monitoring via Azure Monitor, API, PowerShell, Microsoft Operations Management Suite, and health panels on the Azure portal. Data factory provides triggers representing the unit of processing that determines when a pipeline execution needs to be kicked off. Azure integration runtime provides the native compute to move data between cloud data stores in a secure, reliable, and high-performance manner. You can set how many data movement units to use on the copy activity, and the compute size of the Azure IR is elastically scaled up accordingly without you having to explicitly adjust the size of the Azure integration runtime. Azure integration runtime supports connecting to data stores and compute services in public network with public accessible endpoints. Use a self-hosted integration runtime for Azure Virtual Network environment.

Beygelzimer et al. (2013)

Beygelzimer et al. proposed an orchestration system for big data that is designed to use a combination of planning and machine learning to automatically determine the most appropriate data-driven workflows to execute in response to a user-specified object; it uses planning and learning system to dynamically determine the most effective analytic workflow to construct and de-

ploy given our computational resources and user-specified task; the system is designed with two major components, a planner and a learner. The purpose of the planner is to discover the set of goals and parameters that match a specific objective such as predicting patient complications and for each such goal to automatically compose and generate code and deploy an analytic workflow that realized the goal. The learner will continuously reevaluate the current mix of analytic workflows deployed and, when deciding to change this set, communicate with the planner which will compose and deploy the analytic workflows, potentially on multiple platforms. In short summary, the planner is running as a set of plugins in the Equinox OSGI container, while the learner component is running as a stream processing application on the IBM InfoSphere Streams platform.

Open Research Issues

Despite several efforts made in orchestrating big data application solutions, still there are significant open research gaps. The following are some of these gaps in each orchestration operation:

- **Big Data Tools Selection:** As we noted in the last section, most big data orchestration platforms such as Apache YARN and Mesos are designed for cluster environments which do not scale on-demand. Moreover, these platforms require application administrator to determine the exact configurations for application execution such as number of map and reduce tasks in case of MapReduce application and also for hardware resources. They are also designed for monolithic applications not for large solutions requiring integration of multiple big data tools and technologies. Moreover, there are almost no calculators except some branded cloud price ones (<http://calculator.s3.amazonaws.com/>, <http://www.windowsazure.com/en-us/pricing/calculator>) that can recommend or compare configurations across big data processing tools and cloud infrastructure

resources based on given QoS performance objectives. In a narrow domain, recent efforts have attempted to automate the configuration selection of Hadoop frameworks over heterogeneous cluster resources such as by Lee and Katz (2011) and AROMA (Lama and Zhou 2012). These works do provide foundation, but future research must focus on developing holistic decision-making frameworks that automate configuration selection across multiple hardware resource types and big data processing frameworks to ensure QoS objectives.

- **Big Data Application Deployment (Both Design Time and Runtime):** As specified before, after selection of right configurations of big data processing systems and cloud infrastructure resources, there are several other factors that need to be taken into account while deployment. In general cloud infrastructure is shared between different applications. Even though virtualization provides some isolation between different applications, it is not possible to exactly divide usage of underline hardware. In context of big data, other than computing resources, network resources also play a key role. Currently in most of cloud provider, it is not possible to preallocate the network resources. It is also important to note that big data orchestration platforms such as YARN, Mesos, and Amazon Lambda have no support for detecting and handling resource contentions. Therefore, new software-based techniques are required that can learn interference in different cloud resources such as CPU, memory, and network.
- **Monitoring Big Data Application Solution (Runtime):** Several monitoring frameworks are available in the literature for monitoring performance of big data processing platforms and cloud. Cluster-wide monitoring frameworks such as Nagios (Josephsen 2007) and Ganglia (Massie et al. 2004) adopted by big data processing platforms such as YARN, Apache Hadoop, and Apache Spark provide information about hardware resource-level metrics (cluster utilization, CPU utilization, memory utilization, and

nature of application: disk-, network-, or CPU-bound). In public cloud computing space, monitoring frameworks (Amazon CloudWatch used by Amazon Lambda, Azure Fabric Controller) typically monitor an entire CPU or VM resource as a black box and so cannot monitor application-level performance metrics. However, still efforts are needed to integrate these monitoring data for whole big data solution (big data processing software and cloud infrastructure) in terms of QoS requirements of the end user. There is also need of mechanisms and tools that can automatically detect any performance degradation based on specified QoS and analyze collected monitoring logs to identify root cause of failure or degradation in the performance.

- **Runtime Management:** The cloud computing community has done extensive research (Ardagna et al. 2014) in developing workload and resource performance modeling techniques for web applications. Public cloud providers provide simplistic reactive approaches to handle peak loads and detecting response time degradation. However, reactive techniques are not efficient solution when a large big data application with multiple software and hardware is needed to be managed. Currently available prediction models cannot be applied directly to the big data workload which has four unique characteristics (volume, velocity, variety, variability). Moreover, there is a need of prediction models for different types of big data-specific performance metrics (batch processing load, stream processing load, data ingestion load, search query processing load) as big data applications differ from multi-tier web applications. To handle dynamic changes to ingested data, failures, or degraded performance of underline hardware, optimal configuration for different components of big data application should be again computed in minimal time. Thus, there is a need of efficient algorithms that can find optimal configurations that need minimal changes in current deployment.

Conclusion

This chapter discussed big data life cycle and tools that are available for different stages of data processing. Given so many tools, libraries, databases, platforms, and infrastructure option, businesses and different organizations need orchestration support for selection of appropriate tool for building their big data application solutions, its deployment, its monitoring, and runtime management of all components of solution and adjustment in hardware resources. The aim of big data orchestration is to ensure that the application solution meets QoS performance objectives, such as availability, throughput, latency, security, cost, and reliability under uncertainties and variability of data and cloud computing resources. We also discuss these orchestration operations in details with current tools that are available in big data context. It is clear from the short survey of these orchestrating platforms that still there are many open challenges that need to be addressed for designing a fully automatic and flexible orchestration platform for big data application solutions.

Parallel Graph Processing

Da Yan¹ and Hang Liu²

¹Department of Computer Science,

The University of Alabama at Birmingham,
Birmingham, AL, USA

²University of Massachusetts Lowell, Lowell,
MA, USA

Definitions

The term *parallel graph processing* refers to the use of multiple cores to process a graph for the purpose of (1) speeding up of processing and (2) scaling to bigger graphs. The environment can be (1) a stand-alone machine running multiple threads or (2) a distributed cluster of machines (i.e., the shared-nothing architecture).

Overview

Modern big graph processing systems place emphasis on two aspects:

1. user-friendliness: the programming interface should be designed based on an intuitive computation model, to allow algorithm developers to focus on the graph analytics logic without touching low-level execution details (e.g., network communication);

2. efficiency: the underlying execution engine should guarantee high-throughput execution and automatically support fault tolerance and horizontal/vertical scaling.

Since comprehensive surveys of this area already exist (Yan et al. 2017a,d), this chapter aims at a succinct and more up-to-date review of the key programming paradigms and systems for big graph analytics, which are commented based on (1) their computation models and target applications and (2) their execution environments.

We remark that the focus of this chapter is on graph computation, not on graph storage, esp. for distributed systems running with a distributed shared-nothing cluster. For these systems, graph storage is an orthogonal topic, since it can load data from any distributed store, such as Hadoop Distributed File System (HDFS) or even a distributed graph database like TITAN. W.l.o.g, we assume that graph data are stored on HDFS, which provides “parallel IO” and “fault tolerance”: HDFS stores a big input file as blocks of size 64MB each, and each block is replicated on three machines to be tolerant to machine failures. A distributed system loads the data from HDFS in parallel with each machine reads only part of the input data, so that all disks are utilized to achieve an aggregate bandwidth.

We also remark that a distributed system is not necessarily faster than a stand-alone solution (esp. for small graphs). In fact, for data-intensive graph analytic tasks where the data volume to transmit is comparable to the input

graph size, network communication is usually the performance bottleneck. With N machines, each machine only needs to perform computation over about $1/N$ of the vertices, but needs to pay for the additional communication cost incurred by these vertices. In other words, a distributed system is only beneficial if the number of machines is large enough to outweigh the incurred communication overhead.

This chapter uses the following graph notations. Given a graph $G = (V, E)$, we denote the number of vertices $|V|$ by n and the number of edges $|E|$ by m . For an undirected graph, we denote the set of *neighbors* of a vertex v by $\Gamma(v)$ and the *degree* of v by $d(v) = |\Gamma(v)|$. For a directed graph, we denote the set of *in-neighbors* and *out-neighbors* of v by $\Gamma_{in}(v)$ and $\Gamma_{out}(v)$ and the *in-degree* and *out-degree* of v by $d_{in}(v) = |\Gamma_{in}(v)|$ and $d_{out}(v) = |\Gamma_{out}(v)|$, respectively.

Key Research Findings

We now review the three key computing paradigms for big graph analytics, i.e., two vertex-centric paradigms (Pregel-like message passing v.s. shared-memory abstraction) and a subgraph-centric paradigm.

Pregel-Like Systems

Malewicz et al. (2010) pioneered the “think-like-a-vertex” computing model where users develop a distributed graph algorithm simply by specifying the behavior of a generic vertex. Their system, Google’s Pregel, is designed based on the bulk synchronous parallel (BSP) model. It distributes vertices to different machines in a cluster, where each vertex v is associated with its adjacency list. A program in Pregel implements a user-defined function (UDF) *compute()* and proceeds in iterations (called *supersteps*). In each superstep, the program calls *compute(msgs)* for each “active” vertex v to perform the user-specified computation logic on v , such as processing v ’s incoming messages *msgs* (sent in the previous superstep), sending messages to other vertices (to be received in the next superstep), and making

v vote to halt. A halted vertex is reactivated if it receives a message in a subsequent superstep. The program terminates when all vertices vote to halt, and there is no pending message for the next superstep.

Pregel numbers the supersteps so that a user may access the current superstep number in *compute()*. This allows a Pregel algorithm to perform different operations in different supersteps.

Pregel allows users to implement a *combine()* function, which specifies how to combine messages that are to be sent from a machine M_i to the same vertex v in a machine M_j . These messages are combined into a single message, which is then sent from M_i to v in M_j . Combiner is applied only when messages can be aggregated with a commutative and associative operation.

Pregel also supports global communication through “aggregator.” Each vertex can provide a value to an aggregator in *compute()* in a superstep. The system aggregates those values and makes the aggregated result available to all vertices in the next superstep.

We now look at two examples on how to write a vertex-centric program.

Example 1 We present the Hash-Min algorithm (Yan et al. 2015) for computing connected components (CCs) in an undirected graph. Each vertex v maintains the smallest vertex ID it has seen, denoted by $\min(v)$. Hash-Min lets each vertex broadcast the smallest vertex ID seen so far, and when the algorithm terminates, $\min(v)$ equals the smallest vertex ID in v ’s CC.

The algorithm works as follows. In superstep 1, each vertex v sets $\min(v)$ as v ’s ID, broadcasts $\min(v)$ to all its neighbors, and votes to halt. In superstep i ($i > 1$), each vertex v receives messages from its neighbors; let \min^* be the smallest ID received, if $\min^* < \min(v)$, v sets $\min(v)$ to be \min^* and broadcasts \min^* to its neighbors. All vertices vote to halt at the end of a superstep. When the process converges, all vertices are halted, and vertices with the same value of $\min(v)$ constitute a CC. □

In this algorithm, message combining with the MIN operator can be applied to reduce commun-

nication. Specifically, since $compute()$ only cares about the minimum ID received, messages to be sent from a machine toward the same vertex v can be combined into one message that equals their minimum, before being sent to v . However, we remark that message combining is not applicable to an arbitrary Pregel algorithm, and many other Pregel-like systems (Zhou et al. 2014; Zhang et al. 2014) are built on the assumption that message combining is always applicable (to enable more optimization opportunities) but restricts the expressiveness compared with Pregel.

In Pregel, a vertex v does not have to communicate only with its direct neighbor in $\Gamma(v)$ (as in Hash-Min); it can send messages to any vertex u as long as u 's ID is known. Pregel is very suitable to implement parallel algorithms that adopt the pointer jumping (a.k.a. path doubling) technique to achieve good computational complexity. In such an algorithm, a vertex v may communicate with a vertex that is not in $\Gamma(v)$. Consider the following *list ranking* problem, which is a building block of the Euler tour technique (e.g., useful for computing biconnected components).

Example 2 Consider a linked list \mathcal{L} with n objects, where each object v is associated with a value $val(v)$ and a link to its predecessor $pred(v)$. The object v at the head of \mathcal{L} has $pred(v) = null$. For each object v in \mathcal{L} , the *list ranking* problem computes the summed value of v , denoted by $sum(v)$, as the sum of the values of all the objects from v following the predecessor link to the head.

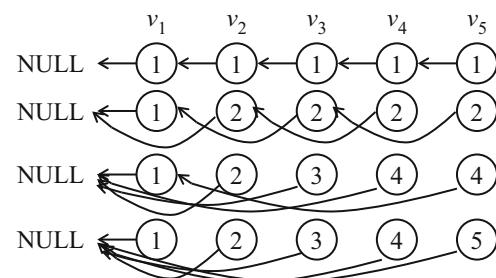

In list ranking, objects in \mathcal{L} are given in arbitrary order. A logical view of \mathcal{L} is simply a directed graph consisting of a single simple path. We now present the Pregel algorithm. Initially, each vertex v sets $sum(v)$ to be $val(v)$. Then in each round, each vertex v does the following: If $pred(v) \neq null$, v sets $sum(v) \leftarrow sum(v) + sum(pred(v))$ and $pred(v) \leftarrow pred(pred(v))$; otherwise, v votes to halt. Note that the if-branch can be accomplished in three steps: (1) v sends a message containing its ID to $u = pred(v)$ requesting for the values of $sum(u)$ and $pred(u)$; (2) u sends back the requested values to v ; and

(3) v updates $sum(v)$ and $pred(v)$. This process repeats until $pred(v) = null$ for every vertex v , at which point all vertices vote to halt and we have $sum(v)$ as desired. \square

Figure 1 illustrates how the algorithm works. Initially, objects v_1-v_5 form a linked list with $sum(v_i) = val(v_i) = 1$ and $pred(v_i) = v_{i-1}$. Let us now focus on v_5 . In Round 1, we have $pred(v_5) = v_4$ and we set $sum(v_5) \leftarrow sum(v_5) + sum(v_4) = 1 + 1 = 2$ and $pred(v_5) \leftarrow pred(v_4) = v_3$. One can verify the states of the other vertices similarly. In Round 2, we have $pred(v_5) = v_3$, and we set $sum(v_5) \leftarrow sum(v_5) + sum(v_3) = 2 + 2 = 4$ and $pred(v_5) \leftarrow pred(v_3) = v_1$. In Round 3, we have $pred(v_5) = v_1$, and we set $sum(v_5) \leftarrow sum(v_5) + sum(v_1) = 4 + 1 = 5$ and $pred(v_5) \leftarrow pred(v_1) = null$. Obviously, the algorithm stops in $O(\log n)$ rounds, and each object v sends (resp. receives) at most one message in each round.

List ranking is yet one of the many fundamental graph problems (including graph connectivity) that can be solved with Pregel using linear cost per superstep and at most $O(\log n)$ supersteps. These Pregel algorithms are scalable and have been studied in Yan et al. (2014b). In contrast, the Hash-Min algorithm can take up to $(|V| - 1)$ supersteps.

Optimizations. Since Pregel is only for internal use in Google, many open-source Pregel-like systems have emerged with various improvements. Giraph (Ching et al. 2015) (resp. Pregel+ Yan et al. 2015) provides a stable

Parallel Graph Processing, Fig. 1 Illustration of list ranking

open-source Pregel implementation in Java (resp. C++). GraphD (Yan et al. 2017c) lets each machine stream the adjacency lists of its assigned vertices, as well as messages toward and generated by those vertices, on local disks to eliminate the memory requirement. There is no sacrifice in performance when the network communication is the bottleneck (as typical to HDD+Ethernet and SSD+Infiniband settings) since disk streaming is overlapped with and covered by the message transmission.

GPS (Salihoglu and Widom 2013) constructs mirrors of each high-degree vertex v in other machines, so that v only needs to send its updated value to its mirror at a machine M which then forwards this update locally to v 's neighbors on M (rather than sending a message to each neighbor on M). Yan et al. (2015) further discover that there is a trade-off between vertex mirroring and message combining (in terms of reducing the message number) and provide analytical results to help determine which vertices should (and should not) be mirrored. The work also provides another technique to avoid the communication bottleneck caused by pointer jumping.

In many analytic tasks, graph computation is just one sub-step among a workflow of heterogeneous operations (e.g., MapReduce for preprocessing raw data into a graph). If different systems are used for different sub-steps, the output from one system has to be written to HDFS and then loaded by another system. General-purpose Big Data systems attempt to maintain a consistent data representation, such as the “RDD” of Apache Spark, to eliminate the data export/import cost between operations. To allow user-friendly programming of graph analytics, these systems are extended with a vertex-centric API, such as Spark’s GraphX (Gonzalez et al. 2014) and Flink’s Gelly (Carbone et al. 2015). Their aim is to achieve less end-to-end processing time by eliminating data exports/imports between consecutive operations.

Block-Centric Paradigm. The vertex-centric model passes updates slowly (one hop per superstep), and almost any communication along an edge requires network transmission. To

overcome this weakness, several systems propose to partition a big graph first and then let messages propagate among partitions (rather than vertices); updates propagated within each partition do not incur network communication.

Giraph++ (Tian et al. 2013) pioneers this idea by letting users define *compute()* over a partition of vertices (rather than each individual vertex). Blogel (Yan et al. 2014a) further allows users to associate status (e.g., values) with each partition (a connected subgraph called block) and allows both a vertex and a block to call a UDF *compute()*. With Blogel, the Hash-Min algorithm can just let blocks maintain and exchange the minimum block ID seen, without any vertex-level processing.

A key issue in the block-centric model is how to track vertices. In Pregel, the machine of a vertex v can be computed through a hash function over v 's ID, and it is called whenever a message needs to be sent to a vertex v . After graph partitioning, vertices in a block should be distributed to the same machine, but it is difficult to find a hash function to capture the vertex-to-machine mapping. Giraph recodes vertex IDs so that their ID-to-machine mapping can be captured with a hash function, while Blogel simply let each vertex ID to comprise the ID of the machine where the vertex locates. Giraph partitions a graph using a METIS-like approach, where METIS (Karypis and Kumar 1998) is classical graph partitioning algorithm with a high partitioning quality but limited scalability. Blogel provides several highly scalable partitioning tools including a general-purpose one based on the idea of graph Voronoi diagram, though the partitioning quality cannot match that of METIS.

Fan et al. (2017) propose the GRAPE system that only requires users to provide sequential graph algorithms; GRAPE uses METIS to partition a graph into high-quality fragments, and since only a small fraction of edges cross different machines, they are tracked by a master machine to decide the direction of message passing. However, the efficiency of this approach depends highly on the partitioning quality, and the sequential algorithms should meet a “monotonic condition.”

Shared-Memory Abstraction

Unlike Pregel where a vertex pushes its update to its neighbors, another kind of vertex-centric paradigm is shared-memory abstraction, where a vertex directly accesses the data of its adjacent vertices and edges during computation. However, these systems just simulate a shared-memory environment, and the actual execution is not shared memory but rather (1) distributed or (2) out of core. In fact, the simulation comes with some costs in both performance (shall be discussed shortly) and expressiveness (e.g., a vertex cannot communicate with a non-neighbor like in Pregel).

GraphLab. GraphLab (Gonzalez et al. 2012) pioneered the shared-memory abstraction in a distributed environment. It partitions edges (rather than vertices) among machines so that the workloads of processing a high-degree vertex can be distributed among multiple machines. However, if an edge (u, v) is distributed to a machine M , M needs to keep the states of both u and v ; therefore, the state of a vertex v is replicated at all machines that keep adjacent edges of v . This adds additional complication in value synchronization among vertex replicas, and it also uses more memory than Pregel. To reduce the number of replicas, GraphLab adopts a greedy strategy to distribute edges to machines, so that an edge (u, v) is more likely to be assigned to a machine that already maintain the states of u and/or v .

GraphLab adopts a Gather-Apply-Scatter (GAS) computation model, where a vertex v first gathers values along adjacent edges, aggregates these values to compute v 's new value, and then scatters value updates along adjacent edges. The model expressiveness is similar to Pregel algorithms where message combining is applicable. However, GraphLab supports asynchronous execution, which is desirable for graph problems where vertex values converge asymmetrically: vertices that converge more slowly can compute for more iterations. For other algorithms, GraphLab's synchronous mode is even faster as was observed by Lu et al. (2014), as asynchronous execution

incurs locking/unlocking cost. Moreover, the result of GraphLab is often approximate since a vertex is considered as converged and stops computation (and thus scattering its update) when the difference of value update is small. Zhang et al. (2014) provide a better solution that guarantees result exactness with synchronous execution, and asymmetric convergence is solved by selecting vertices with top- k largest difference of value update to perform computation in each iteration.

Stand-alone Systems. Shared-memory abstraction is a natural and preferred choice for a stand-alone system (i.e., a system running with a single machine), since there is no network overhead, and faster convergence is achieved through immediate access to the most up-to-date vertex values. Stand-alone systems perform out-of-core graph processing to eliminate the need of huge memory space: they partition vertices according to disjoint ranges of vertex ID and load one vertex partition to memory at a time for processing. The programming models are also just variants of GAS. GraphChi (Kyrola et al. 2012) needs to load all vertices in a partition, along with all their adjacent edges, into memory before processing of the partition begins; it smartly stores the adjacent edges of the vertex partitions (into the so-called shards) so that edge reads/writes are as sequential as possible to maximize disk bandwidth. X-Stream (Roy et al. 2013) only loads all vertices in a partition into memory, while edges are streamed on local disk(s); the model eliminates the need of ordering edges which is required by GraphChi's sharding.

Many other stand-alone graph processing systems have been developed. A number of them feature the efficient execution with new hardware (e.g., SSDs, GPUs). For example, Liu and Huang (2017) developed the Graphene system to fully utilize the bandwidth of an array of SSDs when performing external-memory graph processing; the system hides the details of IO processing from end users. Due to space limit, we refer interested readers to Chaps. 5.2, 9, and 10 of Yan et al. (2017a) for detailed models of the stand-alone systems.

Subgraph-Centric Paradigm

Existing research on parallel graph processing is dominant on problems with low computational complexity, such as iterative operations like random walks and graph traversals. Recall that Yan et al. (2014b) indicate that a Pregel algorithm is scalable if it has $O(n + m)$ cost per iteration and runs for at most $O(\log n)$ iterations, i.e., a complexity bounded by $O((n + m) \log n)$. However, there are many graph mining problems (e.g., community detection, subgraph matching) with a high complexity: the workloads are caused by the huge search space (i.e., subgraphs of a big graph), which can be much larger than the size of the input graph. We call these problems compute-intensive, in contrast to vertex-centric programs that are data-intensive with CPUs underutilized.

In a compute-intensive problem, network communication is no longer the bottleneck, and the goal of a distributed system is to keep the CPUs busy. Since the output of a graph mining problem is defined over subgraphs, a subgraph-centric API is more natural than a vertex-centric one. Some recent works attempt to perform subgraph mining by first constructing subgraph candidates, but the graph construction phase is communication-intensive and CPUs are underutilized. See Chapter 7 of Yan et al. (2017a) for the details.

A satisfactory solution is given by the G-thinker system (Yan et al. 2017b), which decomposes the computation over a big graph G into computations over (possibly overlapping) subgraphs of G that are much smaller, such that each result subgraph can be found in exactly one decomposed subgraph. If a decomposed subgraph is still too big, it can be further decomposed so that the resulting decomposed subgraphs can be distributed to different machines for balanced parallel processing.

We illustrate this divide-and-conquer idea by considering maximal clique enumeration. We decompose the computation over a big graph $G = (V, E)$ into that over a set of G 's subgraphs G_1, G_2, \dots, G_n , where G_i is constructed by expanding from a vertex $v_i \in V$. Let us define $\Gamma_{gt}(v) = \{u \in \Gamma(v) | u > v\}$ where vertices are compared according to their IDs. If we construct

G_i as the subgraph induced by $\{v_i\} \cup \Gamma(v_i)$ (called v_i 's 1-ego network), then we can find all cliques from these 1-ego networks since any two vertices in a clique must be neighbors of each other. To avoid redundant computation, we redefine G_i as induced by $\{v_i\} \cup \Gamma_{gt}(v_i)$, i.e., G_i does not contain any neighbor $v_j < v_i$. This is because any clique containing both v_i and v_j has already been computed when processing G_j . Obviously, any clique C (let the smallest vertex in C be v_i) is only computed once, i.e., when G_i is processed. If v_i has a very high degree, G_i is big which incurs heavy computation workload, and we can recursively generate decomposed subgraphs on G_i from neighbors of v_i , similarly as how we generate the seeding decomposed subgraphs on the original graph G , but conditioned on the fact that v_i is already included in any clique subsequently found.

G-thinker Design. G-thinker performs computation on subgraphs. Each subgraph g is associated with a task, which performs computation on g and grows g by pulling adjacent vertices/edges when needed. Tasks are spawned from individual vertices. Different tasks are independent, while each task performs computation iteratively so that if it is waiting for responses of its data requests, it will be hanged up in a task queue to allow CPUs to process other tasks.

G-thinker loads an input graph by partitioning vertices (along with their adjacency lists) among the memory of different machines, forming a distributed key-value store that returns $\Gamma(v)$ for every request to pull vertex v . Each machine spawns tasks from its loaded vertices, but idle machines may steal tasks from other machines for load balancing. Vertex requests and responses are sent in batches to amortize the round-trip time, and multiple requests for the same vertex v from a machine are merged into one request before sending. The received remote vertices are put in a local vertex cache to allow sharing by all local tasks. The vertex cache maintained by a storage manager is in-memory and has a limited capacity. When a vertex is no longer locked by any local task, it can be deleted to make room for new vertices requested by other tasks.

Users write a G-thinker program by implementing two UDFs. The first is *compute(frontier)*, which specifies how a task computes for one iteration. If $t.\text{compute}()$ returns true, task t needs to be processed by more iterations; otherwise, t is finished after the current iteration. Inside $t.\text{compute}()$, a user may access and update t 's subgraph g and t 's state and call *pull(u)* to request vertex $\Gamma(u)$ for use in t 's next iteration. Here, u is usually in the adjacency list of a previously pulled vertex (tracked by the function input *frontier*), and *pull(u)* expands the frontier of g (usually in a breadth-first manner). A user may also call *add_task(task)* in $t.\text{compute}()$ to add a newly created task to the task queue, which is useful when g is too large and needs further decomposition.

The second UDF is *task_spawn(v)*, which specifies how to create tasks according to a vertex v . Inside the function, users may create 0 or more tasks by examining v 's attribute and adjacency list and add them to the task queue by calling *add_task()*. G-thinker calls this function on every vertex to spawn tasks.

Example of Applications

Vertex-centric algorithms have been developed to solve fundamental graph problems such as breadth-first search, list ranking, spanning tree, Euler tour, pre/post-order traversal, connected components, biconnected components, strongly connected components, etc. (Yan et al. 2014b). It has also been applied to various real applications such as social network analysis (Quick et al. 2012) and genome assembly (Yan et al. 2018).

Subgraph-centric frameworks have been applied for problems including subgraph-structure (triangle, clique, quasi-clique) mining and graph matching (Yan et al. 2017b), motif counting in biological networks, finding social circles, and personalized recommendations (Quamar et al. 2016).

Future Directions for Research

One promising direction of research is the subgraph-centric paradigm for compute-intensive

(and/or recursive) graph analytics, which is still in its infancy. Existing research on graph processing systems dominantly focuses on optimizing data-intensive iterative graph analytics, limiting their applicability.

Another interesting research area is to consider how to optimize vertex-centric and graph-centric workloads on new hardware such as SSDs and GPUs. While stand-alone solutions have been proposed, it would be interesting to see distributed solutions that utilize a cluster of machines equipped with new hardware. This would pose more challenges since the gap between slow data moving (i.e., network communication) and faster computation (e.g., with GPUs) becomes larger.

Finally, it would be interesting to see more applications developed on these big graph processing frameworks. Current research in this area are dominantly on system design and optimizations, and papers discussing applications of these systems are still very limited in number.

Parallel Join Algorithms in MapReduce

Spyros Blanas

Computer Science and Engineering, The Ohio State University, Columbus, OH, USA

Definitions

The MapReduce framework is often used to analyze large volumes of unstructured and semi-structured data. A common analysis pattern involves combining a massive file that describes events (commonly in the form of a log) with much smaller reference datasets. This analytical operation corresponds to a parallel join. Parallel joins have been extensively studied in data management research, and many algorithms are tailored to take advantage of interesting properties of the input or the analysis in a relational database management system. However, the MapReduce framework was designed to operate on a single input and is a cumbersome framework for join processing. As a consequence, a new class of parallel join algorithms has been designed, implemented, and optimized specifically for the MapReduce framework.

Overview

Since its introduction, the MapReduce framework (Dean and Ghemawat 2004) has become extremely popular for analyzing large datasets. The success of MapReduce stems from hiding details of parallelization, fault tolerance, and load balancing over a generic programming abstraction. One frequent data analysis pattern in MapReduce starts with a log of events, such as a click stream, a log of phone call records, or even a sequence of transactions in flat files. MapRe-

duce is then used to combine information in the log with other reference data to compute statistics and derive business insights from the data. This analytical pattern corresponds to a parallel join.

A key reason of the popularity of MapReduce for this task over a traditional database system is the sheer volume of data involved in a join, which can be hundreds of terabytes (Blanas et al. 2010). Merely formatting and loading that much data into a database system in a timely manner is a challenge. In addition, the log records do not always follow the same schema, or the interpretation of a log record may change over time. MapReduce gives users the flexibility to write custom code to parse attributes of interest.

Key Research Findings

It turns out it is possible – but not always straightforward – to implement well-known join strategies in MapReduce. Many join algorithms, in fact, do not require any modification to the basic MapReduce framework and thus can be readily used by existing MapReduce platforms like (Hadoop 2017).

Programming in MapReduce involves defining appropriate *map* and a *reduce* function for the specific analysis task at hand. The map function takes a key-value pair (k, v) as input from a distributed file system and generates one or more pairs of (k^*, v^*) as the output. Each map task processes a non-overlapping chunk of the input file called a *split*. Typically, the size of a split is the block size of the distributed file system. The *reduce* function takes as the input a pair of $(k^*, list(v^*))$, where $list(v^*)$ is a list of all v^* values with key k^* . The reduce function produces yet another key-value pair as the output which is stored in a distributed file system.

Repartition Join

We consider an equi-join between a reference table R and an event log S on a single column. In general, R is much smaller than S . The standard repartition join shuffles data in both R and S such that records with identical join keys are colocated

in the same node and then processes the join locally.

The repartition join can be implemented in a single MapReduce job. In the map phase, each map task works on a split of either R or S . The map function tags the record with its originating table to identify which table an input record is from and creates a composite key of the form $(join\ key, tag)$. The partitioning function is customized so that the hash is computed from just the join key part of the composite key. This way all records with the same join key will be assigned to the same reduce task.

For each join key, the reduce function first separates the input records into two sets according to the table tag. Once the entire input has been split, the repartition algorithm then performs a cross-product between records in these sets.

One optimization is to ensure that the table tags are generated such that the tag for table R lexicographically precedes the tag for table S . This way, the reducer that processes a given join key will see all R records for this join key first. Hence, the reducer can only buffer records from table R and start producing data as soon as the first record from table S is encountered.

P

Broadcast Join

In many instances, the event log S is orders of magnitude larger than the reference table R . Instead of moving both R and S across the network, one can broadcast the smaller table R to all nodes. In a MapReduce context, broadcasting is performed via the distributed file system when all tasks read the same file(s).

A broadcast join can be run as a MapReduce job with no reduce function. (The broadcast join is sometimes referred to as a map-side join because of this property.) Each map task first reads R and builds an in-memory hash table on the join key. Then every map task processes a split of S and probes the hash table with the join key of each record. If the key matches, the two records are joined. The map task thus computes the broadcast join and writes directly to the distributed file system without invoking a reduce function. This avoids sorting both tables and,

more importantly, avoids the network overhead for moving the entire log S in the reduce phase.

The broadcast join is amenable to two optimizations. The first is to dynamically pick the side to build the hash table. The motivating observation is that the default split size (commonly 128 MB) may mean that R is larger than the fraction of L that will be processed by this map task. A common optimization is to build the hash table on the fraction of L and use R to probe into this hash table instead.

The second optimization is to materialize the hash table in the local node. A naive implementation of the broadcast join would reread R from the distributed file system for every map task. Because a node processes multiple map tasks, this means retransmitting R multiple times during join processing. Instead, one can serialize the hash table R in the local file system and redirect subsequent map tasks to the local copy. These temporary files need to be cleared after the job terminates. This amortizes the transmission and processing overhead of R over all the map task invocations in this node.

Semi-join

The repartition and broadcast algorithms transfer all records in R ; although many they may not be referenced by any records in S . For instance, many users of a social network may not have been active in the last hour. The semi-join algorithm avoids reading and manipulating records in R that would not match any record in the log S , but it does this at the cost of an extra scan of S .

A semi-join is implemented as three separate MapReduce jobs that run sequentially. The first phase of the semi-join collects all the unique keys in S . This corresponds to using a reduce function that only emits the join key of each group. An implementation may also aggregate in the map function by building a main-memory hash table to determine the set of unique join keys per split of S . Aggregating in the map function curtails duplicate keys when they appear in the same split in S . This optimization is particularly effective when the actions that are recorded in the log exhibit temporal locality. The second phase of the

semi-join is a broadcast join between the unique keys in S (from phase one) with R to produce the exact subset $R' \subset R$ that is necessary to compute the join. The third and final phase of the semi-join is broadcasting R' (from phase two) and joining with S to produce the join output on the distributed file system.

The semi-join procedure described above ensures that every record in R' matches at least one record in S . However, the third phase of the semi-join will still broadcast unnecessary records for the given split of S that each map task will process. One optimization is to generate a subset R'_i per split S_i of S . This makes the final phase of the semi-join cheaper, since it moves exactly the records that will match in the current split of S . This optimization must be applied judiciously as the first two phases become significantly more involved.

Theta Joins

Many join operations specify join conditions other than key equality. Yet, the reduce function of the MapReduce framework operates on records with identical keys. This design constraint makes it challenging to perform joins with arbitrary join conditions in MapReduce. Okcan and Riedewald have introduced a randomized algorithm, called 1- Bucket-Theta, that evaluates arbitrary joins in a single MapReduce job (Okcan and Riedewald 2011).

The motivating observation is that one can compute arbitrary join conditions in MapReduce inside the reduce function, if each invocation receives a superset of all matching tuples. The question then becomes what reduce key should the map function produce to accomplish this. One naive strategy is to assign every tuple to a single reduce key. The reduce function will compute the correct result, but this strategy does not utilize the parallelism of the MapReduce framework. Another naive strategy is to construct a map function that emits a set (k_i, v) tuples per input record v , where k_i enumerates every key in the key domain. This naive solution is theoretically sound and scalable but infeasible in practice

due to the cost of enumerating the entire key domain.

An efficient theta join algorithm should aim to emit as few reduce keys as possible but also balance the work between reducers. Okcan and Riedewald cast this problem as an optimization problem: given a join matrix between all R and S tuples, what is the optimal assignment of regions of the join matrix to reducers? The optimization function seeks to balance the reducer input (i.e., creating enough k_i keys to balance the load to all reducers) with the cost to produce the output (i.e., not overwhelm any single reduce task with computing a massive Cartesian product of the inputs). The 1-Bucket-Theta algorithm assigns regions of the join matrix to reducers in a randomized fashion to produce a mapping that minimizes job completion time. For each incoming R record, the map function in the 1-Bucket-Theta algorithm randomly chooses a row of the join matrix and emits an output tuple (k_i, v) for each region of S that intersects with this row. Randomization is an important component of the solution because there is no consensus mechanism in MapReduce to find out how many k_i values in the dataset are smaller than the key that the map function is currently processing.

Optimizing MapReduce for Join Processing

The performance of each join algorithm depends on a number of factors, including properties of the input (such as input cardinality, join selectivity, data placement) and the hardware (such as disk throughput, memory capacity). Because of this complex parameter space, many efforts have focused on how to optimize MapReduce for join processing.

The Starfish Project (Herodotou and Babu 2011) develops cost-based optimization methods for Hadoop and the Hadoop Distributed File System. Starfish introduces a profiling module that collects statistical information from MapReduce jobs. These statistics are then forwarded to the “what-if” module that aims to minimize the objective cost function using a cost model. Starfish identifies the split size, the number of reduce tasks, the amount of memory that can

buffer output, and the settings of the multi-pass external sort that computes the inputs to each reduce function as the most crucial performance components of the cost model.

Another avenue for performance improvements are mechanisms to control data placement in MapReduce so as to allow the co-location of related data on the same set of nodes. CoHadoop modifies the data placement policy of the Hadoop distributed file system with a new *locator* property (Eltabakh et al. 2011). Files with the same locator attribute are placed on the same set of nodes, whereas files with no locator are placed using the default locality-oblivious strategy. Co-location can improve I/O performance if datasets are accessed in tandem, but it has important implications for fault tolerance. The probability of losing data because of a failure with co-location is significantly smaller than without co-location, because co-location does not scatter data blocks randomly across the cluster. However, if a failure occurs, more data would be unavailable with co-location. Therefore, co-location decreases the possibility of data loss but amplifies its magnitude.

Database systems optimize a multi-way join by enumerating possible orders of binary joins that construct left-deep, bushy and right-deep plans (Liu and Blanas 2015). The source-agnostic MapReduce framework presents an opportunity to evaluate multi-way joins in a more efficient manner than as a sequence of binary joins. Afrati and Ullman (2010) introduce an algorithm for multi-way join evaluation in MapReduce that is shown to have lower communication cost than evaluating the same multi-way join as a sequence of binary joins. In this algorithm, each join attribute is assigned to a number of “shares.” A “share” corresponds to a hash bucket into which the value of the attribute will be hashed to be transmitted to the appropriate reduce task. The total number of reduce tasks is the product of the “shares” of all attributes. The algorithm uses Lagrange multipliers to optimize the number of “shares” that are assigned to each attribute such that the overall communication cost is minimized.

Other Research Efforts

Ongoing research aims to bridge the gap between the usability of the MapReduce framework and the functionality of database management systems. One research trajectory aims to present a common query interface to the user but synergistically process data between a MapReduce-like framework and a database system in the backend (Bajda-Pawlikowski et al. 2011). Exemplars include HadoopDB (Abouzeid et al. 2009) and Polybase (DeWitt et al. 2013).

The inherent difficulty in expressing arbitrary parallel computation as map and reduce functions motivated the development of big data analytics frameworks for general parallel computation. AsterixDB (2017), Drill (2017), Hive (2017), Impala (2017), Quickstep (2017), and Spark (2017) are all open-source Apache projects that move beyond the MapReduce paradigm for big data processing and natively support parallel joins.

Many machine learning and data mining algorithms are iterative or are designed for datasets that evolve over time. Incremental computation is poorly supported in MapReduce, however, as a task cannot transparently reuse the processing done in a previous phase. Researchers have proposed several solutions for applications that perform incremental computations with new data. Incoop allows unmodified MapReduce programs to reuse intermediate results from previous runs using memoization and stable partitioning (Bhatotia et al. 2011). The resilient distributed dataset abstraction in Spark stores intermediate results in memory to avoid disk I/O across iterations (Zaharia et al. 2012). Dedicated stream processing engines, such as Apache Flink (Carbone et al. 2015), support continuous processing with low latency.

An appealing property of MapReduce is its ability to directly process text data without a cumbersome cleaning and loading step. Research efforts have investigated how database systems can ingest data more efficiently. Invisible loading incrementally imports the data into a database when parsing data in MapReduce (Abouzied et al. 2013). NoDB bypasses data loading in PostgreSQL and directly processes external files

(Alagiannis et al. 2012). Queries in NoDB are accelerated through positional maps and selective parsing. The ScanRAW operator queries data and simultaneously loads frequent accessed data in a database (Cheng and Rusu 2015). This principle can be applied to binary formats such as the HDF5 format for scientific data processing (Blanas et al. 2014).

MapReduce frameworks have adopted storage optimizations found in database systems to accelerate data analytics. Floratou et al. (2011) incorporate column-oriented storage techniques in the Hadoop implementation of MapReduce. Many big data storage formats including RCFFile (He et al. 2011), Apache Parquet (Parquet 2017), and Apache Avro (2017) have embraced columnar data layouts.

Definitions

Discrepancy between the explosive growth rate in data volumes and the improvement trends in processing and memory access speeds necessitates that parallel processing be applied to the handling of extremely large data sets.

Overview

Both data volumes and processing speeds have been on exponentially rising trajectories since the onset of the digital age (Denning and Lewis 2016), but the former has risen at a

much higher rate than the latter. It follows that parallel processing is needed to bridge the gap. In addition to providing a higher processing capability to deal with the requirements of large data sets, parallel processing has the potential of easing the “von Neumann bottleneck” (Markgraf 2007), sometimes referred to as “the memory wall” because of its tendency to hinder the smooth progress of a computation, when operands cannot be supplied to the processor at the required rate (McKee 2004; Wulf and McKee 1995). Parallel processing algorithms and architectures (Parhami 1999) have been studied since the 1950s as a way of improving computer system performance and, more recently, as a way of continuing the exponential rise in performance while keeping the power consumption in check (Gautschi 2017; Gepner and Kowalik 2006; Koomey et al. 2011).

Trends in Parallel Processing

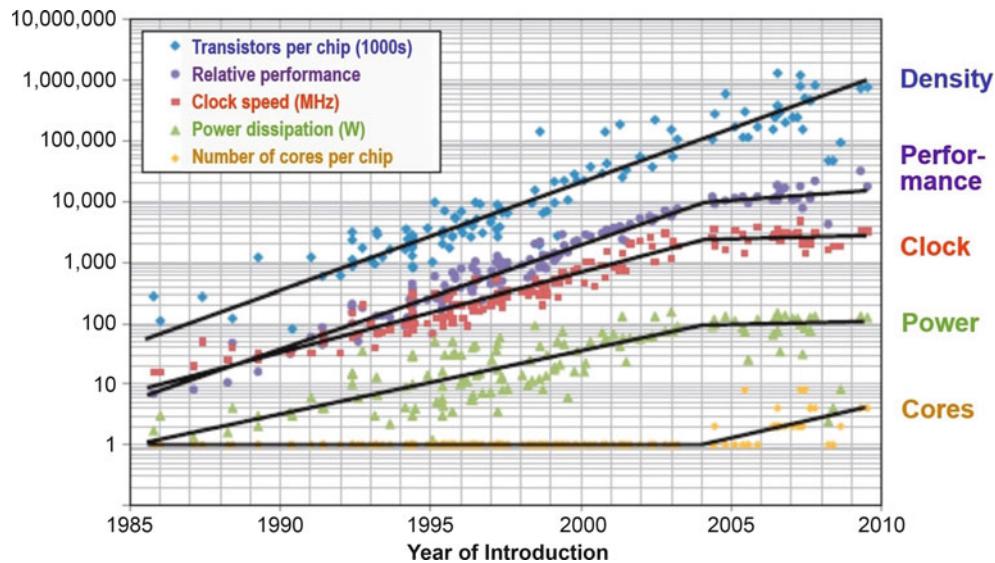

Interest in parallel processing began in the 1960s with the design of ILLIAC IV, generally recognized as the world’s first supercomputer (Hord 2013). The 64-processor machine, later built and operated by Burroughs Corporation, had a single-instruction-stream, multiple-data-stream architecture, SIMD for short (Flynn and Rudd 1996), which uses a single instruction execution unit, with each instruction applied to multiple data items simultaneously. The other main class of parallel architectures is known as MIMD, in which there are multiple instruction streams in addition to multiple data streams. The latter architectural category has a great deal of variation in terms of how memory is implemented (global or distributed) and how the multiple processors communicate and synchronize with each other (shared-variable or message-passing).

Modern supercomputers, including most entries in the Top500 Supercomputers List, which is updated twice a year (Top-500 2017), tend to be MIMD DMMP, meaning that they use distributed memory, whereby processors are endowed with chunks of the memory space, and communicate

via message-passing. Each processor has direct (and thus fast) access to its local memory and indirect (and thus slower) access to nonlocal or remote chunks of memory. Top-of-the-line supercomputers are often used to perform numerically intensive computations involving floating-point numbers. Thus, their performance is measured in floating-point operations per second, or FLOPS. As of late 2017, the top supercomputer in the world had a peak performance of 125 PFLOPS (Peta-FLOPS) and a sustained performance at 75% of the peak. We are now on the verge of achieving a peak performance of 1 EFLOPS (Exa-FLOPS or 10^{18} FLOPS).

The topmost trend line in Fig. 1 shows the exponential rise in the number of transistors that can be placed on a single microchip. This exponential rise in density is known as Moore’s Law, after Intel co-founder Gordon E. Moore, who first observed the trend (Brock and Moore 2006; Mack 2011; Schaller 1997). Up to the early 2000s, the rising chip density was accompanied by exponential improvement in performance, owing to the correspondingly higher clock frequencies. Then, clock frequency and performance trend lines began to flatten out, mostly because the attendant growth in power dissipation led to difficulties in cooling the superdense circuits. Thus, focus on performance enhancement shifted to using multiple independent processors on the same chip, giving rise to multicore processors (Gepner and Kowalik 2006). Using c cores, each with $1/c$, the performance is more energy-efficient, because power consumption is a superlinear function of the single-core performance.

Big data necessitates a reassessment of how we gauge supercomputer performance. While FLOPS rating and IOPS, its integer counterpart, are still important, input/output and storage bandwidth assume a larger role in determining performance. A supercomputer doing scientific calculations may receive a handful of input parameters and a set of equations that define a scientific or engineering model and then compute for days or weeks, before spewing the answers. Many big-data applications require a steady stream of new data to be input, stored, processed, and output, thus possibly straining the memory

Parallel Processing with Big Data, Fig. 1 Trends in transistor density, processor performance, clock frequency, power dissipation, and number of cores on a chip. (NRC 2011)

and I/O bandwidths, which tend to be more limited than computation rate.

Parallel Processing Models

Parallel processing architectures vary greatly in their organizations and user interfaces. Over the years, many abstract models of parallel processing have been introduced in an effort to accurately represent processing, storage, and communication resources, along with their interactions, allowing developers of parallel applications to visualize and take advantage of the available trade-offs, without being bogged down in machine-specific details. At the coarse level, we can distinguish data-parallel and control-parallel approaches to parallel processing (Parhami 1999).

Data parallelism entails partitioning a large data set among multiple processing nodes, with each one operating on an assigned chunk of data, before participating in the process of combining the partial results. It is often the case in big-data applications that the same set of operations must be performed on each data chunk, making SIMD processing the most efficient alternative. In prac-

tice, however, synchronization of a large number of processing nodes introduces overheads and inefficiencies that cut into the speed gains. So, it might be beneficial to direct the processing nodes to execute a single program on multiple data chunks asynchronously, with sparse coordination, giving rise to the SPMD (Darema 2001) parallel processing model.

Google's MapReduce (Dean and Ghemawat 2008, 2010) is the most prominent cloud-based system for SPMD parallel processing. In the map stage, data is distributed within independent tasks on different processing nodes. Each map-stage task produces a set of key-value pairs as its output. These outputs are then fed to reduce-stage tasks, where they are aggregated into a smaller set of key-value pairs that constitute the final output. Hadoop is a widely used open-source implementation of MapReduce on Apache servers (Bu et al. 2010). It consists of Hadoop's version of MapReduce, the Hadoop distributed file system (Shafer et al. 2010; Shvachko et al. 2010), that allows a user to store huge data files across multiple nodes while keeping the image of a centrally located file (stored in one piece), and Hadoop YARN (Vavilapalli et al. 2013), which manages computing resources and allows tasks to be scheduled on them.

The fully open-source Apache Spark (Zaharia et al. 2016) is in many ways similar to MapReduce, with the main differences that it uses a unified engine to replace various other needed subsystems, thus making the programming effort much more manageable and less error-prone, and a data-sharing abstraction, “resilient distributed data sets” or RDDs, which make it significantly more efficient for certain workloads.

In control-parallel schemes, which are more broadly applicable than data parallelism, multiple nodes operate independently on subproblems, synchronizing with each other by sending informational and synchronization messages. The said independence allows heterogeneous and application-specific resources to be employed, without cross-interference or slower resources hindering the progress of faster ones. More on this later. An attractive submodel of control parallelism, that aims to reduce communication and I/O overheads, is bulk synchronous parallel, or BSP, processing (Valiant 1990). BSP computations consist of communication- and synchronization-free supersteps that are executed to conclusion independently, before any communication or synchronization occurs.

Google’s Pregel system (Malewicz et al. 2010) is a practical implementation of BSP for executing iterative graph algorithms, while holding an entire large graph in memory, spread across many nodes, so as to avoid disk access latency. Other examples of the control-parallel paradigm are seen in event processing and stream processing systems commonly used in social media and other notification-driven applications (Abadi et al. 2003; Condie et al. 2010; Eugster et al. 2003; Rixner 2001).

Beyond the two broad kinds of parallel processing, reflected in data-parallel and control-parallel schemes, there are various other kinds of parallelism that can be used as competing or complementary approaches. These include instruction-level parallelism (Rau and Fisher 1993), subword parallelism (Lee 1997), dataflow parallelism (Sakai et al. 1989), and simultaneous-multithreaded parallelism (Eggers et al. 1997), the latter offering the advantage

of lower overhead as well as greater resource sharing in running interdependent tasks in parallel.

Heterogeneity and Hardware Acceleration

Heterogeneous parallel processing entails using multiple processing resources that have diverse designs and performance parameters. Heterogeneity complicates the problems of task assignment and coordination, but it also increases flexibility in matching computational requirements of tasks to hardware and software capabilities. In a heterogeneous system, users can have access to the capabilities of a supercomputer, say, even though their use of such a powerful machine is too limited to justify purchase or even a long-term usage contract.

Within a heterogeneous parallel computing system, some nodes may be specialized for highly efficient execution of certain computations through the use of application-specific hardware-/software and augmentation with accelerators. Examples include use of graphic processing units or GPUs as computation engines (Nvidia 2016; Owens et al. 2008; Singer 2013), units optimized for information retrieval and data mining (Sklyarov et al. 2015), and a variety of other specialized resources made accessible through the cloud (Caulfield et al. 2016).

In addition to fixed acceleration resources, reconfigurable devices, that can be programmed to act as different kinds of acceleration mechanisms, may be deployed. Modern FPGAs (Kuon et al. 2008) offer immense computational resources that can be tailored dynamically to help remove processing bottlenecks. Application-specific circuits, whether custom-designed or implemented on FPGAs, provide additional options for acceleration. For example, sorting networks (Mueller et al. 2012; Parhami 1999) can be used in a wide array of contexts, which include facilitating classification or speeding up subsequent search operations.

Interconnection Networks

Modern parallel computers use commodity processors, often multicore, multithreaded, or GPUs, as computing resources. This allows rapid advances in processor speed and energy efficiency to become immediately available to parallel systems. It follows that the distinction between various parallel processing systems is, to a great extent, determined by the interconnection networks used to allow data exchange between computing nodes. The network connecting processing resources can also be commodity, such as Ethernet. However, it often pays to design a custom network, or at least use a custom configuration of commodity switches, that matches the communication requirements.

Over the years, numerous interconnection network architectures have been proposed and used (Dally and Towles 2004; Duato et al. 2003; Parhami 1999) for different system scales. When computing nodes are on the same electronic chip, they are connected by an on-chip network (Benini and De Micheli 2002), whose design is often more restricted in view of limitations on area and power. Interconnecting processing nodes within a large mainframe or supercomputer system presents challenges in wiring and packaging, with many theoretically superior topologies becoming impractical because they cannot be implemented within the physical limits imposed by partitioning, packaging, signal delays on long wires, and the like (Dally and Towles 2004). Interconnecting servers within a data center presents fewer limitations in terms of topology, but given the scale, energy efficiency considerations, as well as reliability and serviceability factors, become dominant.

Mapping, Scheduling, and Virtualization

A fundamental problem in parallel processing is the mapping of computations to hardware resources. Ideally, this mapping should be automatic and transparent, so as to relieve users from

having to deal with hardware details and configuration changes. However, user-guided mapping can result in better running times and more efficient resource utilization, in view of targeted optimizations in fitting parts of the tasks to capabilities of the available processing resources.

An important kind of mapping, whose roots go back to before computers appeared on the scene, is scheduling. For parallel processing, scheduling refers to the assignment of computational sub-tasks to processing nodes while honoring various constraints, in such a way that an objective function is optimized (Sinnen 2007). The simplest objective function is task completion time, but a variety of more detailed objectives, such as meeting deadlines and minimizing energy consumption, may also enter into the picture.

Virtualization (Nanda and Chiueh 2005) allows system resources to be used effortlessly among different users while isolating and protecting them from one another to ensure privacy and security. The techniques used represent extensions of, and improvements upon, time-sharing schemes of the 1960s (Wilkes 1972) that fell out of favor when compact and inexpensive hardware became available in the form of minicomputers and, eventually, microcomputers. Virtual-machine monitors (Rosenblum and Garfinkel 2005) isolate users from hardware details, resource fluctuations, and configuration changes, thus allowing greater focus on application correctness and high-level trade-offs. Reliability is also improved, both because software bugs are isolated within virtual machines, preventing their spread, and because any detected hardware malfunction can be circumvented by rescheduling affected tasks on other operational virtual machines.

P

Future Directions

While parallel processing technologies have matured over more than five decades, requirements of big-data applications are already creating new challenges, which will pose greater difficulties with the continued exponential growth in data

volumes. This explains the proliferation of proposals for hardware architectures, software aids, and virtualization schemes to ease the key bottlenecks.

Studies on expected direction of computer architecture research over the coming decades (Ceze et al. 2016; Stanford University 2012) point to substantial growth in the use of parallel processing for performance, scalability, energy economy, and reliability reasons. Changes in parallel architectures and attendant virtualization techniques will both influence and be driven by the evolution of cloud computing systems (Agrawal et al. 2011). As data volumes grow and the scope of hardware resources for big-data processing expands, energy efficiency, which is already a major design and cost consideration, will grow in importance (Koomey et al. 2011).

Pattern Recognition

Alessandro Margara

Politecnico di Milano, Milano, Italy

Synonyms

Complex event processing; Event pattern recognition

Definitions

Complex event recognition (CER) refers to the detection of situations of interest – *complex events* – from streams of *primitive events*. Event recognition is performed on the fly, as new events are observed from the input streams, to enable timely reactions.

Overview

Complex event recognition (CER) aims to detect high-level situations of interest, or *complex events*, on the fly from the observation of streams of lower-level *primitive events*, thus offering the opportunity to implement proper reactive or proactive measures (Artikis et al. 2017). Examples of CER come from many different applicative domains. Environmental monitoring applications observe data coming from sensors to detect critical situations and anomalies. Financial applications require constant analysis of stocks to detect trends. Fraud detection tools monitor streams of credit card transactions to prevent frauds.

The research and development of CER focus on two main aspects: (i) identifying suitable *languages* to define complex events from event *patterns* that predicate on the occurrence, content, and temporal relations of primitive events in the input streams and (ii) defining recognition algorithms and processing techniques that efficiently analyze large volumes of input data – *high throughput* – and produce new results as soon as possible, *low delay*.

To concretely illustrate a typical CER pattern, let us refer to the following event definition D expressed in the TESLA language (Cugola and Margara 2010) adopted by the T-Rex event recognition engine (Cugola and Margara 2012a).

Definition D

```
define Fire(area: string)
from Smoke(area=$a) and last
Temp(value>40,area=$a)
within 5 min
from Smoke and
not Rain(area=$a)
between Temp and Smoke
where Fire.area=Smoke.area
```

Intuitively, definition D recognizes a (complex event of type) fire in a given area a whenever (primitive events of) smoke and high temperature in area a are observed from the input streams within 5 min from each other and without any observation of rain in between.

Several CER languages and systems have been proposed in the last years (Etzion and Niblett 2010; Cugola and Margara 2012c; Artikis et al.

2012), which provide different data and temporal models, pattern languages, processing algorithms, and architectures. The remainder of this chapter overviews the dominant approaches to pattern definition and detection.

Applications

As anticipated in the overview, CER is relevant for disparate application domains. Before discussing the CER models and technologies, we present some of these applications.

CER has been adopted for monitoring and surveillance of vehicles. In maritime surveillance, CER can extract trajectories from streams of positions and detect suspicious or potentially dangerous situations, such as loitering, vessels passing through protected areas, and unsafe shipping (Patroumpas et al. 2015). In the context of vehicular ad hoc networks (VANET), CER can detect traffic jams (Terroso-Saenz et al. 2012). In vehicle sharing applications, CER can help matching requests and availability of suitable vehicles (Alli et al. 2012).

CER has also been used to provide real-time access to monitoring data and enable anomaly detection and resource optimization in the context of grid infrastructures (Balis et al. 2011), health applications and hospitals (Yao et al. 2011), and inventory management (Wu et al. 2006).

In online monitoring applications, CER can track the behavior of users on the Web to improve the usability of Web sites or to better select the advertisements (Ali et al. 2009).

Finally, CER can be used to extract statistics and highlights in sports events (Mutschler et al. 2013).

Data Models

Event recognition evaluates input streams of (primitive) events to produce output streams of (complex) events. This section analyzes the most common approaches to model events and event streams.

Events are the core elements of the data model. Each event represents the notification of occurrence of an aspect of interest in the environment under analysis, such as a reading from a sensor. Several formats are possible to encode events,

the most common being attribute/value pairs. Other formats include JSON, XML, or native structures or objects in a specific programming language. Most often, events are characterized by a *type* (or *schema*) that determines their structures. For instance, if an event is encoded using attribute/value pairs, the type determines the number, names, and types of the attributes that appear in the event.

As an example, definition D above defines an event of type *Fire* with a single attribute *area* of type *string*. Within the pattern, it selects events of type *Smoke*, *Temp*, and *Rain*, and predicates on the content of their attributes (*area* and *value*).

Streams can be *homogeneous* or *heterogeneous*. The former include events of the same type, whereas the latter can include events of different types. In the presence of homogeneous streams, the processing engine can be optimized to leverage the fixed structure of the events coming from that stream.

Given the central role of time in event recognition, events always include a temporal attribute or *timestamp*. Depending on the semantics of the recognition, the timestamp can represent the actual time of occurrence of the event, as measured by the event producer (for instance, a sensor), the time in which the event is received by the recognition system, or the time in which the event is processed. In the first case, we say that the recognition adopts *event time* semantics; in the second case it adopts, *ingestion time* semantics; and in the third case, it adopts *processing time* semantics. These policies have various implications on the order in which the events are processed: the interested reader can refer to the “Time Management” chapter.

Furthermore, timestamps can represent a single point in time or an interval. In the second case, they encode the interval of validity of the event. Interval time can be more expressive but complicates the definition of the semantics of event recognition (White et al. 2007).

Event Recognition Languages

Event recognition languages build on a set of primitive operators that predicate on the content

and temporal relations between events and provide abstractions to combine these operators into complex event definitions.

This section first presents the set of operators most commonly found in existing languages and then introduces the main classes of abstractions for event recognition.

Operators for Event Recognition

To present the most common operators for event recognition, let us refer again to definition D. At a high level, it consists of three parts: the *define* clause specifies the type and content of the complex event to be generated upon recognition, the *from* clause specifies the pattern to be recognized, and the *where* clause defines the content – values for the attributes – of the complex event based on the content of primitive events.

Selection. Selection operators isolate primitive events relevant for the pattern based on their type and on the value of their attributes. For instance, definition D *selects* events of type *Smoke* and *Temp* and further constrains the content of *Temp* by requesting a *value* larger than 40. Depending on the specific language, the predicates on the content of events can have different forms, including regular expressions, as well as conjunctions and disjunctions of constraints on one or more attributes.

Conjunctions and sequences. Conjunctions demand for the presence of multiple events by combining individual selection operators. For instance, the pattern in definition D requires the presence of *both* an event of type *Smoke* and an event of type *Temp*. Sequence operators are a special kind of conjunction that further require the events to appear in a specific temporal order. Many languages only offer conjunctions in the form of sequences, thus enforcing the definition of a specific order between the events to be detected.

Temporal constraints. Temporal constraints express time boundaries for the entire pattern or for some parts of it. For instance, Rule R requires

`Smoke` and `Temp` to occur within no more than 5 min from each other.

Parameters. Parameters bind the values of different events that appear in the pattern. For instance, definition D requires that `Smoke` and `Temp` share the same value for the attribute `area`.

Negations. Negations express things that must *not* occur. For instance, the pattern in definition D is recognized if no `Rain` event is detected between the occurrence of `Temp` and `Smoke`. Negations can be only evaluated within temporal boundaries; otherwise it becomes impossible to determine if the negated situation will eventually occur some time in the future. For instance, definition D uses the occurrences of `Temp` and `Smoke` to define the boundaries for the negation.

Aggregates. Aggregates extract a value from the content of multiple primitive events. For instance, definition D could be modified to predicate on the *average* value of the temperature in a given area rather than considering a single occurrence of temperature. Aggregate values can be used both to constrain the validity of a pattern – for instance, by enforcing a minimum threshold to the average temperature measured in a given area – and to define the value of some attribute of the complex event generated.

Hierarchies. Most languages enable reusing complex events within the definition of other complex events, thus promoting modularity and composability. With reference to definition D, a new definition D could reuse the concept of fire in area a to recognize a severe alert when some people are moving toward area a.

Selection and consumption policies. Selection policies define the semantics of recognition when the pattern is satisfied by multiple set of events from the input streams. For instance, definition D specifies that in the presence of multiple temperature events with the desired values and within the given time span only the most recent – the last – has to be considered. Other valid pos-

sibilities would be selecting the oldest – the first – temperature event or selecting all temperature events and generate a fire recognition for each of them.

Consumption policies define which events remain valid after a recognition and which ones do not – they are *consumed*. With reference to definition D, the consumption policy defines what happens in case one temperature event is followed by two smoke events: if the temperature is not consumed after the first recognition, then the second smoke event can reuse the temperature event to trigger a new recognition, otherwise it cannot. By default, TESLA definitions do not consume events, but an optional consuming clause can express the events to be consumed on a per-rule basis.

Selection and consumption policies have been first introduced in the domain of event processing in active database systems (Chakravarthy and Mishra 1994), when they were combined in a set of predefined default choices called *contexts*.

Models for Event Recognition

We now overview different models for event recognition that integrate the operators discussed above (Artikis et al. 2017).

Automata-based models. Automata-based models compile complex event definitions into some form of automata that are later adopted for recognition. Automata states represent primitive events to be recognized: upon recognition of a primitive event, an automaton transitions through an outgoing edge to a subsequent state. Edges can be decorated with pattern constraints that must be satisfied to enable the transition: examples are temporal constraints and parameters.

New automata are instantiated on demand to initiate a new recognition: an automaton reaches an accepting state and produces a complex event when it has recognized all the primitive events in the pattern; conversely, an automaton reaches a failure state and gets deleted if it violates some constraint expressed in the pattern.

Examples of languages and systems that adopt automata-based models include Cayuga (Brenna

et al. 2007), SASE (Wu et al. 2006), and SASE+ (Gyllstrom et al. 2008).

Languages that rely on this model resemble regular expressions that concatenate individual events into sequences. In some cases, regular expressions predicate over contiguous events on the input streams (Brenna et al. 2007), while in other cases, they accept and ignore the presence of intermediate events within the stream that are not related with the pattern (Wu et al. 2006). Some languages offer operators similar to Kleene plus in regular expressions to define repetitions of given sub-patterns one or more times.

Automata-based models typically assume that the events in a stream are received in order and exploit this property to advance the automata as soon as an event becomes available, without waiting for possible events received out of order.

Tree-based models. Tree-based models combine operators hierarchically to form a tree. When the operator representing a node of the tree is satisfied, the parent node is evaluated. A complex event is generated when the operator in the root node is satisfied.

A tree-based model promotes sharing of operators across definitions and decouples the order of arrival of events in the stream from the order of evaluation of operators.

Examples of systems that adopt tree-based models include ZStream (Mei and Madden 2009), which uses operator trees for pattern specification, and NextCEP (Schultz-Møller et al. 2009) and Esper (Esper 2017), which adopt tree-based structures for pattern recognition.

Logic-based models. Logic-based models ground the semantics of recognition into some logic-based formalism. In some cases, systems that rely on logic-based models encode definitions using logic programming and use inference to detect complex events. For instance, ETALIS (Anicic et al. 2011) builds on the Prolog language and inference mechanism. In most cases, however, logic-based definitions are translated to exploit ad hoc data structures and algorithms for improved efficiency. For instance, the semantics of TESLA definitions are defined in terms of metric tempo-

ral logic formulas, but recognition adopts custom algorithms.

We present two main logic-based formalisms that are considered good representatives of logic-based modeling (Artikis et al. 2017): chronicle recognition (Dousson and Le Maigat 2007) and event calculus (Artikis et al. 2012).

Chronicle recognition relies on temporal logic and encodes event recognition as logic predicates that evaluate the content and time of occurrence of primitive events, as well as temporal and contextual constraints. As already mentioned, TESLA is a representative of this model.

Event calculus builds on fluents, which are properties holding different values over time. Event calculus specifies how the occurrences of events alter the values of fluents. Situations of interest are encoded as fluents and recognition translates to observing specific values in some fluents. An example of this model is the Real-Time Event Calculus (RTEC) (Artikis et al. 2015).

Event Recognition Algorithms

This section discusses algorithms and techniques to efficiently recognize patterns in streams of events.

P

Incremental algorithms. Automata-based models are often associated to incremental recognition algorithms, which instantiate new automata on demand to represent partial recognition and use the input events to move each automaton from state to state until it reaches an accepting state – and recognizes a complex event – or it reaches a failure state and it is discarded. Incremental algorithms can efficiently recognize sequences of events with content and temporal constraints. One main limitation of these algorithms is that the number of candidate automata can rapidly become very large (Zhang et al. 2014), thus requiring a large amount of memory and forcing the analysis of many partial automata upon the arrival of new events. To mitigate this problem, various compression techniques have been studied that combine common parts shared by different automata (Wu et al. 2006).

Lazy algorithms. Lazy algorithms accumulate events and postpone expensive analysis as much as possible. For instance, tree-based models decouple the order of events from the order of evaluation: each node in the tree stores events in a buffer and produces results upon request. This approach enables optimizing the order of evaluation – query optimization (Schultz-Møller et al. 2009) – and parallelizing the analysis of independent nodes.

Lazy algorithms have been also proposed for automata-based (Kolchinsky et al. 2015) and for logic-based models (Cugola and Margara 2012b), where they proved to be suitable for implementations that take advantage of many core hardware such as GPUs.

Summary

Complex event recognition aims to detect situations of interest – complex events – from streams of primitive events on the fly, to enable timely reactions. The research and development of event recognition target two main aspects: the definition of suitable languages to define complex events from primitive ones and the design of efficient processing algorithms and techniques. Different language models exist that define and combine basic operators using automata, tree-based, or logic models. Recent evaluation algorithms and techniques aim to adopt data structures that are memory efficient and enable parallel processing within and across event definitions.

- Big Data performance characterization

Definitions

Evaluating the performance of Big Data systems is the usual way of getting information about the expected execution time of analytics applications. These applications are generally used to extract meaningful information from very large input datasets. There exist many high-level frameworks for Big Data analysis, each one oriented to different fields like machine learning and data mining, like Mahout (Apache Mahout 2009), or graph analytics like Giraph (Avery 2011). These high-level frameworks allow to define complex data

processing pipelines that are later decomposed into more fine-grained operations in order to be executed by Big Data processing frameworks like Hadoop (Dean and Ghemawat 2008), Spark (Zaharia et al. 2016), and Flink (Apache Flink 2014). Therefore, the performance evaluation of these frameworks is key to determine their suitability for scalable Big Data analysis.

Big Data processing frameworks can be broken down in several layers, which typically include a data processing engine (e.g., Hadoop MapReduce), a resource manager (e.g., YARN), and a distributed storage system (e.g., HDFS). In order to provide scalability, these frameworks are deployed over the nodes of a cluster, which has a certain set of characteristics (e.g., number of nodes, CPU model, disk, and network technology). Hence, the performance of Big Data systems is affected by multiple factors related both to the software components of the frameworks and the available resources in the cluster.

Most performance evaluation studies are oriented to compare several Big Data frameworks and/or different configuration alternatives. In order to do so, a set of experiments is carried out, which involves generating some input datasets, process them using several representative Big Data workloads and extract the corresponding performance metrics. The obtained results are then analyzed to find performance bottlenecks or potential optimizations.

Overview

The performance evaluation of Big Data systems typically takes into account at least one of the following metrics:

Execution Time

Execution time is generally regarded as the main performance metric. It determines the wall-clock time that users have to wait for the result of their applications when executed with a particular Big Data framework.

Scalability

Scalability is the ability of a Big Data system to increase its performance when adding more resources. Two different kinds of scalability can be considered, vertical scalability (scaling up) and horizontal scalability (scaling out). On the one hand, vertical scalability involves obtaining faster nodes with more powerful processors and more memory. On the other hand, horizontal scalability involves adding more nodes to the system and operates in a distributed environment.

Resource Utilization

The leveraging of system resources (e.g., CPU, network, disk) determines the adaptability of the frameworks to a particular system. Performance bottlenecks can be due to underutilization or overloading of these resources.

Energy Efficiency

Performance is closely related to energy efficiency, as the energy consumed when executing a workload is determined by the power specifications of the system and the execution time. Modifying the underlying system by increasing the cluster size or the computational capabilities of the nodes can reduce execution time, but it may increase the power consumption of the workload. Therefore, determining whether an optimization can improve energy efficiency requires a thorough analysis.

Microarchitectural Behavior

Accessing hardware performance counters that are present in modern processors, like the number of instructions executed or cache misses, can provide meaningful information to characterize the interaction between frameworks and hardware. Moreover, these metrics can be utilized to compare different alternatives in a more fine-grained fashion than just considering overall metrics like execution time. The values of the counters can be accessed in several ways, using APIs like PAPI (Browne et al. 2000) or monitoring tools like perf and Oprofile.

Key Research Findings

Many works have assessed and optimized the performance of Big Data systems taking into account different factors. A summary of the main results obtained is provided next.

Data Processing Engine

A crucial factor for the performance of Big Data frameworks is the underlying data processing engine, which defines the kind of operations that the user can perform to process the input dataset. MapReduce has been one of the most popular batch engines so far, and Hadoop is its de facto standard implementation. However, Hadoop presents some performance overheads, like the writing of intermediate results to disk, which has led to the development of different alternatives that optimize its performance. They whether modify some of its components, like NativeTask (Yang et al. 2013), or redesign the entire underlying architecture, like Flame-MR (Veiga et al. 2016c). Although these works significantly improve the performance of Hadoop, they are still limited by the nature of the MapReduce model.

More advanced in-memory frameworks like Spark and Flink are designed to provide a wider range of data operators than MapReduce, as well as support for other scenarios (e.g., real-time/streaming processing). Although they support map and reduce functions, existing MapReduce applications must be adapted to their new programming model. The increased flexibility of Spark and Flink along with the caching of intermediate results in memory can reduce Hadoop execution times by 77% and 70% on average, respectively (Veiga et al. 2016a).

Other works have explored the possibilities offered by paradigms traditionally oriented to high-performance computing (HPC). For example, parallel programming paradigms like the message passing interface (MPI) can increase significantly the performance of Big Data workloads (Liang et al. 2014; González et al. 2017). However, MPI offers a low-level API that provides poor programming productivity compared to MapReduce, so its use is not feasible for real Big Data scenarios.

File System

Big Data frameworks typically use the Hadoop Distributed File System (HDFS) to distribute the storage of large datasets over the nodes of a cluster, collocating storage and compute services on the same nodes. However, its use is not widespread in HPC systems, which separate compute and storage services by using parallel file systems like GPFS, OrangeFS, or Lustre. This situation has caused the appearance of several works that evaluate the performance of both storage approaches, concluding that GPFS behaves better at low concurrency, while HDFS is more suited to high concurrency (Fadika et al. 2012). Some other works have shown that parallel file systems can also provide performance improvements, like MARIANE (Fadika et al. 2014), which uses a custom MapReduce implementation onto GPFS. Another approach presented by Xuan et al. (2017) uses a two-level storage system by integrating the in-memory file system Tachyon with OrangeFS to obtain higher performance than just using HDFS.

P

Disk Technology

Traditional hard disk drives (HDDs) are progressively being replaced by faster technologies like solid-state drives (SSDs), which obtain significantly better performance but at higher cost per byte. Using SSDs has been reported to improve the performance of Big Data frameworks. Hadoop can store HDFS data and intermediate results on SSDs to eliminate disk bottlenecks when executing I/O-bound workloads. However, SSD disks can increase dramatically the total cost of the system components (Moon et al. 2014). Regarding Spark, its performance can be improved by 23% when using SSDs to store intermediate results compared to the memory-only approach (Choi et al. 2015).

SSDs can also be leveraged actively, performing some simple operations over the stored data. In Lee et al. (2016), a new technique called external sorting utilizes SSDs to perform sort operations during the MapReduce phase, reducing the execution time of Hadoop by up to 36%.

Network Interconnects

Early works claimed that the use of high-performance interconnects like InfiniBand would not have a great impact on the execution time of MapReduce workloads, unless the shuffle algorithm and communication protocol were modified (Fadika et al. 2012). However, more modern evaluations have shown that up-to-date Hadoop versions can leverage this kind of networks by using IP over InfiniBand (IPoIB), obtaining significant performance improvements (Veiga et al. 2016b).

Other works modify the shuffle components to take advantage of remote direct memory access (RDMA) communications. That is the case of the network-levitated merge algorithm (Wang et al. 2011) and RDMA-Hadoop (Wasi-Ur-Rahman et al. 2013). The latter claims to reduce the execution time of Hadoop and the network-levitated merge algorithm by 32% and 21%, respectively, for the TeraSort benchmark. The use of RDMA has also been studied for Spark, showing up to 46% performance improvement for several workloads (Lu et al. 2016b).

Memory Management

As Big Data applications read and generate a lot of data, managing the available memory resources correctly is key to achieve good performance and avoid memory overflows. Most Big Data frameworks are written in some managed language (e.g., Java, Scala) executed by the Java virtual machine (JVM). In this context, objects are tracked to release their memory once they stop being referenced. This process is performed by the garbage collector and can cause significant performance overheads when processing large datasets.

Modifying the original JVM memory management to adapt it to the characteristics of Big Data systems can lead to significant performance improvement. That is shown by proposals like Broom (Gog et al. 2015), which uses a region-based algorithm to allocate data objects. Another example, Yak (Nguyen et al. 2016), implements a hybrid approach that utilizes generation-based and region-based algorithms for control and data objects, respectively. As these memory managers

are implemented in Java, they can be generically applied to any JVM-based framework.

Other solutions are specific to a certain framework, like Deca (Lu et al. 2016a), which modifies the management of data containers in Spark to estimate their lifetime, allocating memory regions accordingly. This mechanism, combined with other optimizations like the use of byte arrays to store data objects, is able to achieve up to 41.6× speedup in cases with data spilling.

Manycore Accelerators

The great majority of Big Data frameworks rely only on CPUs to perform the computations. However, some works propose the use of manycore accelerators, typically available in heterogeneous systems, like GPUs, FPGAs, or Xeon Phi accelerators.

GPUs are a suitable option to accelerate Big Data workloads due to their widespread use and high degree of data parallelism. For example, Mars (Fang et al. 2011) supports the processing of MapReduce workloads using CPU, GPU, or hybrid computations. The combination of Hadoop with Mars can provide a maximum speedup of 2.8. GPUs have also been employed to improve the performance of Spark (Yuan et al. 2016) and Flink (Chen et al. 2017).

Another popular type of accelerator is the Xeon Phi manycore processor that can execute unmodified CPU code. However, the source code of Big Data frameworks must be adapted in order to fully leverage the computational power of this accelerator, as presented by Lu et al. (2015).

Finally, FPGAs are hardware devices that can be programmed to build custom accelerators. Neshatpour et al. (2015) assess the benefits of accelerating typical machine learning and data mining applications by offloading some of their kernels to FPGAs. They obtain a speedup of 2.72, although it must be taken into account that the accelerated framework is highly application-specific.

System Architecture

Some studies have evaluated the performance of “big” Intel Xeon nodes compared to the use of “small” nodes like ARM or Intel Atom. Loghin

et al. (2015) state that “big” nodes are more efficient for CPU-intensive jobs, while “small” ones perform better for I/O-intensive workloads. Malik et al. (2015) conclude that “big” nodes are more efficient as the computational size of the problem increases.

Other evaluations focus on determining whether horizontal scalability is more beneficial than vertical scalability. The results are highly dependent on the framework used and the workload characterization. In general terms, horizontal scalability provides better performance for Hadoop (Li and Shen 2017), while Spark presents better energy efficiency when using vertical scalability (Yoo et al. 2016).

Examples of Application

A wide range of tools have been developed to evaluate the performance of Big Data systems and frameworks. Most of them are benchmark suites that provide multiple kinds of workloads to assess the performance of different use cases. Although the great majority is oriented to Hadoop, like HiBench (Huang et al. 2010) or BigDataBench (Wang et al. 2014), some new ones target in-memory frameworks, like SparkBench (Li et al. 2017) for Spark.

Other evaluation tools not only provide a set of benchmarks but also ease the execution of the experiments. That is the case of MRBS (Sangroya et al. 2012), which is able to automatically set up a Hadoop cluster in a public cloud provider. Once the cluster is running, it injects the dataset and executes the workloads, obtaining execution time, throughput, and cost metrics.

BDEV (formerly MREv, Veiga et al. 2015) is another evaluation tool that supports several flavors of Hadoop, Spark, and Flink. Once the user configures a set of experimental parameters, it launches the frameworks, generates the input datasets, and performs the experiments. It also automatically records several metrics, including execution time, resource utilization, energy efficiency, and hardware performance counters.

Big Data Watchdog (BDWatchdog) (Enes et al. 2017) is another tool that enables to record resource utilization statistics for the individual processes involved in the execution of the frameworks (e.g., DataNode, Spark Executor). Moreover, it can provide real-time profiling information about the execution of the JVM code.

Future Directions for Research

As explained in previous sections, performance is affected by multiple factors. Although different studies have addressed the performance evaluation of Big Data analysis, end users rarely benefit from the research findings provided by these studies. There is still work to be done regarding the development of tools that can bring more meaningful insights to users.

Users that want to select a Big Data framework to utilize in a certain infrastructure can compare their options by performing several experiments. This involves the deployment of several frameworks (e.g., Hadoop, Spark) and testing their performance. In addition to the effort associated to this evaluation, the optimal choice may still require a more thorough analysis, taking also into account different classes of workloads that the user may be willing to execute (e.g., CPU-intensive, I/O-intensive) and varying the configuration parameters of the frameworks (e.g., maps per node, executors per node). Furthermore, some information must be given to the user regarding the performance bottlenecks that may exist and which system resource may be the best option for improving.

Although there are some evaluation tools that ease the execution of these tasks, future ones must incorporate some knowledge to help users to make decisions, not only retrieving raw performance information.

Predictive Business Process Monitoring

Chiara Di Francescomarino

Fondazione Bruno Kessler – FBK, Trento, Italy

Synonyms

Forecasting business process future; Predictive monitoring of business processes

Definitions

Predictive monitoring of business processes aims at predicting the future of an ongoing (uncomplete) process execution. Predictions related to the future of an ongoing process execution can pertain to numeric measures of interest (e.g., the completion time), to categorical outcomes (e.g., whether a given predicate will be fulfilled or violated), or to the sequence of future activities (and related payloads).

P

Overview

Predictive monitoring of business processes aims at providing predictions about the future of an ongoing (incomplete) process execution. The entry provides an overview of predictive process monitoring by introducing the dimensions that typically characterize existing approaches in the field, as well as using them to classify existing state-of-the-art approaches.

Introduction

Process mining deals with the analysis of business processes based on their behavior, observed

and recorded in *event logs*. In this context, an event log is a collection of execution *traces*, each representing one execution of the process (a.k.a. a *case*). Each trace consists of a sequence of time-stamped events, each capturing the execution of an activity. Each event may carry a data payload, i.e., a set of attribute-value pairs such as the resource(s) involved in the execution of the activity or other data recorded with the event.

Predictive business process monitoring (Maggi et al. 2014) is a branch of process mining that aims at predicting the future of an ongoing (uncompleted) process execution. Typical examples of predictions of the future of an execution trace relate to its completion time, to the fulfilment or violation of a certain predicate, or to the sequence of its future activities. Being able to predict in advance the time that a process instance will require to complete, or whether a predicate will be fulfilled, is of the utmost importance in different domains and scenarios, ranging from production to organizational processes. Indeed, this would allow organizations to prevent issues and delays and hence to save money, effort, and resources.

Predictive process monitoring approaches usually leverage past historical complete executions in order to provide predictions about the future of an ongoing case. They are typically characterized by two phases: a *training phase*, in which a predictive model is learned from historical traces, and a *prediction phase*, in which the predictive model is queried for predicting the future of an ongoing case.

Predictions in predictive business process monitoring approaches can pertain to different aspects or measures of interest related to the future of one or more process executions. Examples of outputs generated by predictive process monitoring approaches range from numeric or continuous measures as the remaining time or the overall cost of an ongoing execution, to categorical or boolean predictions, such as the risk associated to an ongoing execution or whether a given predicate will be fulfilled or violated, or even to the sequence of future activities characterizing a given case.

The rest of this entry is structured as follows: after a brief introduction about the importance of predictions in the context of business processes (section “[The Need of Predictions in Business Process Monitoring](#)”), the main features and dimensions characterizing predictive monitoring approaches for business processes are presented (section “[Predictive Process Monitoring Dimensions](#)”). The next three sections describe state-of-the-art approaches that produce, respectively, numeric predictions (section “[Numeric Predictions](#)”), predictions related to an outcome (section “[Outcome-Based Predictions](#)”), and predictions related to sequences of future activities (section “[Activity Sequence Predictions](#)”). Finally, section “[Multitype Predictions](#)” presents few frameworks collecting approaches providing more than one type of predictions, and section “[Conclusion](#)” concludes the entry.

The Need of Predictions in Business Process Monitoring

The capability to check the execution of business process instances in terms of correctness, as well as of timely completion, is an imperative for several organizations. Several research efforts have been carried out to address the problem of business process monitoring such as in Maggi et al. (2011b), Maggi et al. (2011a), Maggi et al. (2012), Ly et al. (2011), and Weidlich et al. (2011). Given a process model and a set of predicates, the aim is to monitor ongoing process executions in order to assess whether they comply with the predicates.

However, all these monitoring approaches are *reactive*. Indeed, the violation or the delay is identified only after its occurrence. Predicting the violation before would instead allow for supporting users in *preventing* it. We can think, for instance, about the preventive measures we would be able to take by knowing in advance that our train is delayed. Similarly, in the everyday life, organizations would get a number of benefits by knowing in advance about violations, deviances, and delays. This would indeed allow them to take preventive measures (e.g., reallocating resources)

in order to avoid the occurrence of those situations and, as often happens, to avoid money loss.

Predictive Process Monitoring Dimensions

Although predictive business process monitoring is a relatively young field, it has been growing fast in the latest years. The literature on predictive business process monitoring can be classified along three main dimensions:

- Type of prediction (i.e., the type of predictions provided as output).
- Type of adopted approach and technique.
- Type of information exploited in order to get predictions (i.e., the type of information taken as input).

Concerning the type of prediction, we can classify the existing prediction types into three main big categories:

- Predictions related to numeric or continuous measures of interest (*numeric predictions*). Typical examples in this setting are predictions related to the remaining time of an ongoing execution and predictions related to the duration or to the cost of an ongoing case.
- Predictions related to categorical or boolean outcomes (*outcome-based predictions*). Typical examples in this scenario are predictions related to the class of risk of a given execution or to the fulfilment of a predicate along the life cycle of a case.
- Predictions related to sequences of future activities (*activity sequence predictions*). Typical examples of predictions falling under this category refer to the prediction of the sequence of the future activities (and of their payload) of a process case upon its completion.

Predictive process monitoring approaches are usually characterized by two phases. In a first phase, the *training or learning* phase, one or

more prediction models are built or enriched by leveraging the information contained in the execution log. In the second phase, the *runtime or prediction phase*, the prediction model(s) is (are) exploited in order to get predictions related to one or more ongoing execution traces. We can identify two main groups of approaches dealing with the prediction problem:

- Approaches relying on an explicit model, e.g., annotated transition systems. The explicit model can either be discovered from the event log or enriched with the information the log contains, if it is already available.
- Approaches leveraging machine learning and statistical techniques, e.g., classification and regression models and neural networks. These approaches only rely on (implicit) predictive models built by encoding event log information in terms of features to be used as input for machine/deep learning techniques.

Finally, we can identify four different types of information that can be used as input to the predictive process monitoring approaches, e.g., for building a model annotated with execution information or for building the features to be used by machine learning approaches:

- Information related to the control flow, i.e., the sequence of events.
- Information related to the structured data payload associated to the events.
- Information related to unstructured (textual) content, which can be available together with the event log.
- Information related to process context, such as workload or resource availability.

In several approaches, more than one of these types of information is used in order to learn from the past.

In the following sections, the research works characterizing each of the three prediction type macro-categories, i.e., numeric, outcome-based, and activity sequence predictions, are presented. They are further classified based on the specific

output type and approach, as well as exploited input information.

Numeric Predictions

We can roughly classify the works dealing with numeric predictions in three groups, based on the specific type of predictions returned as output:

- Time predictions
- Cost predictions
- Generic performance predictions

Time predictions. The group of works focusing on the time perspective is a rich group. Several works, in this context, rely on explicit models. In van der Aalst et al. (2011), the authors present a set of approaches in which transition systems, which are built based on a given abstraction of the events in the event log, are annotated with time information extracted from the logs. Specifically, information about elapsed, sojourn, and remaining time is reported for each state of the transition system. The information is then used for making predictions on the completion time of an ongoing trace. Further extensions of the annotated transition system are proposed in Polato et al. (2014, 2018), where the authors apply machine learning techniques to the annotated transition system. In detail, in Polato et al. (2014), the transition systems are annotated with machine learning models such as naïve Bayes and support vector regression models. In Polato et al. (2018), instead, the authors present, besides two completely new approaches based on support vector regression, a refinement of the work in Polato et al. (2014) that takes into account also data. Moreover, the authors evaluate the three proposed approaches both on static and dynamic processes. Other extensions of the approach presented in van der Aalst et al. (2011) that also aim at predicting the remaining time of an ongoing trace, are the works presented in Folino et al. (2012, 2013). In these works the annotated transition system is combined with a context-driven predictive clustering approach. The idea behind predictive clustering

is that different scenarios can be characterized by different predictors. Moreover, contextual information is exploited in order to make predictions, together with control flow (Folino et al. 2012) or control flow and resources (Folino et al. 2013). Another approach based on the extraction of (explicit) models (*sequence trees*) is presented in Ceci et al. (2014) to predict the completion time (and the next activity) of the current ongoing case. Similarly to the predictive clustering approach, the sequence tree model allows for clustering traces with a similar sequence of activities (control flow) and to build a predictor model for each node of the sequence tree by leveraging data payload information. In Rogge-Solti and Weske (2013), the authors use generally distributed transition stochastic Petri nets (GDT-SPN) to predict the remaining execution time of a process instance. In detail, the approach takes as input a stochastic process model, which can be known in advance or inferred from historical data, an ongoing trace, and some other information as the current time in order to make predictions on the remaining time. In Rogge-Solti and Weske (2015), the authors also exploit the elapsed time since the last event in order to make more accurate predictions on the remaining time and estimating the probability to miss a deadline.

Differently from the previous approaches, in van Dongen et al. (2008), the authors only rely on the event log in order to make predictions. In detail, they develop an approach for predicting the remaining cycle time of a case by using nonparametric regression and leveraging activity duration and occurrence as well as other case-related data. In Bevacqua et al. (2013) and Cesario et al. (2016), the contextual clustering-based approach presented in Folino et al. (2012, 2013) is updated in order to address the limitation of the approaches based on transition systems, i.e., requiring that the analyst chooses the log abstraction functions. To this aim, the transition system predictor is replaced with standard regression algorithms. In Cesario et al. (2016), the clustering component of the approach is further improved in order to address scalability and accuracy issues. In Pandey et al. (2011) hidden Markov models

(HMM) are used for making predictions on the remaining time. A comparative evaluation shows that HMM provides more accurate results than annotated transition systems and regression models. In Senderovich et al. (2017) *inter-case feature predictions* are introduced for predicting the completion time of an ongoing trace. The proposed approach leverages not only the information related to the ongoing case but also the status of other (concurrent) cases (e.g., the number of concurrent cases) in order to make predictions. The proposed encodings demonstrated an improvement of the results when applied to two real-life case studies.

A prediction type which is very close to time but slightly different is the prediction of the delay of an ongoing case. In Senderovich et al. (2015), queuing theory is used to predict possible online delays in business process executions. The authors propose approaches that either enhance traditional approaches based on transition systems, as the one in van der Aalst et al. (2011), to take queueing effects into account or leverage properties of queue models.

Cost predictions. A second group of works focuses on cost predictions. Also in this group, we can find works explicitly relying on models as the work in Tu and Song (2016). In such a work, cost predictions are provided by leveraging a process model-enhanced cost (i.e., a frequent-sequence graph enhanced with cost) taking into account information about production, volume, and time.

Performance predictions. Finally, a third category of works deals with general numeric performance criteria, e.g., key performance indicators (KPIs). In Kang et al. (2011), the authors propose a predictive process monitoring technique, which starts by constructing a transition system from the event log. A state in this transition system represents the set of events that have occurred in the prefix of a case. Transitions are annotated with probabilities. The resulting transition system is used at runtime to predict key performance indicators of a running case.

The authors of the work in Zeng et al. (2008), use, instead, the ARIMA forecasting method for

aggregated key performance indicators rather than for metrics related to a single instance. In Castellanos et al. (2005), the authors present a business operation management platform equipped with forecasting functionalities. The platform allows for predictions of metric values related to a single running process instance (e.g., the completion time of the ongoing instance), as well as for predictions of aggregated values related to future instances (e.g., the number of orders that will be placed next Monday).

Outcome-Based Predictions

The second family of prediction approaches predicts outcomes related to an ongoing case. In this settings, two main specific types of predictions can be identified:

- Risk predictions
- Predicate fulfilment predictions

Risk predictions. A first large group of works falling under the umbrella of outcome-based predictions deals with the prediction of risks.

Also in this case, an important difference among state-of-the-art approaches is the existence of an explicit model guiding the prediction. For example, in Conforti et al. (2013), the authors present a technique for reducing process risks. The idea is supporting process participants in making risk-informed decisions, by providing them with predictions related to process executions. Decision trees are generated from logs of past process executions, by taking into account information related to data, resources, and execution frequencies provided as input with the process net. The decision trees are then traversed and predictions about risks returned to the users. In Conforti et al. (2015, 2016), two extensions of the work in Conforti et al. (2013) are presented. In detail, in the former, i.e., Conforti et al. (2015), the framework for risk-informed decisions is extended to scenarios in which multiple process instances run concurrently. Specifically, in order to deal with the risks related to different instances

of a process, a technique that uses integer linear programming is exploited to compute the optimal assignment of resources to tasks to be performed. In the latter, i.e., Conforti et al. (2016), the work in Conforti et al. (2013) is extended so that process executions are no more considered in isolation, but, rather, the information about risks is automatically propagated to similar running instances of the same process in real-time in order to provide early runtime predictions. In Metzger et al. (2015), three different approaches for the prediction of process instance constraint violation are investigated: machine learning, constraint satisfaction, and QoS aggregation. The authors, beyond demonstrating that all the three approaches achieve good results, identify some differences and propose their combination. Results on a real case study show that combining these techniques actually allows for improving the prediction accuracy.

Other works, devoted to risk prediction, do not take into account explicit models. For instance, in Pika et al. (2013a), the authors make predictions about time-related process risks by identifying and leveraging process risk indicators (e.g., abnormal activity execution time or multiple activity repetition) by applying statistical methods to event logs. The indicators are then combined by means of a prediction function, which allows for highlighting the possibility of transgressing deadlines. In Pika et al. (2013b), the authors extend their previous work by introducing a method for configuring the process risk indicators. The method learns from the outcomes of completed cases the most suitable thresholds for the process risk indicators, thus taking into account the characteristics of the specific process and hence improving the accuracy.

Predicate fulfilment predictions. A second group of predictions relates to the fulfilment of predicates. Almost all works falling under this category do not rely on any explicit model. For example, in Maggi et al. (2014) a framework for predicting the fulfilment (or the violation) of a predicate in an ongoing execution is introduced. Such a framework makes predictions by leveraging (i) the sequence of

events already performed in the case and (ii) the data payload of the last activity of the ongoing case. The framework is able to provide accurate results, although it demands for a high runtime overhead. In order to overcome such a limitation, the framework has been enhanced in Di Francescomarino et al. (2016b) by introducing a clustering preprocessing step in which cases sharing a similar behavior are clustered together. A predictive model – a classifier – for each cluster is then trained with the data payload of the traces in the cluster. In Di Francescomarino et al. (2016a), the framework is enhanced in order to support users by providing them with a tool for the selection of the techniques and the hyperparameters that best suit their datasets and needs. In Leontjeva et al. (2015), the authors consider traces as complex symbolic sequences, that is, sequences of activities each carrying a data payload consisting of attribute-value pairs. By starting from this assumption, the authors focus on the comparison of different feature encoding approaches, ranging from traditional ones, such as counting the occurrences of activities and data attributes in each trace, up to more complex ones, relying on hidden Markov models (HMM). In Verenich et al. (2016), the solution presented in Leontjeva et al. (2015) is enhanced with clustering, by proposing a two-phase approach. In the first phase, prefixes of historical cases are encoded as complex symbolic sequences and clustered. In the second phase a classifier is built for each of the clusters. At runtime, (i) the cluster closest to the current ongoing process execution is identified; and (ii) the corresponding classifier is used for predicting the process instance outcome (e.g., whether the case is normal or deviant). In Teinemaa et al. (2016), in order to improve prediction accuracy, unstructured (textual) information, contained in text messages exchanged during process executions, is also leveraged, together with control and data flow information. Specifically, different combinations of text mining (bag-of-n-grams, Latent Dirichlet Allocation and Paragraph Vector) and classification (random forest and logistic regression) techniques have been proposed and exercised. In Márquez-

Chamorro et al. (2017), an approach based on evolutionary algorithms is presented. The approach, which uses information related to a window of events in the event log, is based on the definition of process indicators (e.g., whether a process instance is completed in time, whether it is reopened). At training time, the process indicators are computed, the training event log encoded, and the evolutionary algorithms applied for the generation of a predictive model composed of a set of decision rules. At runtime, the current trace prefix is matched against the decision rules in order to predict the correct class for the ongoing running instance.

A special subclass of this category of works is the one related to papers focusing on the prediction of the violation of specific predicates. For instance, in Kang et al. (2012), the authors propose an approach for predicting abnormal termination of business processes at runtime and generating alarms for the early notification of probable abnormal terminations. They apply a fault detection technique based on the k-nearest neighbor algorithm to the attributes of process instances to estimate the probability that a fault occurs. In Cabanillas et al. (2014), an overall framework aiming at checking the safe execution of tasks and alerting in case of potential misbehaviors is presented. The prediction phase is only one of the framework phases, which also include the definition of the monitoring points and the expected behavior, the actual monitoring information collection, the event collection and normalization, and the deviance identification. Predictions are carried out by applying a support vector machine (SVM) approach to classify the successful completion of a process execution. To this aim both control and data flow information are taken into account.

Activity Sequence Predictions

A third more recent family of works deals with predicting the sequence of one, many, or all the future activities and their payload given the activities observed so far, as in Polato et al. (2018), Tax et al. (2017), Evermann et al. (2016),

and Di Francescomarino et al. (2017). In Polato et al. (2018), the authors propose an approach for predicting the sequence of future activities of a running case by relying on an annotated data-aware transition system, obtained as a refinement of the annotated transition system proposed in van der Aalst et al. (2011).

Other approaches, e.g., Evermann et al. (2016, 2017); Tax et al. (2017), make use of RNNs with LSTM cells. In particular, in Evermann et al. (2016, 2017) an RNN with two hidden layers trained with back propagation is presented, while in Tax et al. (2017), an LSTM and an encoding based on activities and timestamps is leveraged to provide predictions on the sequence of future activities and their timestamps. Finally, the work in Di Francescomarino et al. (2017) investigates how to take advantage of possibly existing a priori knowledge for making predictions on the sequence of future activities. To this aim, an LSTM approach is equipped with the capability of taking into account also some a priori sure knowledge.

Multitype Predictions

Some of the works available in the literature are general frameworks which are able to provide both numerical and categorical predictions. For instance the work in Leitner et al. (2013) describes a general framework for predicting the violation of service-level agreements (SLA) for business processes implemented as service composition by using data-driven statistical methods. Specifically, ANN-based regression is used for instance level violations, time series are used for aggregated metrics, and decision trees for nominal value predictions. The work presented in de Leoni et al. (2016) provides a general process mining framework which allows for correlating process and event characteristics (independent variables) with other characteristics (dependent variables). By collecting different types of approaches and techniques, it also allows for predicting different types of measures and outcomes. Finally, in Jorbina et al. (2017) the *Nirdizati* tool, a web-based tool for the generation of predictions

about running cases of a business process, is presented. Nirdizati, which is composed of a *training* and a *runtime* component, is able to continuously provide predictions of different types (both numerical and outcome-based) of performance indicators. In detail, the training component supports the users in the selection and tuning of the best predictive technique to deal with a specific dataset, by providing him/her with estimations of the accuracy of the results on a testing set. Once the most suitable technique has been selected, it is sent to the runtime component which uses it for continuously monitoring the ongoing executions and providing predictions related to the desired performance indicator at runtime.

Conclusion

Predictive monitoring of business processes has been gaining importance and raising more and more interest within the scientific community. This entry provides an overview of the literature related to the predictive business process monitoring. The main concepts related to the topic, as well as the main dimensions (e.g., the type of prediction, approach, and information exploited for providing predictions) characterizing the works related to the predictive monitoring of business processes, have been identified and presented. The main research works populating the literature related to such an emerging field have been classified and described.

Synonyms

Sentiment-based privacy preserving data publishing techniques for social networks

Definitions

Actor: The *individual* or *organizations* involved in a social network.

Post: Thoughts expressed by the actors.

People: Either a group of people who are the author or about the people mentioned in the post.

Place: Place of origin or about what the post is. Place of interest of the individual or where they belongs to.

Time: Time of the post or the time frame the post talks about. Time frame of the people involved.

Privacy coordinate: A Cartesian coordinate system that uses people, place, and time as its axes. These three parameters act like the *basis* through which post/actors are defined.

Sensitivity: Vulnerability due to social, religious, or some other factors.

Sentiment: A view or opinion that is held or expressed.

Privacy in Social Networks

Web 2.0 provides a two-way knowledge and information sharing platform. Many of these information of the Web 2.0 may lead different types of interpretation and perception by the audience or the consumer of this information. The biggest challenge is that the content creator has no control over this *response*. This response may be positive or negative and sometimes very frustrating. Apart from this the social media is prone to different kinds of privacy threats mentioned in these survey papers (Díaz and Ralescu 2012; Gunatilaka 2011). Among privacy issues like de-anonymization attack and neighborhood attack, the biggest threat is the threat of privacy leakage, which is caused by leakage through poor privacy setting or leakage of information to third-party application or leakage of information to third-party domain. Identity theft, spam, and malware issues are quite prevalent in social media.

Problem Formulation

Sensitivity and Privacy

Sensitivity is one of the most important social virtues, and this sensitivity has no formal representation yet. Some information may be very sensitive to a group of people and for some it is absolute okay. Closely monitoring, a general observation came that this variation is due to three main parameters:

- **People:** Who they are, their belief, and their ideology and in case of an event who are and what kind of people are involved.
- **Time:** What is the time frame of occurrence of event or time period in which the people lived.
- **Place:** Where the event has taken place or where the people belongs to.

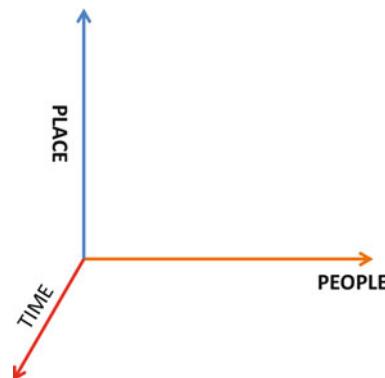

Modelling Sensitivity

Sensitivity can be modelled as score ranging from -1 to $+1$ through 0 . This score is an indicator of how individuals or an event and individual align themselves in a coordinate system whose axes are **people, place, and time** as shown in Fig. 1. This three-dimensional vector simulates both the social actors and information.

Algorithmic Framework

Core Idea

Privacy cube approach is based on the core Ideas that “*Only Relevant Information should be Displayed irrespective of Friends sharing it or not & Information and People should be treated alike*” which is an extension to the approach mentioned in Babu et al. (2013, 2014). In order to achieve this goal, we need to find a common *basis* that a social network post and a social actor share. Three of such basis are (1) people, (2) place, and (3) time. A person is known from the people he knows, places he has interest or he belongs in, and time period he belongs to. Similar thing can be said about the information too. Information are about these three or involve these three. Thus we are able to map the two differently perceived

Privacy Cube, Fig. 1 Privacy coordinate

objects into a common *Basis*. This makes evaluation of similarity between a social actor and information more effective.

Scoring Mechanism: SentSim

SentSim is a scoring mechanism that indicates the *sentimental similarity* between two actors, or an actor and information is proposed. This metric measures the *cosine of the angle between* two *social vectors* (social actors and social post). Table 1 explains our scoring mechanism as follows:

P

Flowchart

A detail flowchart explains the process given in Fig. 2. The following points explain the terms used in the flow chart.

POST The social network post or actor that we are going to, which is the input to the system.

TAGS Tags are the provision through which the author provides information about the people, place, and time involved.

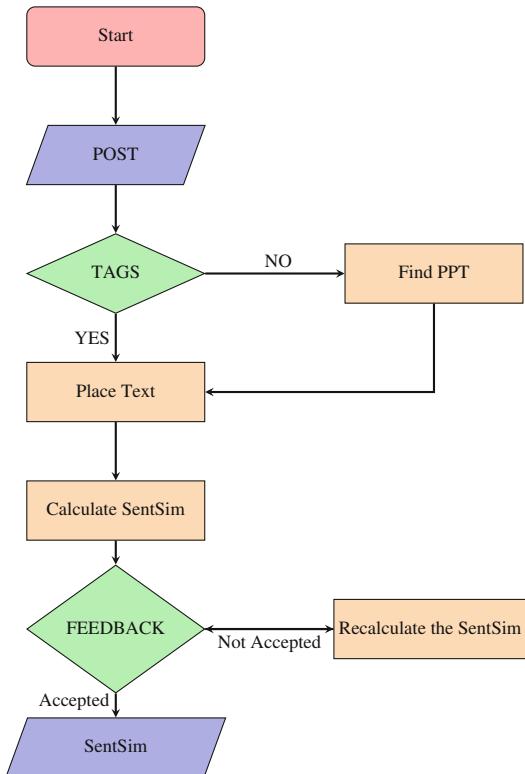

FindPPT This module is responsible for extracting name of the people, place, and time using natural language processing techniques from the post.

PlaceText Use the extracted people, place, and time to place the information in the privacy coordinate.

FEEDBACK It is a mechanism through which the calculated *SentSim* is verified of the information under consideration. Thresholds

Privacy Cube, Table 1 Scoring mechanism

SentSim	Geometry	Inference
+1	Both the vectors are aligned in the same direction as angle between them is 0	The information may have highest positive influence on the actor
0	Both the vectors are orthogonal to each other as angle between them is 90	The information has no or minimum influence on the actor
-1	Both vectors are aligned in opposite direction as angle between them is 180	The information may have highest negative influence on the actor

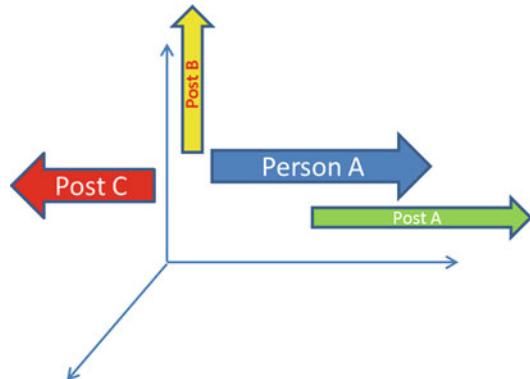

**Privacy Cube, Fig. 2** Flow chart describing the process

were to be fixed. If the $|SentSim_i - SentSim_{i+1}| \leq Threshold$, the score is accepted. If not then the iteration runs again.

Example

Consider the scenario explained in Fig. 3.

Scenario 1 *Post A* is sentimentally aligned with *Person A*, as the angle between them is zero. In this case Person A is very much interested

**Privacy Cube, Fig. 3** Example explaining the work of privacy cube

in Post A. *Post A* must be placed high up in the time line of Person A

Scenario 2 *Post B* is vertically aligned with *Person A*. The angle between them is 90. *Post B* is neutral to Person A. So there is a least chance that post be sentimentally hurt Person A.

Scenario 3 *Post C* is sentimentally aligned in opposite direction. This post has the highest probability to hurt the sentiment or breach the privacy of the persons involved in Post C. This post must not be displayed to Person A

Conclusion and Future Work

Though privacy and sentiment seem not to be correlated, in fact they are very much related virtues of human spirit. People love to be with the people with whom they share common sentimental values, which this model ensures through geometrical interpretation. This plays an important role in preserving privacy of individuals. This works so far based on this philosophy. By categorizing

social actor and social post, we can better the experience of social networking.

The advantage of privacy cube is that it brought both social actor and social post into common basis, i.e., people, place, and time. Due to this any analysis to be done would have more accuracy if we use some different basis for actors and posts. However like all method, *privacy cube* has some limitations which primarily due to its dependence on other modules, like *FindPPT* and calculation of *SentSim*. Future work is concentrated on the following area:

- *Proper noun classification* An efficient mechanism needs to be formulated that is capable of handling ever-changing social lingo.
- Developing a mechanism to calculate the sentimental similarity of *SentSim*. This can be done by developing a mechanism that studies the sentimental pattern of a group of people based upon their privacy axes. Accordingly it tries to predict the sentimental similarity of the actor or post in question.
- Developing a *Feedback* mechanism that perfectly suit these kind of environment.

Definitions

P

Definition 1 *Personal data protection* means measures aiming to guarantee that processing of data concerning identified or identifiable persons (data subjects):

- takes place based on a consent of the data subject or is otherwise explicitly permitted by law,
- is confined solely to the purpose of processing,
- is secure by design and by default:

whereas *processing* is any operation on personal data, including in particular storing, removing, and giving access to it.

Definition 2 *Pseudonimization* is a process of translating identifiers into pseudonyms and replacing the identifiers in a data set with the corresponding pseudonyms. A pseudonimization

process should be irreversible, except for a deanonymization procedure (if defined).

Deanonymization is a process which links back the pseudonyms with the identifiers. It should require the use of appropriate cryptographic secret keys.

Definition 3 A *domain* is a virtual area of activity, where all data concerning one physical person should be linked and be available as corresponding to the same person.

Definition 4 A *domain pseudonyms scheme* is a pseudonymization scheme such that an identifier pointing to a particular person is mapped to a set of *different* pseudonyms, one per each domain where the person may be present. The pseudonyms in different domains should be *unlinkable*.

Definition 5 A domain pseudonym scheme fulfills the *unlinkability* property, if it is impossible to distinguish with a non-negligible advantage between the two sets of pseudonyms:

- the pseudonyms generated according to the scheme for any one domain,
- the pseudonyms generated independently at random for each identifier and all other domains.

Definition 6 By a *domain signature scheme*, we mean a digital signature scheme, where:

- the signature points to a domain pseudonym and not to the identity of the signatory,
- a signatory uses a single private key for creating signatures in all domains,
- verification process is based on the domain pseudonym, signature, signed data, domain parameters, and, optionally, additional domain-specific data of the signatory.

If the scheme supports revocation, then the verification process uses current revocation data.

Definition 7 *Unlinkability* of a domain signature scheme is satisfied, if conditions of Definition 5 are fulfilled, but where the distinguisher may request also signatures corresponding to pseudonyms and where in case of the second situation the signing key is chosen independently at random for each domain.

Definition 8 By *revocation*, we mean a process that enables declaration of certain domain pseudonyms as *revoked*. Thereafter, the verification of a signature corresponding to any of these pseudonyms should yield the result invalid.

Overview

This chapter provides a concise discussion on ways of obtaining privacy of users' digital activities by means of pseudonymization schemes and their application in activity domains.

Legal rationale behind the introduction of these mechanisms is provided along with definitions of elementary concepts of such systems as domain pseudonyms and pseudonymous signatures. A number of possible solutions are provided along with references to already published papers on the subject.

GDPR Regulation of European Union

GDPR Scope

The General Data Protection Regulation (GDPR) of The European Parliament and the Council of the European Union (2016) establishes strict rules concerning processing of personal data, where:

personal data – is understood as any data concerning identified or identifiable person.

processing – means any operation on personal data, in particular:

collection, recording, organisation, structuring, storage, adaptation or alteration, retrieval, consultation, use, disclosure by transmission, dissemination or otherwise making available,

alignment or combination, restriction, erasure or destruction.

The GDPR regulation applies to the processing of personal data by automated means (hence in practically all IT systems) and in filing systems. There are a few exceptions (e.g., it does not cover processing for purely personal use and by law enforcement bodies); however, profiling users does fall into the scope of the GDPR.

The GDPR regulation applies to:

- any processing that is related to the activities (of the processor) performed in the European Union,
- processing data of persons in the European Union, if it is related to the offering of goods or services as well as profiling such users.

The regulation applies regardless of the location where the processing is executed – e.g., profiling European customers by an establishment in the USA falls into the scope of the regulation.

Thereby, in most cases big data processing is likely to fall into the scope of the GDPR regulation, and the data processor is obliged by law to conform with its rules.

GDPR Rules

There are the following fundamental principles of personal data processing:

lawfulness, fairness, and transparency – processing requires a legal basis (in most cases an explicit consent of the data subject); it should be fair and transparent to the data subject; in particular, the data subject may request access to information concerning processing their data;

purpose limitation – personal data may be collected and processed only for specified, explicit, and legitimate purposes; in particular, changing the purpose and scope of processing is forbidden (without the subject's explicit consent);

data minimization – processing must be adequate, relevant, and limited to the purpose of processing; in particular, if there is a legal

basis for processing, its goal must be achieved with minimal amount of personal data;

accuracy – processing must be accurate; the data must be kept up to date (if necessary, in other cases, see point below); in particular, the processing party must provide means for the data subject to correct their data;

storage limitation – personal data should be kept:

in a form which permits identification of data subjects for no longer than is necessary for the purposes for which the personal data are processed

integrity and confidentiality – the party processing personal data has to ensure:

appropriate security of the personal data, including protection against unauthorised or unlawful processing and against accidental loss, destruction or damage, using appropriate technical or organisational measures

accountability – compliance with the rules of GDPR should be demonstrated. The system used for processing must be secure by design.

One of the detailed rights is the right-to-be-forgotten: at any time, a data subject may withdraw his consent to process their personal data.

P

Pseudonymization

Following the rules of the GDPR regulation may require a lot of effort. One of the pragmatic approaches is to:

- change the status of personal data to non-personal data.

Such a conversion occurs, whenever

- it is no longer possible to link the data to a physical person.

As a minimum, such a process requires a pseudonymization – the conversion of all identifiers of a physical person into pseudonyms.

This concerns both the explicit identifiers (such as name, personal ID number, etc.) and the implicit identifiers (such as a public key, postal address, non-anonymous email address, unique position, artistic pseudonym, etc.). Of course, pseudonymization is only a necessary condition and not a sufficient one. Nevertheless, pseudonymization is explicitly pointed to by the GDPR regulation. It states among others that:

the [data] controller should adopt the principles of data protection by design and data protection by default. Such measures could consist, inter alia, of minimising the processing of personal data, pseudonymising personal data as soon as possible

In order to be effective, derivation of pseudonyms must be automated. The following basic methods can be applied:

1. encryption of each identifier I by its ciphertext $Enc_K(I)$, where K is the private key of the party performing pseudonymization,
2. converting each identifier I by $F(I, K)$, where F is a one-way function and K is a secret key.
3. converting each identifier I by $F(I)$, where F is a one-way function.

The first method is reversible: if necessary, the party holding the key K can convert the pseudonym back to its corresponding identifier. This can both be an advantage and disadvantage: for the party holding the key K , the data have still the status of personal data, as the physical person is still identifiable by this party. This enforces on the party application of adequate measures for processing the data. On the other hand, if data may be used as personal data in the future, then reversibility is a necessary condition.

The second method can be used whenever data should permanently lose the status of personal data and the data set should undergo as minimal changes as possible.

The third method has the additional advantage that many parties may perform anonymization of different parts of the same data set, while the records concerning the same person will remain linkable. On the downside, after pseudonymization, everybody can check whether a pseudonym

P corresponds to an identifier I by checking whether $P = F(I)$. Therefore this option has very limited applicability.

Domains

By definition, pseudonymization is a process of replacing an identifier with a pseudonym. However, it does not mean that one identifier should correspond always to the same pseudonym. If that were the case, then such unique mapping might facilitate the linking of a pseudonym to its original identifier without breaking the cryptographic mechanism used for generating pseudonyms. The attacker, in the process called profiling, might analyze all data corresponding to a single pseudonym and create a set of features that uniquely define one particular person, thus revealing the identity of the pseudonym owner.

Following the data minimization principle of GDPR and aiming to reduce the chances of the above mentioned attack,

- an identifier I should be replaced by the same pseudonym only when it is necessary to maintain the information that such anonymized data correspond to the same (anonymous) person.

The concept of domains is a framework that aims to achieve this goal.

Separation Concept

The following assumptions about the information processing model are made:

- there are separate (virtual) domains of data processing,
- data concerning one person should be linkable within a domain,
- linking data from different domains but concerning the same person should be prevented.

The model originates from Austrian Bürgerkarte and separation of domains in the public administration of that country.

Domain-Specific Pseudonyms

The following rules are set:

1. for each identity there is a single pseudonym per domain (domain-specific pseudonym),
2. each user has a single identity and a single private key,
3. in order to generate a domain-specific pseudonym, it is necessary to use the private key.

Domain-Specific Signatures

A domain signature scheme is a digital signature scheme, where:

- each signature corresponds to a single domain and a single domain pseudonym,
- each user holds a single private key and uses it for creating his domain pseudonyms and domain signatures in all domains,
- the verification process refers to a domain pseudonym instead of the real identity of the signatory, as well as domain parameters.

Deanonymization

For various reasons it might be necessary to trace back the links between the real identity and pseudonym(s) or between pseudonyms of the same person. This may happen, for instance, due to law enforcement (linking a pseudonym with a real identity) or merging two domains after merging two web services (linking pseudonyms in two domains in order to merge accounts).

There are the following basic use cases for deanonymization procedures:

- find the domain pseudonym for a given real identity and a domain,
- find the real identity corresponding to a given domain pseudonym,
- given a domain pseudonym from domain A , find the domain pseudonym of the same person for domain B .

By definition, such operations can be easily done by the owner of the pseudonym(s) by applying adequate pseudonym generation

algorithms. However, for practical reasons, the deanonymization scheme must also include a scenario where the pseudonym owner is not involved in the procedure. And in order to prevent deanonymization by non-authorized parties, the procedure should not be possible without certain secret keys remaining solely in the possession of authorized entities.

Security Requirements

Seclusiveness

One of the basic properties of domain pseudonyms is the rule stating that *each user has one pseudonym per domain*. In order to fulfill this property in organizational way, the following architecture is adopted:

- a person can be enabled to join the system only with the consent of the Issuer, after authenticating his identity (joining procedure),
- the Issuer enables only one private key per physical person.

The joining procedure comprises in particular of:

- generation of a private key of the person (either by the Issuer, or the joining person, or by both of them),
- creating cryptographic material (if necessary), which can be used to show that the private key has been confirmed by the Issuer.

The *seclusiveness* property means that the following statements always hold for any valid pseudonym I for domain D :

- there exists a real person A that went through the joining procedure, and ...
- the pseudonym I is equal to the pseudonym of A in domain D created according to the joining procedure.

In order to break the seclusiveness property, the adversary may collude with the persons that

have already joined the system and in particular have access to their cryptographic material.

Solution Examples

Domain Identifiers

For all solutions discussed below, there is a unique public key associated with each domain. Let PK_D^{sector} denote the public key for sector D . Some authors call it *domain parameter*, as there might be no private key corresponding to PK_D^{sector} .

Below we present two options which can be traced back to the BSI (2016) Technical Recommendation (and its former versions).

Ad Hoc Domains

An ad hoc domain does not require management activities in order to create a domain. The public key is typically generated as

$$PK_D^{\text{sector}} := \text{Hash}(D),$$

where D is the official domain identifier and Hash is a hash function mapping into a group used for generating pseudonyms.

Additional requirement is that the discrete logarithm of PK_D^{sector} is not publicly known. It is easy to satisfy this constrain. For example, deriving Hash function from the SHA family assures that this requirement holds (i.e., it is infeasible to derive the discrete logarithm of PK_D^{sector}). Similarly, one can use the Pedersen hash Pedersen (1991) in the following way:

$$PK^{\text{sector}} := g^{\text{Hash}_1(D)} \cdot \beta^{\text{Hash}_2(D)}$$

where the discrete logarithm of β with respect to g is unknown (except for an authority or authorities performing deanonymization) and Hash_1 and Hash_2 are independent hash functions. The above computations are performed in a group, where at least the Discrete Logarithm Problem is hard.

Created Domains

In this case a domain emerges through some activity of an authority creating domains. As a

result, the existence of a domain is somehow confirmed, e.g., via:

trusted list – a (white)list of all domains registered. The list should be authenticated via a digital signature, analogously to CRL lists.
certificate – a certificate confirming PK_D^{sector} .

The second option has been used in Germany for domains defined for personal identity cards (*Berechtigungszertifikat*) and Restricted Identification scheme BSI (2016).

Domain Pseudonyms

Pseudonyms Based on DH Problem

The most popular method of generating domain pseudonyms for a user holding a secret key x is to derive

$$I := (PK_D^{\text{sector}})^x.$$

Given a public key $y = g^x$ of a person holding x and a domain pseudonym I , it should be infeasible to determine whether $I = (PK_D^{\text{sector}})^x$, unless the discrete logarithm of PK_D^{sector} is known to the verifier. Answering this question is related to solving the decisional Diffie-Hellman Problem (and, more directly, solving the DH linking problem Kutyłowski et al. 2011).

German Restricted Identification

The Restricted Identification scheme implemented on German ID cards uses a slightly different version of pseudonyms (BSI 2016). Namely, the pseudonym of a user holding key x is computed as

$$\text{Hash}\left((PK_D^{\text{sector}})^x\right).$$

Introducing the hash function is an additional security measure, since a party receiving the pseudonym does not learn the input for the DDH problem. So if two sectors have public keys $PK_{D_1}^{\text{sector}}$ and $PK_{D_2}^{\text{sector}}$ and somehow learn r such that $(PK_{D_1}^{\text{sector}})^r = PK_{D_2}^{\text{sector}}$, then they still cannot convert the pseudonyms from D_1 to pseudonyms in D_2 .

Computing the Pseudonyms by the Domain Manager

When a domain manager knows the discrete logarithm r of the domain's public key, $PK_D^{sector} = g^r$, then it can create domain pseudonyms based on user's public key $y = g^x$:

$$I := y^r \quad (\text{1st scheme})$$

or

$$I := \text{Hash}(y^r) \quad (\text{2nd scheme}).$$

Thereby, the user does not need to provide his pseudonyms: it can be computed later by the domain manager and the pseudonymization may be performed without interacting with the user.

Authenticating Data with Domain Signature

Whitelist-Based Scheme

The simplest scheme may be based on replacing the base element with PK_D^{sector} in DSA signature. The user holds a sector key x and his domain pseudonym is $(PK_D^{sector})^x$. The domain signature for data m is defined as usual for DSA:

- choose $k \in \mathbb{Z}_q$ at random,
- compute

$$r := ((PK_D^{sector})^k \bmod p) \bmod q,$$
- compute

$$s := k^{-1}(\text{Hash}(m) + xr) \bmod q,$$

The verification procedure is the same as for DSA, except that the generator g is now replaced by PK_D^{sector} .

The main problem with this solution is that seclusiveness is achieved by whitelist generation separately for each domain: given user's public key $y = g^x$, the entry $(PK_D^{sector})^x$ is generated as

$$y^d,$$

where $PK_D^{sector} = g^d$. Value of d can be distributed among two or more authorities. If $PK_D^{sector} = g^{d_1 \cdot d_2}$, then the authority holding d_1

computes $y_1 := y^{d_1}$ and the second authority computes $y_2 := y_1^{d_2}$.

Application scope of this scheme is limited to specific applications where the set of domain identifiers is closed.

German Pseudonymous Signature

The pseudonymous signature scheme Bender et al. (2012) is closely related to Okamoto signatures. It is based on Discrete Logarithm Problem, and in particular it requires neither pairings nor any kind of certificate, whitelist, etc. The price paid is the requirement for unconditionally secure hardware devices implementing signature keys.

There are two system secrets in this scheme, SK_{ICC} and $SK_M < q$, where q is the (prime) order of the group used. The corresponding public keys are defined as follows:

$$PK_{ICC} = g^{SK_{ICC}}, \quad PK_M = g^{SK_M}.$$

A user joining the system gets secrets x_0, x_1 , where x_1 is chosen at random and x_0 satisfies the quality:

$$SK_{ICC} = x_0 + x_1 \cdot SK_M \quad \bmod q.$$

The corresponding public keys are $P_0 = g^{x_0}$ and $P_1 = g^{x_1}$, and they are used exclusively in the case of deanonymization.

The domain public key PK_D^{sector} is created as g^d (or $g^{d_1 \cdot d_2}$ if the secret d has to be split).

A user holding keys x_0, x_1 has *two* valid domain pseudonyms (in each domain). They are defined as

$$\begin{aligned} I_{D,0} &= (PK_D^{sector})^{x_0} \\ I_{D,1} &= (PK_D^{sector})^{x_1}. \end{aligned}$$

A signature over m for a domain with the public key PK_D^{sector} is created as follows:

1. choose at random $k_0, k_1 < q$,
2. compute $Q := g^{k_0} \cdot PK_M^{k_1}$,
3. compute:

$$A_0 := (PK_D^{sector})^{k_0},$$

$$A_1 := (PK_D^{sector})^{k_1},$$

4. compute $c := \text{Hash}(Q, I_{0,D}, A_0, I_{1,D}, A_1, PK_D^{\text{sector}}, m)$,
5. compute:
 $s_0 := k_0 - c \cdot x_0 \bmod q,$
 $s_1 := k_1 - c \cdot x_1 \bmod q.$

The resulting signature is

$$\sigma(m) = (c, s_0, s_1).$$

The verification process for a signature (c, s_0, s_1) and domain pseudonyms $I_{0,D}, I_{1,D}$ is executed as follows:

- $Q' := (PK_{ICC})^c \cdot g^{s_0} \cdot (PK_M)^{s_1},$
- $A'_0 := (PK_D^{\text{sector}})^{s_0} \cdot (I_0)^c,$
- $A'_1 := (PK_D^{\text{sector}})^{s_1} \cdot (I_1)^c,$
- check whether
 $c \stackrel{?}{=} \text{Hash}(Q', I_{0,D}, A'_0, I_{1,D}, A'_1, PK_D^{\text{sector}}, m).$

In fact, the signature is a non-interactive proof of possession of x_0 and x_1 such that

$$SK_{ICC} = x_0 + x_1 \cdot SK_M \bmod q.$$

Deanonymization of a person holding pseudonyms $I_{0,D}, I_{1,D}$, when $PK_d^{\text{sector}} = g^d$, is based on deriving his public keys $P_0 = I_{0,D}^{1/d}$ and $P_1 = I_{1,D}^{1/d}$.

There are a few serious disadvantages of this scheme. First, the secret keys must be stored securely. Indeed, an adversary holding two pairs of private keys may derive SK_{ICC} and SK_M by solving a system of two linear equations. Another problem is that the Issuer knows the private keys of the user. This can be patched via a procedure from Kutyłowski et al. (2016); however, in that case further changes are required to enable deanonymization.

Pairing-Based Solutions

Pairings enable to provide schemes where the following fundamental conditions are fulfilled:

- seclusiveness,
- lack of whitelists, certificates per domain, etc.,
- the private key of a participant is not known to the Issuer.

The main disadvantage is using pairing groups, which still are not widely deployed in practice.

A pairing $e : G_1 \times G_2 \rightarrow G_T$ is a mapping such that $e(a^s, b^r) = e(a, b)^{s \cdot r}$ for any $a \in G_1, b \in G_2, s, r \in \mathbb{Z}$ and where $e(g_1, g_2) \neq 1$, for generators g_1, g_2 of, respectively, G_1 and G_2 .

The first scheme of this kind has been shown in Bringer et al. (2014). A later example is Hanzlik et al. (2016). A short outline of the first solution is provided below.

The scheme is defined for groups G_1, G_2, G_T of a prime order p , a pairing $e : G_1 \times G_2 \rightarrow G_T$, and generators $g_1, h, u \in G_1, g_2 \in G_2$. The system is based on a secret key y and the corresponding public key $(y_1, y_2) = (h^y, g_2^y)$.

The domain public key PK_D^{sector} is determined as g_1^r , where the secret r is chosen at random.

To join the system, a person must execute an interactive procedure which yields their private key (f, A, x) such that

$$A = (u \cdot h^f)^{1/(x+y)}.$$

First, the person computes $C = h^{f'}$ for some random f' and proposes C to the Issuer. Next, the Issuer chooses f'' and x at random, computes $A := (u \cdot C \cdot h^{f''})^{1/(x+y)}$, and returns (f'', A, x) . Finally, the person computes $f := f' + f'' \bmod p$.

The secret key is used to calculate the pseudonym given domain's public key:

$$N = h^f \cdot (PK_D^{\text{sector}})^x.$$

The signing procedure is based on multiple Schnorr signatures computed in parallel. For a message m , domain public key D , and domain pseudonym N , the following steps are executed:

1. choose $a, r_f, r_x, r_a, r_b, r_d < p$ at random,
2. $T := A \cdot h^a,$
3. $R_1 := h^{r_f} \cdot D^{r_x},$
 $R_2 := N^{r_a} \cdot h^{r_d} \cdot D^{r_b},$
 $R_3 := e(T^{r_x} \cdot h^{r_f r_b} \cdot (y_1)^{r_a}, g_2),$
4. $c := \text{Hash}(D, N, T, R_1, R_2, R_3, m),$
5. $s_x := r_x + c \cdot x \bmod p,$

$$\begin{aligned}s_f &:= r_f + c \cdot f \pmod{p}, \\ s_a &:= r_a + c \cdot a \pmod{p}, \\ s_b &:= r_b + c \cdot a \cdot x \pmod{p}, \\ s_d &:= r_d + c \cdot a \cdot f \pmod{p}.\end{aligned}$$

The signature is a tuple

$$\sigma(m) = (T, c, s_x, s_f, s_a, s_b, s_d).$$

As for Schnorr signatures, verification is based on reconstruction of the hash arguments R_1 , R_2 , and R_3 :

$$\begin{aligned}R'_1 &:= h^{s_f} \cdot D^{s_x} \cdot N^c \\ R'_2 &:= N^{s_a} \cdot h^{s_d} \cdot D^{s_b} \\ R'_3 &:= e(T^{s_x} \cdot h^{s_f s_b} \cdot u^c, G2) \cdot e(h^{s_a} \cdot T^c, y_2).\end{aligned}$$

In the last step, it is checked whether $c = \text{Hash}(D, N, T, R'_1, R'_2, R'_3, m)$.

Lifecycle Issues

Revocation

In the case of losing control over the key by a person, his pseudonyms and signatures are not trustworthy anymore. In order to deal with this problem, a revocation scheme is needed, which invalidates the pseudonyms and the corresponding signatures.

A standard approach in such cases are blacklists (separate for each domain). However, this method may effectively compromise the unlinkability property: when at some moment a single pseudonym in each domain is invalidated, then it is clear that these pseudonyms correspond to the same person. On the other hand, revocation should be done without undue delay, so we cannot wait with publication until a sufficient number of pseudonyms get revoked.

In order to alleviate this problem, one can use cryptographic accumulators known as anonymous credentials. Another, simpler, option is to use Bloom filters: in order to insert a revoked pseudonym $dnym$ in the Bloom filter with sequence number i , we inserts 1's in the filter on positions:

$$\text{Hash}(1, dnym, i), \dots, \text{Hash}(k, dnym, i),$$

where k is chosen so that false positives have sufficiently low probability.

Transition to New Keys

Any anonymization scheme must take into account the fact that a key may get lost or the device implementing it may break down due to hardware aging. Nevertheless, a person must not lose his domain identities.

This problem has been studied in Baldimtsi et al. (2015) in the context of anonymous credentials, and a solution based on commuting signatures Fuchsbauer (2011) was proposed. The problem with domain pseudonyms is that changing the private key would lead to the change of pseudonyms and thereby to re-pseudonymization, which may be a very demanding process for big data.

A general solution to this problem is to export the private key in a permanent form (e.g., printed as a 2D code on a piece of paper) and store it in a private vault. The exported key should be additionally encrypted to safeguard against illegitimate use.

Such encryption and adding a third party to the scheme can be employed to prevent uncontrolled cloning of the devices creating domain signatures, i.e., implementing the same secret key into more than one device. The following procedure may be applied:

- during export, the key is encrypted with the conditional digital encryption scheme Klonowski et al. (2005); the encryption has to be conditioned with a signature of an ID Transition Authority,
- after receiving an authenticating request, the ID Transition Authority verifies its validity and creates a conditional digital signature enabling decryption of the exported key. The signature can be encapsulated by encrypting it with the public key of the user's new device.
- The user uploads the encrypted key and the (encrypted) signature to the new device, and if the device is capable of decrypting the signature, the key may be installed.

Summary

The signature schemes based on pseudonyms related to specific domains of application are a feasible means for providing the level of anonymity

required by law. Their introduction is supported by considerable research in that area, and the already deployed schemes provide good proving grounds for their further improvements.

Introduction

Nowadays, many modern online services continuously collect users' private data for real-time analytics. This data normally arrives as a data

stream and in huge volumes, requiring real-time stream processing based on distributed systems (Carbone et al. 2015; Apache Spark Streaming).

In the current ecosystem of data analytics, the analysts usually have direct access to users' private data and must be trusted not to abuse it. However, this trust has been violated in the past ([HealthCare.gov Sends Personal Data to Dozens of Tracking Websites; SEC Charges Two Employees of a Credit Card Company with Insider Trading](#)). A pragmatic ecosystem has two desirable but contradictory design requirements: (i) stronger privacy guarantees for users and (ii) high-utility stream analytics in real time. Users seek stronger privacy, while analysts strive for high-utility analytics in real time.

To meet these two design requirements, there is a surge of novel computing paradigms that address these concerns, albeit *separately*. Two such paradigms are *privacy-preserving analytics* to protect user privacy and *approximate computation* for real-time analytics.

Privacy-preserving analytics. Recent privacy-preserving analytics systems favor a distributed architecture to avoid central trust (see section “[Related Work](#)” for details), where users’ private data is stored locally on their respective client devices. Data analysts use a publish-subscribe mechanism to perform aggregate queries over the distributed private dataset of a large number of clients. Thereafter, such systems add noise to the aggregate output to provide useful privacy guarantees, such as differential privacy (Dwork 2006). Unfortunately, these state-of-the-art systems normally deal with single-shot batch queries, and, therefore, these systems cannot be used for real-time stream analytics.

Approximate computing. Approximate computation is based on the observation that many data analytics jobs are amenable to an approximate rather than the exact output (see section “[Related Work](#)” for details). Such applications include speech recognition, computer vision, machine learning, and recommender systems. For such an approximate

workflow, it is possible to trade accuracy by computing over a subset (usually selected via a sampling mechanism) instead of the entire input dataset. Thereby, data analytics systems based on approximate computation can achieve low latency and efficient utilization of resources. However, the existing systems for approximate computation assume a centralized dataset, where the desired sampling mechanism can be employed. Thus, existing systems are not compatible with the distributed privacy-preserving analytics systems.

Combining privacy-preserving analytics and approximate computing. This paper makes the observation that the two computing paradigms, i.e., privacy-preserving analytics and approximate computation, are complementary. Both paradigms strive for an approximate instead of the exact output, but they differ in their *means* and *goals* for approximation. Privacy-preserving analytics adds explicit *noise* to the aggregate query output to protect user privacy, whereas approximate computation relies on a representative *sampling* of the entire dataset to compute over only a subset of data items to enable low-latency/efficient analytics. Therefore, this work combines these two existing paradigms together in order to leverage the benefits of both. The high-level idea is to achieve privacy (via approximation) by directly computing over a subset of sampled data items (instead of computing over the entire dataset) and then adding an explicit noise for privacy preservation.

To realize this combination, this paper presents the design of an approximation mechanism that also achieves privacy-preserving goals for stream analytics. This design targets a distributed setting, where users’ private data is stored locally on their respective personal devices, and an analyst issues a streaming query for analytics over the distributed private dataset of users. The analyst’s streaming query is executed on the users’ data periodically (a configurable epoch), and the query results are transmitted to a centralized aggregator via a set of proxies. The analyst interfaces with the aggregator to get the aggregate query output periodically.

Two core techniques are employed to achieve the goal. Firstly, *sampling* (Moore 1999) is directly employed at the user site for approximate computation, where each user randomly decides whether to participate in answering the query in the current epoch. Since the sampling is employed at the data source, instead of sampling at a centralized infrastructure, the proposed approach can squeeze out the desired data size (by controlling the sampling parameter) from the very first stage in the analytics pipeline, which is essential in low-latency environments.

Secondly, if the user participates in the query answering process, a *randomized response* (Fox and Tracy 1986) mechanism is performed to add noise to the query output at the user site, again locally at the source of the data in a decentralized fashion. In particular, each user locally randomizes the truthful answer to the query to achieve the differential privacy guarantees (section “[Step II: Answering Queries at Clients](#)”). Since the noise is added at the source of data, instead of adding the explicit noise to the aggregate output at a trusted aggregator or proxies, the proposed approach enables a truly “synchronization-free” distributed architecture, which requires *no coordination* among proxies and the aggregator for the mandated noise addition.

The last, but not the least, silver bullet of the design: it turns out that the combination of the two aforementioned techniques (i.e., sampling and randomized response) leads us to achieve zero-knowledge privacy (Gehrke et al. 2011), a privacy bound tighter than the state-of-the-art differential privacy (Dwork 2006).

To summarize, this paper presents the design of PRIVAPPROX— a practical system for privacy-preserving stream analytics in real time. In particular, the system is a novel combination of the sampling and randomized response techniques, as well as a scalable “synchronization-free” routing scheme which employs a light-weight XOR-based encryption scheme (Chen et al. 2013). The resulting system ensures zero-knowledge privacy, anonymization, and unlinkability for users (section “[System Model](#)”).

Overview

System Architecture

PRIVAPPROX is designed for privacy-preserving stream analytics on distributed users’ private dataset. This system consists of four main components: clients, proxies, aggregator, and analysts.

Clients locally store users’ private data on their respective personal devices and subscribe to queries from the system. *Analysts* publish streaming queries to the system and also specify a query execution budget. The query execution budget can either be in the form of latency guarantees/S-LAs, output quality/accuracy, or the computing resources for query processing. PRIVAPPROX ensures that the computation remains within the specified budget.

At a high-level, the system works as follows: a query published by an analyst is distributed to clients via the aggregator and proxies. Clients answer the analyst’s query locally over the users’ private data using a privacy-preserving mechanism. Client answers are transmitted to the aggregator via anonymizing *proxies*. The *aggregator* aggregates received answers from the clients to provide privacy-preserving stream analytics to the analyst.

System Model

Query model. PRIVAPPROX supports the SQL query language for *analysts* to formulate streaming queries, which are executed periodically at the clients as sliding window computations (Bhatotia et al. 2012a). While queries can be complex, the results of a query are expressed as counts within histogram buckets, i.e., each bucket represents a range of the query’s answer values. Specifically, each query answer is represented in the form of binary buckets, where each bucket stores a value “1” or “0” depending on whether or not the answer falls into the value range represented by that bucket. For example, an analyst can learn the driving speed distribution across all vehicles in San Francisco

by formulating an SQL query “SELECT speed FROM vehicle WHERE location=‘San Francisco’.” The analyst can then define 12 answer buckets on speed: “0,” “1~10,” “11~20,” …, “81~90,” “91~100,” and “> 100.” If a vehicle is moving at 15 mph in San Francisco, it answers “1” for the third bucket and “0” for all others.

The query model supports not only numeric queries as described above but also non-numeric queries. For non-numeric queries, each bucket is specified by a matching rule or a regular expression.

Threat model. Analysts are potentially malicious. They may try to violate the PRIVAPPROX’s privacy model (described later), i.e., de-anonymize clients, build profiles through the linkage of queries and answers, or remove the added noise from answers.

Clients are potentially malicious. They could generate false or invalid responses to distort the query result for the analyst. However, the proposed system does not defend against the Sybil attack (Douceur 2002), which is beyond the scope of this work (Wang et al. 2016a).

Proxies are also potentially malicious. They may transmit messages between clients and the aggregator in contravention of the system protocols. PRIVAPPROX includes at least two proxies, and there are at least two proxies which do not collude with each other. The *aggregator* is assumed to be honest but curious. The aggregator faithfully conforms to the system protocols but may try to exploit the information about clients. The aggregator does not collude with any proxy nor the analyst.

Privacy model. PRIVAPPROX provides three important privacy properties: (i) zero-knowledge privacy, (ii) anonymity, and (iii) unlinkability.

All aggregate query results in the system are independently produced under the *zero-knowledge privacy* guarantees (Gehrke et al. 2011). The zero-knowledge privacy metric builds upon differential privacy (Dwork 2006) and

provides a tighter bound on privacy guarantees compared to differential privacy. Informally, zero-knowledge privacy states that essentially everything that an adversary can learn from the output of an zero-knowledge private mechanism could also be learned using the aggregate information. *Anonymity* means that no system component can associate query answers or query requests with a specific client. Finally, *unlinkability* means that no system component can join any pair of query requests or answers to the same client, even to the same anonymous client. The formal definition, analysis, and proof are described in the technical report (Quoc et al. 2017a).

Design

PRIVAPPROX consists of two main phases: *submitting queries* and *answering queries*. In the first phase, an analyst submits a query (along with the execution budget) to clients via the aggregator and proxies. In the second phase, the query is answered by the clients in the reverse direction.

Submitting Queries

To perform statistical analysis over users’ private data streams, an analyst creates a query using the query model described in section “[System Model](#)”. In particular, each query consists of the following fields and is signed by the analyst for non-repudiation:

$$\text{Query} := \langle Q_{ID}, SQL, A[n], f, w, \delta \rangle \quad (1)$$

- Q_{ID} denotes a unique identifier of the query. This can be generated by concatenating the identifier of the analyst with a serial number unique to the analyst.
- SQL denotes the actual SQL query, which is passed on to clients and executed on their respective personal data.
- $A[n]$ denotes the format of a client’s answer to the query. The answer is an n -bit vector where

each bit associates with a possible answer value in the form of a “0” or “1” per index (or answer value range).

- f denotes the answer frequency, i.e., how often the query needs to be executed at clients.
- w denotes the window length for sliding window computations (Bhatotia et al. 2014). For example, an analyst may only want to aggregate query results for the last ten minutes, which means the window length is ten minutes.
- δ denotes the sliding interval for sliding window computations. For example, an analyst may want to update the query results every one minute, and so the sliding interval is set to one minute.

After forming the query, the analyst sends the query, along with the query execution budget, to the aggregator. Once receiving the pair of the query and query budget from the analyst, the aggregator first converts the query budget into system parameters for sampling and randomization. The system operator can set the sampling fraction using resource prediction model (Wieder et al. 2010a, b, 2012) for any given SLA. Hereafter, the aggregator forwards the query and the converted system parameters to clients via proxies.

Answering Queries

After receiving the query and system parameters, the query is answered by clients and processed by the system to produce the result for the analyst. The query answering process involves four steps including (i) sampling at clients for low-latency approximation, (ii) randomizing answers for privacy preservation, (iii) transmitting answers via proxies for anonymization and unlinkability, and finally, (iv) aggregating answers with error estimation to give a confidence level on the approximate result. (The detailed algorithms are covered in Quoc et al. (2017a, b).)

Step I: Sampling at Clients

PRIVAPPROX makes use of approximate computation to achieve low-latency execution by computing over a subset of data items instead of the entire input dataset. Specifically, the system

builds on sampling-based techniques (Krishnan et al. 2016; Quoc et al. 2017c, d). To keep the private data stored at individual clients, PRIVAPPROX applies an input data sampling mechanism locally at the clients. In particular, the system uses *simple random sampling* (SRS) (Moore 1999).

Note that, this work assumes that all clients produce the input stream with data items following the same distribution, i.e., all clients’ data streams belong to the same stratum. The sampling mechanism can be further extended with the *stratified sampling* technique (Krishnan et al. 2016; Quoc et al. 2017c, d) to deal with varying distributions of data streams. The algorithm and evaluation of stratified sampling are covered in the technical report (Quoc et al. 2017a).

Step II: Answering Queries at Clients

Clients that participate in the query answering process make use of the *randomized response* technique (Fox and Tracy 1986) to preserve answer privacy, with *no* synchronization among clients. Randomized response works as follows: suppose an analyst sends a query to individuals to obtain the statistical result about a sensitive property. To answer the query, a client locally randomizes its answer to the query (Fox and Tracy 1986). Specifically, the client flips a coin, if it comes up heads, then the client responds its truthful answer; otherwise, the client flips a second coin and responds “Yes” if it comes up heads or “No” if it comes up tails. The privacy is preserved via the ability to refuse responding truthful answers (see details in Quoc et al. (2017a, b)).

It is worth mentioning that, combining the randomized response with the sampling technique described in Step I, PRIVAPPROX achieves not only differential privacy but also zero-knowledge privacy (Gehrke et al. 2011) which is a privacy bound tighter than differential privacy. The detailed proof is described in the technical report (Quoc et al., 2017a).

Step III: Transmitting Answers via Proxies

After producing randomized responses, clients transmit them to the aggregator via the prox-

ies. To achieve anonymity and unlinkability of the clients against the aggregator and analysts, PRIVAPPROX utilizes the XOR-based encryption together with source rewriting, which has been used for anonymous communications (Chen et al. 2013; Dingledine et al. 2004). The underlying idea of this encryption is simple: if Alice wants to send a message M of length l to Bob, then Alice and Bob share a secret M_K (in the form of a random bit-string of length l). To transmit the message M privately, Alice sends an encrypted message " $M_E = M \oplus M_K$ " to Bob, where " \oplus " denotes the bit-wise XOR operation. To decrypt the message, Bob again uses the bit-wise XOR operation: $M = M_E \oplus M_K$ (see details in Quoc et al. 2017a, b).

Step IV: Generating Result at the Aggregator

At the aggregator, all data streams ((M_{ID}, M_E) and (M_{ID}, M_{K_i})) are received and can be joined together to obtain a unified data stream. Specifically, the associated M_E and M_{K_i} are paired by using the message identifier M_{ID} . To decrypt the original randomized message M from the client, the XOR operation is performed over M_E and M_K : $M = M_E \oplus M_K$ with M_K being the XOR of all M_{K_i} : $M_K = \bigoplus_{i=2}^n M_{K_i}$. As the aggregator cannot identify which of the received messages is M_E , it just XORs all the n received messages to decrypt M .

Note that an adversarial client might answer a query many times in an attempt to distort the query result. However, this problem can be handled, for example, by applying the *triple splitting* technique (Chen et al. 2013).

Error bound estimation. PRIVAPPROX provides an error bound estimation for the aggregate query results. The accuracy loss in PRIVAPPROX is caused by two processes: (i) sampling and (ii) randomized response. Since the accuracy loss of these two processes is statistically independent (see details in Quoc et al. (2017b, a)), PRIVAPPROX estimates the accuracy loss of each process separately. In addition, independent of the error induced by randomized response, the error coming from sampling is simply being added upon. Following

this, the system sums up both independently estimated errors to provide the total error bound of the query results. To estimate the accuracy loss of the randomized response process, PRIVAPPROX makes use of an experimental method. It performs several micro-benchmarks at the beginning of the query answering process (without performing the sampling process) to estimate the accuracy loss caused by randomized response. On the other hand, to estimate the accuracy loss of the sampling process, PRIVAPPROX applies the statistical theory of the sampling techniques (see details in Quoc et al. (2017b, a)).

Related Work

Privacy-preserving analytics. Since the notion of differential privacy (Dwork 2006; Dwork et al. 2006b), a plethora of systems have been proposed to provide differential privacy with centralized databases (McSherry and Mahajan 2010; Mohan et al. 2012). In practice, however, such central trust can be abused, leaked, or subpoenaed (HealthCare.gov Sends Personal Data to Dozens of Tracking Websites; SEC Charges Two Employees of a Credit Card Company with Insider Trading).

To overcome the limitations of the centralized database schemes, recently a flurry of systems have been proposed with a focus on preserving user privacy (mostly, differential privacy) in a distributed setting where the private data is kept locally (Guha et al. 2011; Chen et al. 2013; Dwork et al. 2006a). However, these systems are designed to deal with the "one-shot" batch queries only, whereby the data is assumed to be static.

To overcome the limitations of the aforementioned systems, several differentially private stream analytics systems have been proposed (Dwork et al. 2010; Chan et al. 2011, 2012; Shi et al. 2011; Rastogi and Nath 2010). Unfortunately, these systems still contain several technical shortcomings that limit their practicality. One of the first systems (Dwork et al. 2010) updates the query result only if the user's private data changes significantly and does

not support stream analytics over an unlimited time period. Subsequent systems (Chan et al. 2011; Hubert Chan et al. 2012) remove the limit on the time period but introduce extra system overheads. Some systems (Shi et al. 2011; Rastogi and Nath 2010) leverage expensive secret sharing cryptographic operations to produce noisy aggregate query results. These systems, however, cannot work at large scale under churn; moreover, in these systems, even a single malicious user can substantially distort the aggregate results without detection. Recently, some other privacy-preserving distributed stream monitoring systems have been proposed (Chan et al. 2012). However, they all require some form of synchronization and are tailored for heavy-hitter monitoring only. Streaming data publishing systems like Wang et al. (2016b) use a stream-privacy metric at the cost of relying on a trusted party to add noise. In contrast, PRIVAPPROX does not require a trusted proxy or aggregator to add noise. Furthermore, PRIVAPPROX provides stronger privacy properties (i.e., zero-knowledge privacy).

Sampling and randomized response. Sampling and randomized response, also known as input perturbation techniques, are being studied in the context of privacy-preserving analytics, albeit they are explored separately. For instance, the relationship between sampling and privacy is being investigated to provide k-anonymity (Chaudhuri and Mishra 2006), differential privacy (Mohan et al. 2012), and crowd-blending privacy (Gehrke et al. 2012). In contrast, this paper shows that sampling combined with randomized response achieves the zero-knowledge privacy, a privacy bound strictly stronger than the state-of-the-art differential privacy.

Approximate computation. Approximation techniques such as sampling (Al-Kateb and Lee 2010), sketches (Cormode et al. 2012), and online aggregation (Hellerstein et al. 1997) have been well-studied over the decades in the databases community. Recently, sampling-based systems (Quoc et al. 2017c, d; Krishnan et al. 2016) have also been shown effective for “Big

Data” analytics. In particular, our work builds on IncApprox (Krishnan et al. 2016), a data analytics system that combines incremental computation (Bhatotia et al. 2011a, b, 2012b, 2015; Bhatotia 2015) and approximate computation. However, PRIVAPPROX differs in two main aspects. First, the system performs sampling in a distributed way as opposed to sampling in a centralized dataset. Second, PRIVAPPROX extends sampling with randomized response for privacy-preserving analytics.

Conclusion

This paper presents PRIVAPPROX, a privacy-preserving stream analytics system. The approach in PRIVAPPROX builds on the observation that both computing paradigms – privacy-preserving data analytics and approximate computation – strive for approximation and can be combined together to leverage the benefits of both.

Definitions

Given several databases containing person-specific data held by different organizations, privacy-preserving record linkage (PPRL) aims to identify and link records that correspond to the same entity/individual across different databases based on the matching of personal identifying attributes, such as name and address, without revealing the actual values in these attributes due to privacy concerns. The output is a set of matching clusters containing records of the same entity.

Overview

In the current era of Big Data, personal data about people, such as customers, patients, tax payers, and clients, are dispersed in multiple different sources collected by different organizations. Businesses and services have begun to leverage tremendous opportunities and insights provided by linked and integrated data. Examples range from healthcare, businesses, and social sciences to government services and national security. Linking data is also used as a preprocessing step in many data mining and analytics projects in order to clean, enrich, and understand data for quality results (Christen, 2012).

However, the growing concerns of privacy and confidentiality issues about personal data pose serious constraints to share and exchange such data across organizations for linking. Since a unique entity identifier is not available in different data sources, linking of records from different databases needs to rely on available personal identifying attributes, such as names, dates of birth, and addresses. Known as quasi identifiers (QIDs), these values in combination not only allow uniquely identifying individuals but also reveal private and sensitive information about them (Vatsalan et al., 2013).

Privacy-preserving record linkage (PPRL) aims to identify the same entities from different databases by linking records based on encoded and/or encrypted QIDs, such that no sensitive

information of the entities is revealed to any internal (parties involved in the process) and external (external adversaries and eavesdroppers) parties. While a variety of techniques and methodologies have been developed for PPRL over the past two decades, as surveyed in (Vatsalan et al., 2013), this research field is still open to several challenges, especially with the Big Data revolution.

A typical PPRL process involves several steps, starting from preprocessing databases, encoding or encrypting records using the privacy masking functions (Vatsalan et al., 2013), applying blocking or other forms of complexity reduction methods (Christen, 2012), then matching records based on their QIDs using approximate comparison functions (Christen, 2012), and finally clustering or classifying matching records that correspond to the same entity. Additional steps of evaluation of the linkage as well as manual review of certain records are followed in non-PPRL applications. However, these two steps require more research for PPRL as they generally require access to raw data and ground truth which is not possible in a privacy-preserving context.

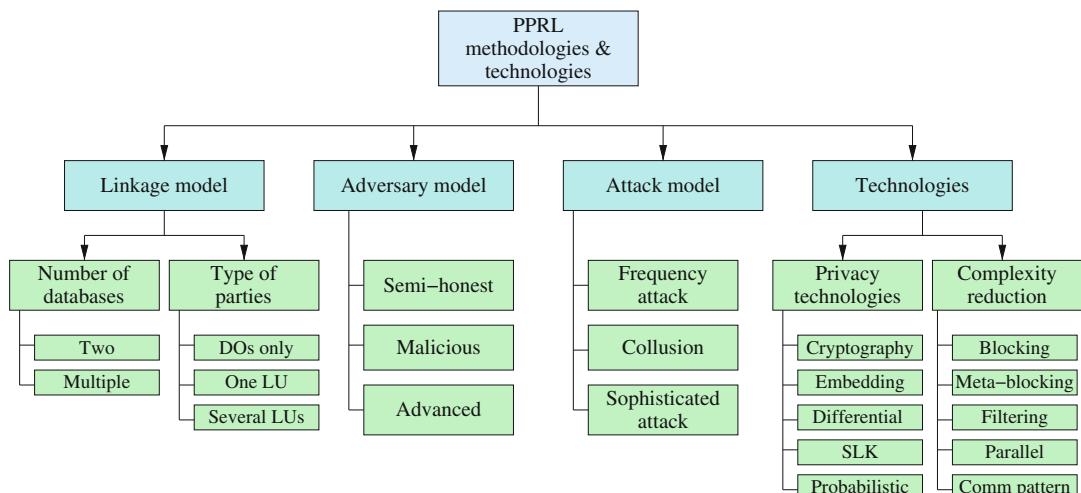

Despite several challenges, the output of PPRL could certainly bring in enormous potential in the Big Data era for businesses, government agencies, and research organizations. PPRL has been an active area of research in the recent

times, and it is now being applied in real-world applications (Boyd et al., 2015; Randall et al., 2014). In this chapter, we will describe some of the key research findings of PPRL and example PPRL applications. We also discuss directions for future research in PPRL.

Key Research Findings

In this section, we present the key research findings in PPRL with regard to the methodologies and technologies used, as characterized in Fig. 1. Considering the number and type of parties involved, the linkage models can be categorized as:

- Two database owners (DOs)** involve in two-party protocols in order to identify the matching records in their databases. This linkage model requires more sophisticated techniques to ensure that the parties do not learn any sensitive information about each other's data. Linking two databases has a naive complexity of quadratic in the size of databases.
- Two DOs with a linkage unit (LU)** participate in three-party protocols where a trusted LU (third party) conducts the linkage. A major drawback of LU-based protocols is that they require a trusted LU in order to avoid possible collusion attacks, as described below.

Privacy-Preserving Record Linkage, Fig. 1 A taxonomy of methodologies and technologies used in PPRL

3. **Two DOs with several LUs** is the model where several LUs are used to link two databases. For example, one is responsible for secret keys management, and another one for facilitating the complexity reduction step, while matching of records is conducted by a different LU. Separating the tasks across several LUs reduces the amount of information learned by a single party; however collusion could compromise the privacy.
4. **Multiple DOs without or with LU(s)** involve in multiparty linkage where the aim is to identify cluster of records from multiple (more than two) databases that refer to the same entity. The naive complexity of linking multiple databases becomes exponential, and the linkage process becomes complicated with the increase of number of databases. Processing can be distributed among multiple parties to improve efficiency as well as privacy by reducing the amount of information learned by a single party.

Different adversary models are assumed in PPRL methodologies (Vatsalan et al., 2013):

1. **Honest-but-curious/semi-honest** model is the most commonly used adversary model in existing PPRL techniques (Vatsalan et al., 2013), where the parties are assumed to honestly follow the steps of the protocol while being curious to learn from the information they received throughout the protocol. This model is not realistic in real applications due to the weak assumption of privacy against adversarial attacks.
2. **Malicious model** provides a strong assumption of privacy by assuming that the parties involved in the protocol may not follow the steps of the protocol in terms of deviating from the protocol, sending false input, and behaving arbitrarily. More complex and advanced privacy techniques are required to make the protocols resistant against such malicious adversaries.
3. **Advanced models** are hybrid models that lie in between the semi-honest model, which is not realistic, and the malicious model, which requires computationally expensive

techniques. Two such advanced models are accountable computing and covert model.

Several attack models have been developed for PPRL techniques to investigate the resistance of such techniques:

1. **Frequency-based attacks** are most commonly used, where the frequency of encoded values is mapped to the frequency of known unencoded values (Vatsalan et al., 2014).
2. **Collusion** attacks are possible in LU-based and multiparty models where subsets of parties collude to learn another party's data (Vatsalan et al., 2014).
3. **More sophisticated attacks** have been developed against certain privacy techniques. For example, Bloom filters (as described below) are susceptible to cryptanalysis attacks, which allow the iterative mapping of hash-encoded values back to their original values depending upon the parameter settings (Christen et al., 2017; Kuzu et al., 2011).

With regard to privacy technologies, a variety of techniques has been developed for PPRL. We categorize the key findings as:

1. **Cryptography** refers to secure multiparty computation techniques, such as homomorphic encryptions, secret sharing, and secure vector operations (Lindell and Pinkas, 2009). These techniques are provably secure and highly accurate; however, they are computationally expensive. An example PPRL technique based on cryptographic techniques is the secure edit distance algorithm for matching two strings or genome sequences (Atallah et al., 2003), which is quadratic in the length of the strings.
2. **Embedding techniques** allow data to be mapped into a multidimensional metric space while preserving the distances between original data. It is difficult to determine the appropriate dimensionality for the metric space. A recent work proposed a framework for embedding string and numerical data with theoretical guarantees for rigorous specifi-

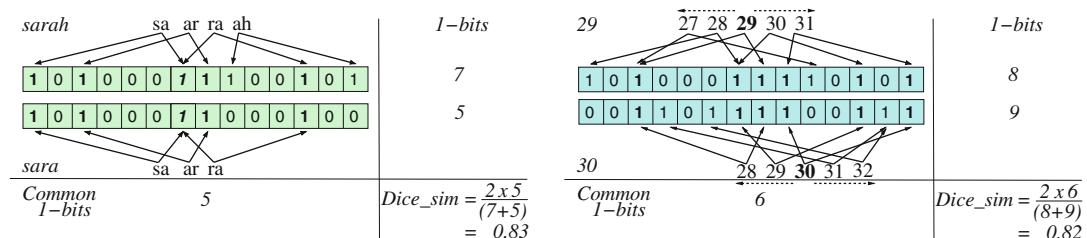

- cation of space dimensionality (Karapiperis et al., 2017).
3. **Differential privacy** is a rigorous definition that provides guarantees of indistinguishability of an individual in the data with high probability. It has been used in PPRL to perturb data by adding noise such that every individual in the dataset is indistinguishable (Vatsalan et al., 2013, 2014). However, adding noise incurs utility loss and volume increase.
 4. **Statistical linkage key (SLK)** contains derived values from QIDs which is generated using a combination of components of a set of QIDs. An example is the SLK-581 consisting of the second and third letters of first name; the second, third, and fifth letters of surname; full date of birth; and sex, which was developed by the Australian Institute of Health and Welfare to link records from the Home and Community Care datasets (Randall et al., 2016). A recent study has shown that SLK-based techniques fall short in providing sufficient privacy protection and sensitivity (Randall et al., 2016).
 5. **Probabilistic methods** are the most widely used techniques for practical PPRL applications due to their efficiency and controllable privacy-utility trade-off. These methods use probabilistic data structures for mapping/encoding data such that the actual distances between original data are preserved depending on the false-positive probability of the mapping. A recent study has shown that, if effectively used, probabilistic techniques can achieve high linkage quality comparable to using unencoded records (Randall et al., 2014).

For example, Bloom filter encoding is one probabilistic method that has been used in several PPRL solutions (Durham, 2012; Randall et al., 2014; Schnell et al., 2009; Sehili et al., 2015; Vatsalan and Christen, 2012, 2014). A Bloom filter b_i is a bit array of length l bits where all bits are initially set to 0. k independent hash functions, h_j , with $1 \leq j \leq k$, are used to map each of the elements s in a set S into the Bloom filter by setting the bit positions $h_j(s)$, $1 \leq j \leq k$ to 1. As shown in Fig. 2 (left), the set S of q -grams (substrings of length q) of QID values of each record can be hash-mapped into a Bloom filter. The resulting Bloom filters can be matched using a similarity function, such as the Dice-coefficient (Christen, 2012):

$$\text{Dice_sim}(b_1, \dots, b_P) = \frac{P \times c}{\sum_{i=1}^P x_i}, \quad (1)$$

where P is the number of Bloom filters compared, c is the number of common bit positions that are set to 1 in all P Bloom filters, and x_i is the number of bit positions set to 1 in b_i , $1 \leq i \leq P$. The matching can either be done by a LU (Durham, 2012; Schnell et al., 2009) or collaboratively by the DOs (Vatsalan and Christen, 2012, 2014). Recently, Bloom filter-based matching of numerical data has been developed, which hash-maps a set S of neighbor values to allow approximate matching (shown in Fig. 2 (right)) (Vatsalan and Christen, 2016).

Counting Bloom filter is another probabilistic method where counts of elements are

Privacy-Preserving Record Linkage, Fig. 2 Bloom filter-based matching for string (Schnell et al., 2009) (left) and numerical (Vatsalan and Christen, 2016) (right) data

stored in an integer array. Counting Bloom filter has been used for PPRL of multiple databases (Vatsalan et al., 2016) where the Bloom filters from different databases are summed to generate a counting Bloom filter which is used by the LU to classify the set of records as matches or not. Counting Bloom filters provide improved privacy compared to Bloom filters as they store only the summary information; however, they incur increased memory cost. Count-min sketch is a memory-efficient probabilistic data structure that can be used to store count information and has been used for linking multiple databases (Karapiperis et al., 2015).

The bottleneck of the PPRL process is the comparison of records among different databases, which is equal to the product of the sizes of the databases. Computational technologies have been used to improve the scalability of PPRL:

1. **Blocking** is defined on selected attributes and it partitions the records in a database into several blocks or clusters such that comparison can be restricted to the records of the same block. A variety of blocking techniques has been developed (Vatsalan et al., 2013). Recent examples are randomized blocking methods based on locality-sensitive hashing, which provide theoretical guarantees for identifying similar record pairs in the embedding space with high probability (Durham, 2012; Karapiperis and Verykios, 2015).
2. **Meta-blocking** is the process of restructuring a collection of generated blocks to be compared in the next step such that unnecessary comparisons are pruned. Block processing for PPRL only received much attention in the recent years with the aim to improve the scalability in Big Data applications by employing such techniques along with blocking techniques (Karakasidis et al., 2015; Ranbaduge et al., 2016).
3. **Filtering** is an optimization for a particular comparison function which utilizes different filtering or thresholding techniques to elimi-

nate pairs/sets of records that cannot meet the similarity threshold for the selected similarity measures (Sehili et al., 2015; Vatsalan and Christen, 2012).

4. **Parallel/distributed processing** for PPRL has only seen limited attention so far. Parallel linkage aims at improving the execution time proportionally to the number of processors (Dal Bianco et al., 2011; Karapiperis and Verykios, 2015). This can be achieved by partitioning the set of all record pairs to be compared, for example, using blocking, and conducting the comparison of the different partitions in parallel on different processors.
5. **Advanced communication patterns** can be used to reduce the exponential growth of complexity. Such communication patterns include sequential, ring-by-ring, tree-based, and hierarchical patterns. Some of these patterns have been investigated for PPRL on multiple databases (Vatsalan et al., 2016).

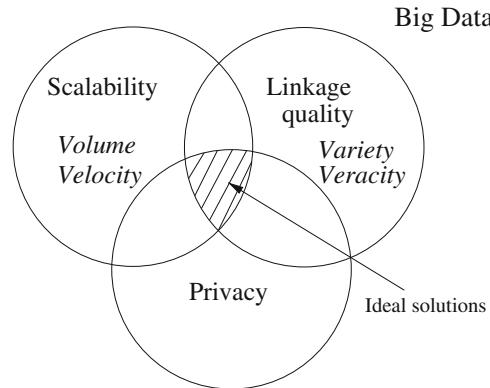

Examples of Application

Linking data is increasingly being required in a number of application areas (Christen, 2012). When databases are linked within a single organization, then generally privacy and confidentiality are not of great concern. However, linking data from several organizations imposes legal and ethical constraints on using personal data for the linkage, as described by the Australian Data-Matching Program Act (<https://www.legislation.gov.au/Details/C2016C00755>), the EU Personal Data Protection Act (<http://ec.europa.eu/justice/data-protection/>), and the HIPAA Act in the USA (<http://www.hhs.gov/ocr/privacy/>). PPRL is therefore required in several real applications, as the following examples illustrate:

1. **Health applications:** Several health applications ranging from health surveillance, epidemiological studies, and clinical trials to pub-

lic health research require PPRL as an efficient building block. For example, researchers are interested in aggregating health databases for quality health data mining. Health outbreak systems require data to be integrated from several sources, including human health, travel, and consumed drug, to allow the early detection of infectious diseases before they spread widely (Kelman et al., 2002). Similar patient matching is another application that requires linking different health databases, for clinical trials and customized patient care (Vatsalan and Christen, 2016).

2. **Government services and research:** The traditionally used small-scale survey studies have been replaced by linking databases to develop policies in a more efficient and effective way (Kelman et al., 2002). The research program “Beyond 2011” established by the Office for National Statistics in the UK, for example, aimed to study the options for production of population statistics for England and Wales, by linking anonymous data (Office for National Statistics, 2013). Social scientists use PPRL in the field of population informatics to study insights into our society (Kum et al., 2014).
3. **Business collaboration:** Many businesses take advantage of linking data across different organizations, such as suppliers, retailers, wholesalers, and advertisers, for improving efficiency, targeted marketing, and reducing costs of their supply chains. PPRL can be used for cross-organizational collaborative decision making which involves a great deal of private information that businesses are often reluctant to disclose (Zhu et al., 2017).
4. **National security applications:** PPRL techniques are being used by national security agencies and crime investigators to identify individuals who have committed fraud or crimes (Phua et al., 2012). These applications integrate data from various sources, such as law enforcement agencies, Internet service providers, the police, tax agencies, government services, as well as financial institutions to enable the accurate identification of crime and fraud or of terrorism suspects.

Privacy-Preserving Record Linkage, Fig. 3
Challenges of PPRL for Big Data

Future Directions for Research

In this section we describe the various open challenges and directions of PPRL for Big Data applications, as categorized in Fig. 3.

Scalability

The *volume* of data increases both due to the large size of databases and the number of different databases. Challenges of linking large databases have been addressed by using computational techniques to reduce the number of required comparisons between records, as described in section “Key Research Findings.” However, these techniques do not solve the scalability problem for Big Data completely, as they still result in exponential complexity. For example, even small blocks of records resulting from a blocking technique can still lead to a large number of comparisons between records with the increasing volume of data. Moreover, only limited work has been done to address the challenges of linking multiple databases.

Scalable blocking techniques are required that generate blocks of suitable sizes across multiple databases, as are advanced filtering techniques that effectively prune potential non-matches even further. With multiple databases, identifying subsets of records that match across only a subset of databases (e.g., patients in three out of five hospital databases) is even more challenging due to the large number of combinations

of subsets. Advanced communication patterns, distributed computing, and adaptive comparison techniques are required toward this direction for scalable PPRL applications. These techniques are largely orthogonal so that they can be combined to achieve maximal efficiency.

Another major aspect of Big Data is the *velocity*, i.e., the dynamic nature of data. Current techniques are only applicable in batch mode on static and well-defined relational data. Required are approaches for dynamic data, real-time integration, and data streams, for adaptive systems to link data as they arrive at an organization, ideally in (near) real time.

Linkage Quality

Big Data are often complex, noisy, and erroneous, which refer to the *veracity* and *variety* aspects. The linkage can be affected by the quality of data, especially in a privacy-preserving context where linkage is done on the masked or encoded version of the data. Masking data reduces the quality of data to account for privacy and therefore the quality of data would have an adverse effect on the whole PPRL process leading to low linkage quality. The trade-off between quality and privacy needs to be handled carefully for different privacy masking functions. The effect of poor data quality on the linkage quality becomes worse with increasing number of databases. Only two recent approaches support approximate matching for PPRL on multiple databases (Vatsalan and Christen, 2014; Vatsalan et al., 2016). More advanced classification techniques, such as collective (Bhattacharya and Getoor, 2007) and graph-based (Kalashnikov and Mehrotra, 2006) techniques, need to be investigated to address the linkage quality problem of PPRL.

Assessing the linkage quality in a PPRL project is very challenging because it is generally not possible to inspect linked records due to privacy concerns. Knowing the quality of linkage is crucial in many Big Data applications such as in the health or security domains. An initial work has been done on proposing interactive PPRL (Kum et al., 2014) where parts of sensitive

values are revealed for manual assessment in such a way that the privacy compromise is limited. Implementing such approaches in real applications is an open challenge that must be solved.

Privacy

Another open challenge in PPRL is how resistant the techniques are against different adversarial attacks. Most work in PPRL assumes the *semi-honest* adversary model (Lindell and Pinkas, 2009) and the trusted LU-based model. Furthermore, these works assume that the parties do not collude with each other (Vatsalan et al., 2013). Only few PPRL techniques consider the *malicious* adversary model as it imposes a high complexity (Vatsalan et al., 2013). More research is therefore required to develop novel security models that lie between these two models and prevent against collusion risks for PPRL.

Sophisticated attack methods (Christen et al., 2017; Kuzu et al., 2011) have been recently developed that exploit the information revealed during the PPRL protocols to iteratively gather information about sensitive values. Therefore, existing PPRL techniques need to be hardened to ensure they are not vulnerable to such attacks. Evaluation of PPRL techniques is challenged due to the absence of benchmarks, datasets, and frameworks. Different measurements have been used (Durham, 2012; Vatsalan et al., 2013, 2014), making the comparison of different PPRL techniques difficult. Synthetic datasets that are generated based on the characteristics of real data using data generators (Tran et al., 2013) have been used as an alternative to benchmark datasets. This limits the real evaluation of PPRL techniques to assess their application in the real setting.

Further, there has not been much interaction between practitioners and researchers of PPRL to allow better understanding of the whole data life cycle and to evaluate the applicability of PPRL in real applications. A comprehensive privacy strategy is essential including a closely aligned PPRL and privacy-preserving data technologies for strategic Big Data applications.

Uncertain data integration

Definitions

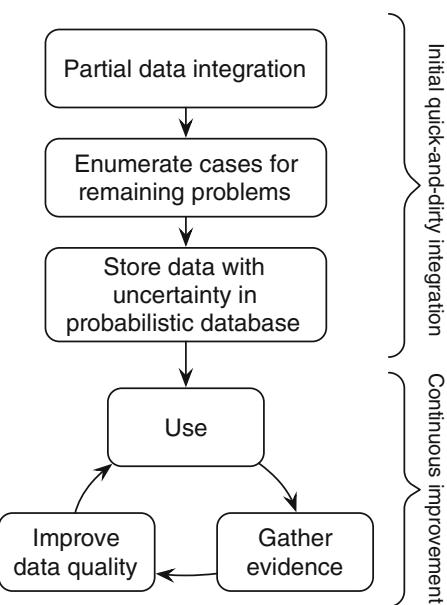

Probabilistic data integration (PDI) is a specific kind of data integration where integration problems such as inconsistency and uncertainty are handled by means of a probabilistic data representation. The approach is based on the view that data quality problems (as they occur in an integration process) can be modeled as uncertainty (van Keulen, 2012), and this uncertainty is considered an important result of the integration process (Magnani and Montesi, 2010).

The PDI process contains two phases (see Fig. 1): (i) a quick partial integration where certain data quality problems are not solved immediately, but explicitly represented as uncertainty in the resulting integrated data stored in a probabilistic database; (ii) continuous improvement by using the data – a probabilistic database can be queried directly resulting in possible or approximate answers (Dalvi et al., 2009) – and gathering evidence (e.g., user feedback) for improving the data quality.

A *probabilistic database* is a specific kind of DBMS that allows storage, querying, and manipulation of uncertain data. It keeps track of alternatives and the dependencies among them.

Overview

This chapter explains a special kind of data integration approach, called Probabilistic Data Integration. We first define the concept as well as the related notion of a Probabilistic Database. After presenting an illustrative example that is used

Probabilistic Data Integration, Fig. 1 Probabilistic data integration process (van Keulen and de Keijzer, 2009)

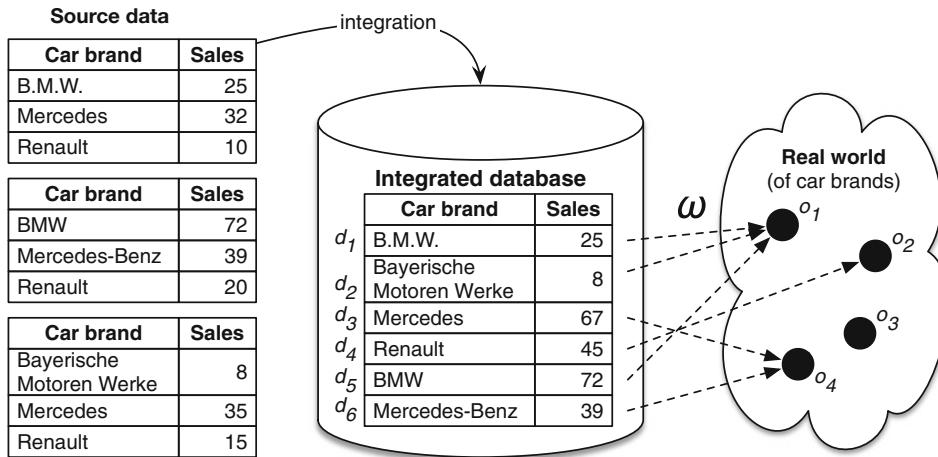

throughout the chapter, a motivation for the PDI approach is given based on its strengths in dealing with the main problems in data integration.

The technical part of this chapter first addresses the notion of a probabilistic database capable of storing and querying probabilistic representations, and then explains which probabilistic representations can be used for various data integration problems. We conclude with example applications and future developments.

Example

As a running example taken from van Keulen (2012), imagine a manufacturer of car parts supplying major car brands. For a preferred customer program (preferred customer defined as one with sales over 100) meant to avoid loosing important customers to competitors, data of three production sites needs to be integrated.

Figure 2 shows an example data integration result and a part of the real world it is supposed to represent. Observe that at first glance there is no preferred customer due to *semantic duplicates*: The “same” car brand occurs more than once

Probabilistic Data Integration, Fig. 2 An uncareful data integration leading to a database with semantic duplicates

under different names because of different conventions. Importantly, data items d_3 and d_6 refer to the same car brand, and their combined sales is 106, so “Mercedes-Benz” should be a preferred customer.

Typical data-cleaning solutions support duplicate removal that merges data items when they likely refer to the same real-world object, such as d_1 and d_5 merged into a new data item d_{15} ; $d_3, d_6 \mapsto d_{36}$ analogously. But, it is quite possible that an algorithm would not detect that also d_2 refers to “BMW.” Note that this seemingly small technical glitch has a profound business consequence: it determines whether “BMW” is considered a preferred customer or not, risking loosing it to a competitor.

What do we as humans do if we suspect that “BMW” stands for “Bayerische Motoren Werke”? *We are in doubt.* Consequently, humans simply consider both cases, reason that “BMW” *might* be a preferred customer and act on it if we decide that it is important and likely enough. It is this behavior of “doubting” and “probability and risk assessment” that probabilistic data integration is attempting to mimic.

Motivation

“Data integration involves *combining* data residing in different *sources* and providing users

with a *unified view* of them” (Lenzerini, 2002). Applications where uncertainty is unavoidable especially call for a probabilistic approach as the highlighted terms in the definition illustrate:

- It may be hard to extract information from certain kinds of sources (e.g., natural language, websites).
- Information in a source may be missing, of bad quality, or its meaning is unclear.
- It may be unclear which data items in the sources should be combined.
- Sources may be inconsistent complicating a unified view.

Typically, data integration is an iterative process where mistakes are discovered and repaired, analyses are repeated, and new mistakes are discovered... Still, we demand from data scientists that they act responsibly, i.e., they should know and tell us about the deficiencies in integrated data and analytical results.

Compared to traditional data integration, probabilistic data integration allows:

- postponement of solving data integration problems, hence, provides an initial integration result much earlier;
- better balancing of trade-off between development effort and resulting data quality;

- an iterative integration process with smaller steps (Wanders et al., 2015);
- leveraging human attention based on feedback; and
- more robustness being less sensitive to wrong settings of thresholds and wrong actions of rules (van Keulen and de Keijzer, 2009).

Probabilistic Databases

Probabilistic data integration hinges on the capability to readily store and query a voluminous probabilistic integration result as provided by a probabilistic database. The two main challenges of a probabilistic database is that it needs both to *scale* to large data volumes and also to do *probabilistic inference* (Dalvi et al., 2009).

The formal semantics is based on *possible worlds*. In its most general form, a probabilistic database is a probability space over the possible contents of the database. Assuming a single table, let I be a set of tuples (records) representing that table. A probabilistic database is a discrete probability space $PDB = (W, P)$, where $W = \{I_1, I_2, \dots, I_n\}$ is a set of possible instances, called possible worlds, and $P : W \rightarrow [0, 1]$ is such that $(\sum_{j=1..n} P(I_j)) = 1$.

In practice, one can never enumerate all possible worlds; instead a more concise representation is needed. Many representation formalisms have been proposed differing a.o. in expressiveness (see Panse 2015, Chp.3 for a thorough overview).

Figure 3 shows a probabilistic integration result of our running example of Fig. 2 where possible duplicates are probabilistically merged; see section ‘Record Level’. The used representation formalism is based on U-relations (Antova et al., 2008), which allows for dependencies between tuples, for example, tuples d_3 and d_6 (top left in Fig. 3) both exist together or are both absent.

Relational probabilistic database systems that, to a certain degree, have outgrown the laboratory bench include MayBMS (Koch, 2009; Antova et al., 2009), Trio (Widom, 2004), and MCDB (Jampani et al., 2008). MayBMS and Trio focus on tuple-level uncertainty where probabilities

are attached to tuples, while MCDB focuses on attribute-level uncertainty where a probabilistic value generator function captures the possible values for the attribute.

Besides probabilistic relational databases, probabilistic versions of other data models and associated query languages can be defined by attaching a probabilistic ‘sentence’ to data items and incorporating probabilistic inference in the semantics of the query language that adheres to the possible worlds semantics (Wanders and van Keulen, 2015). For example, several probabilistic XML (Abiteboul et al., 2009; van Keulen and de Keijzer, 2009) and probabilistic logic formalisms have been defined (Fuhr, 2000; Wanders et al., 2016; De Raedt and Kimmig, 2015).

Probabilistic Data Integration

In essence probabilistic data integration is about finding probabilistic representations for data integration problems. These are discussed on three levels: attribute value, record, and schema level.

Value Level

Inconsistency and ambiguity Integrated sources may not agree on the values of certain attributes, or it is otherwise unknown which values are correct. Some examples: text parsing may be ambiguous: in splitting my own full name ‘Maurice Van Keulen,’ is the ‘Van’ part of my first name or my last name? Differences in conventions: one source may use first name-last name (as customary in the West) and another last name-first name (as customary in China). Information extraction: is a phrase a named entity of a certain type or not?

In the formalism of the previous section, this is represented as:

	Firstname	Lastname	
d_1^a	Maurice	Keulen	$(r_4 \mapsto 0)$
d_1^b	Maurice	Van Keulen	$(r_4 \mapsto 1)$
d_2^a	Zhang	Li	$(r_5 \mapsto 0)$
d_2^b	Li	Zhang	$(r_5 \mapsto 1)$
d_3	Paris	Hilton	$(r_6 \mapsto 0)$

Probabilistic Data Integration, Fig. 3

Example of a probabilistic database (resulting from indeterministic deduplication of Fig. 2) with a typical query and its answer (Taken from van Keulen 2012)

PDB		Worlds	
car	sales	rva	P
d_1	25	$(r_1 \mapsto 0)$	$(r_1 \mapsto 0) 0.1$ ‘ d_1, d_2, d_5 different’
d_2	8	$(r_1 \mapsto 0)$	$(r_1 \mapsto 1) 0.6$ ‘ d_1, d_5 same’
d_5	72	$(r_1 \mapsto 0)$	$(r_1 \mapsto 2) 0.3$ ‘ d_1, d_2, d_5 same’
d_{15}	97	$(r_1 \mapsto 1)$	$(r_2 \mapsto 0) 0.2$ ‘ d_3, d_6 different’
d_2	8	$(r_1 \mapsto 1)$	$(r_2 \mapsto 1) 0.8$ ‘ d_3, d_6 same’
d_{125}	105	$(r_1 \mapsto 2)$	
d_4	45		$Q = \text{SELECT SUM(sales)}$
d_3	67	$(r_2 \mapsto 0)$	FROM carsales
d_6	39	$(r_2 \mapsto 0)$	WHERE sales ≥ 100
d_{36}	106	$(r_2 \mapsto 1)$	‘sales of preferred customers’

All possible worlds with their answer to Q

World descr.	World	Probability	Q
I_1 $(r_1 \mapsto 0), (r_2 \mapsto 0)$	$\{d_1, d_2, d_3, d_4, d_5, d_6\}$	$0.1 \cdot 0.2 = 0.02$	0
I_2 $(r_1 \mapsto 1), (r_2 \mapsto 0)$	$\{d_{15}, d_2, d_3, d_4, d_6\}$	$0.6 \cdot 0.2 = 0.12$	0
I_3 $(r_1 \mapsto 2), (r_2 \mapsto 0)$	$\{d_{125}, d_3, d_4, d_6\}$	$0.3 \cdot 0.2 = 0.06$	105
I_4 $(r_1 \mapsto 0), (r_2 \mapsto 1)$	$\{d_1, d_2, d_{36}, d_4, d_5\}$	$0.1 \cdot 0.8 = 0.08$	106
I_5 $(r_1 \mapsto 1), (r_2 \mapsto 1)$	$\{d_{15}, d_2, d_{36}, d_4\}$	$0.6 \cdot 0.8 = 0.48$	106
I_6 $(r_1 \mapsto 2), (r_2 \mapsto 1)$	$\{d_{125}, d_{36}, d_4\}$	$0.3 \cdot 0.8 = 0.24$	211

where r_i ($i \in \{4, 5, 6\}$) govern the uncertainty which names are correct or preferred.

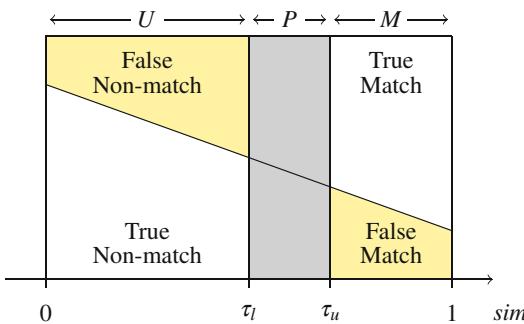

Data imputation A common approach to dealing with missing values is data imputation, i.e., using a most likely value and/or a value that retains certain statistical properties of the data set. Especially for categorical attributes, imputing with a wrong value can have grave consequences. In general, an imputation method is a classifier that predicts a most suitable value based on the other values in the record or data set. A classifier can easily not only predict one value but several possible ones each with an associated probability of suitability. By representing the uncertainty around the missing value probabilistically, the result is more informative and is more robust against imperfect imputations.

Record Level

Semantic duplicates, entity resolution

A semantic duplicate is almost never detected with absolute certainty unless both records are identical. Therefore, there is a gray area of record pairs that may or may not be semantic duplicates. Even if an *identifier* is present, in practice it may not be perfectly reliable. For example, it has once been reported in the UK that there were 81 million National Insurance numbers but only 60 million eligible citizens.

Traditional approaches for deduplication are based on pairwise tuple comparisons. Pairs are classified into *matching* (M) and *unmatching* (U) based on similarity, then clustered by transitivity, and, finally, merged by cluster. The latter may require solving inconsistencies (Naumann and Herschel, 2010).

Probabilistic Data Integration, Fig. 4 Grey area in tuple matching (Taken from Panse et al. 2013)

In such approaches with an absolute decision for tuples being duplicates or not, many realistic possibilities may be ignored leading to errors in the data. Instead, a probabilistic database can directly store an indeterministic deduplication result (Panse et al., 2013). In this way, all significantly likely duplicate mergings find their way into the database, and any query answer or other derived data will reflect the inherent uncertainty.

Indeterministic deduplication deviates as follows (Panse et al., 2013). Instead of M and U , a portion of tuple pairs are now classified into a third set P of *possible matches* based on two thresholds (see Fig. 4). For pairs in this *gray area*, both cases are considered: a match or not. Duplicate clustering now forms clusters for $M \cup U$ (in Fig. 2, there are 3 clusters: $\{d_1, d_2, d_5\}$, $\{d_4\}$, $\{d_3, d_6\}\}$. For each cluster, the possible worlds are determined, e.g., d_1, d_2, d_5 all different, d_1, d_5 the same and d_2 different, or d_1, d_2, d_5 all the same. To represent the probabilistic end result, a random variable is introduced for each cluster with as many values as possible worlds for that cluster, and merged and unmerged versions of the tuples are added according to the situation in the world. Figure 3 shows the end result.

A related problem is that of entity resolution (Naumann and Herschel, 2010). The goal of data integration is often to bring together data on the same real-world entities from different sources.

In the absence of a usable identifier, this matching and merging of records from different sources is a similar problem.

Repairs Another record-level integration problem is when a resulting database state does not satisfy some constraints. Here the notion of a *database repair* is useful. A repair of an inconsistent database I is a database J that is consistent and “as close as possible” to I (Wijsen, 2005). Closeness is typically measured in terms of the number of “insert,” “delete,” and “update” operations needed to change I into J . A repair, however, is in general not unique. Typically, one resorts to *consistent query answering*: the intersection of answers to a query posed on all possible repairs within a certain closeness bound. But, although there is no known work to refer to, it is perfectly conceivable that these possible repairs can be represented with a probabilistic database state.

Grouping data While integrating grouping data also inconsistencies may occur. A grouping can be defined as a membership of elements within groups. When different sources contain a grouping for the same set of elements, two elements may be in the same group in one source and in different groups in the other. Wanders et al. (2015) describe such a scenario with groups of orthologous proteins which are expected to have the same function(s). Biological databases like Homologene, PIRSF, and eggNOG store results of determining orthology by means of different methods. An automatic (probabilistic!) combination of these sources may provide a continuously evolving unified view of combined scientific insight of higher quality than any single method could provide.

Schema Level

Probabilistic data integration has been mostly applied to instance-level data, but it can also be applied on schema level. For example, if two sources hold data on entity types T and T' , and

these seem similar or related, then a number of hypotheses may be drawn up:

- T could have exactly the same meaning as T' ,
- T could be a subtype of T' or vice versa, or
- T and T' partially overlap and have a common supertype.

But it may be uncertain which one is true. It may even be the case that a hypothesis may only be partially true, for example, with source tables “student” and “PhD student.” In most cases, a PhD student is a special kind of student, but in some countries such as the Netherlands, a PhD student is actually an employee of the university. Also employees from a company may pursue a PhD. In short, not all tuples of table “PhD student” should be integrated into “student.” This also illustrates how this schema-level problem may be transformed into a record-level problem: a representation can be constructed where all tuples of a type probabilistically exist in a corresponding table. The uncertainty about two attributes being “the same” is an analogous problem.

Data Cleaning

Probabilistic data allows new kinds of cleaning approaches. High quality can be defined as a high probability for correct data and low probability for incorrect data. Therefore, cleaning approaches can be roughly categorized into uncertainty reducing and uncertainty increasing.

Uncertainty Reduction: Evidence If due to some evidence from analysis, reasoning, constraints, or feedback, it becomes apparent that some cases are definitely (not) true, then uncertainty may be removed from the database. For example, if in Fig. 3 feedback is given from which it can be derived that d_3 and d_6 are for certain the same car brand, then in essence $P(r_2 \mapsto 0)$ becomes 0 and $P(r_2 \mapsto 1)$ becomes 1. Consequently, all tuples that need

$(r_2 \mapsto 0)$ to be true to exist can be deleted (d_3 and d_6). Furthermore, random variable r_2 can be abolished, and the term $(r_2 \mapsto 1)$ can be removed from all probabilistic sentences. It effectively removes all possible worlds that contradict with the evidence. van Keulen and de Keijzer (2009) have shown that this form of cleaning may quickly and steadily improve quality of a probabilistic integration result.

If such evidence cannot be taken as absolutely reliable, hence cannot justify the cleaning actions above, the actual cleaning becomes a matter of massaging of the probabilities. For example, $P(r_2 \mapsto 1)$ may be increased only a little bit. In this approach, a probability threshold may be introduced above which the abovedescribed random variable removal is executed. As evidence accumulates, this approach converges to a certain correct database state as well, so data quality improvement is only slowed down provided that the evidence is for a large part correct.

Uncertainty Increase: Casting Doubt Perhaps counterintuitive, but increasing uncertainty may improve data quality, hence could be an approach for cleaning. For example, if due to some evidence it becomes unlikely that a certain tuple is correct, a random variable may be introduced, and possible repairs for tuples may be inserted. In effect, we are casting doubt on the data and insert what seems more likely. Consequently the uncertainty increases, but the overall quality may increase, because the probability mass associated with incorrect data decreases and the probability mass for correct data increases (assuming the evidence is largely correct).

Measuring uncertainty and quality The above illustrates that uncertainty and quality are orthogonal notions. Uncertainty is usually measured by means of entropy. Quality measures for probabilistic data are introduced by (van Keulen and de Keijzer, 2009): expected precision and expected recall. These notions are based on the intuition that the quality of a correct query answer is better if the system dares to claim that it is correct with a higher probability.

Example Applications

A notable application of probabilistic data integration is the *METIS* system, “an industrial prototype system for supporting real-time, actionable maritime situational awareness” (Huijbrechts et al., 2015). It aims to support operational work in domains characterized by constantly evolving situations with a diversity of entities, complex interactions, and uncertainty in the information gathered. It includes natural language processing of heterogeneous (un)structured data and probabilistic reasoning of uncertain information. METIS can be seen as an open-source intelligence (OSINT) application.

Another notable and concrete example of an existing system is *MCDB-R* (Arumugam et al., 2010). It allows risk assessment queries directly on the database. Risk assessment typically corresponds to computing interesting properties of the upper or lower tails of a query result distribution, for example, computing the probability of a large investment loss.

Probabilistic data integration is in particular suited for applications where much imperfection can be expected but where a quick-and-dirty integration and cleaning approach is likely to be sufficient. It has the potential of drastically lowering the time and effort needed for integration and cleaning, which can be considerable since “analysts report spending upwards of 80% of their time on problems in data cleaning” (Haas et al., 2015).

Other application areas include:

- Machine learning and data mining: since probabilistically integrated data has a higher information content than “data with errors,” it is expected that models of higher quality will be produced if probabilistic data is used as training data.
- Information extraction from natural language: since natural language is inherently ambiguous, it seems quite natural to represent the result of information extraction as probabilistic data.
- Web harvesting: websites are designed for use by humans. A probabilistic approach may lead

to more robust navigation. Subtasks like finding search results (Trieschnigg et al., 2012) or finding target fields (Jundt and van Keulen, 2013) are typically based on ranking “possible actions.” By executing not only one but a top- k of possible actions and representing resulting data probabilistically, consequences of imperfect ranking are reduced.

Future Developments

Probabilistic data integration depends on scalable probabilistic database technology. An important direction of future research is the development of probabilistic database systems and improving their scalability and functionality. Furthermore, future research is needed that compare the effectiveness of probabilistic data integration vs. non-probabilistic data integration approaches for real-world use cases.

Process Model Repair

Abel Armas Cervantes

University of Melbourne, Melbourne, VIC,
Australia

Definitions

In the context of Process Mining, Process model repair is a model enhancement operation for reconciling a set of existing differences between an event log and a model. The aim of this operation is to reconcile the set of differences while preserving, as much as possible, the resemblance between the original and the repaired model.

Overview

Business processes are core assets in modern organizations. Oftentimes they are captured as models to ease their understanding for the involved participants and enable the identification and prevention of issues that could arise during their execution. In addition to their descriptive nature, process models can be also prescriptive since they can be used to automate the process executions. Thus, it is crucial that process models stay up to date and reflect the intended behavior.

Modern information systems supporting business processes can maintain detailed data about the executions of such processes. This data can be extracted as event logs, where every execution of a process is recorded as a trace, i.e., as a sequence of activity occurrences, a.k.a. *events*. While models describe or prescribe the expected behavior of a process, event logs capture the observed behavior. Thus, it can contain both positive deviations, e.g., work-arounds implemented by the participants of the process to improve process performance, and negative deviations, e.g., violations of compliance rules.

Conformance checking, one of the three main operations in process mining, compares the expected versus the observed behavior. A conformance checker takes a log and a model as input,

computes the best alignment between the behavior they represent, and, as output, spells out the differences between them. There exist exact and approximate conformance checking techniques, and they can be broadly categorized depending on the execution semantics they adopt (interleaving or true concurrency) or the type of feedback they generate (low-level or high-level feedback). The differences detected between a model and a log can be used to identify violations that should be corrected or work-arounds with a positive impact in the process performance that should be integrated into the model. A more extensive explanation about conformance checking can be found in the previous chapter.

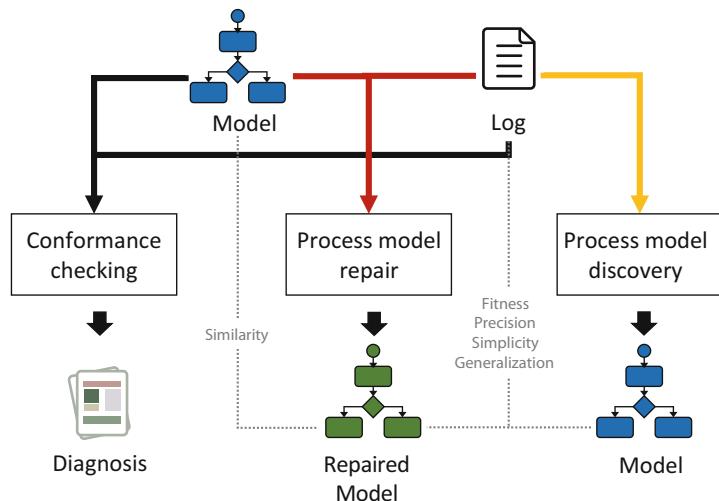

Process model repair, a type of *enhancement*, is another operation in process mining, which consists on modifying the model to better reflect reality, such that the performed modifications reconcile existing differences between the expected (model) and the observed behavior (log). Thus, process model repair can be seen as a step forward after the detection of differences via a conformance checker. Given the organic nature of organizations, as well as continuous changes that are external to the company, process model repair provides a way for maintaining models up to date and true to the processes they represent. Note, however, that the majority of the existing techniques have focused their attention on repairing control-flow problems, while little attention has been devoted to problems related to other aspects of the process, e.g., resources. This entry presents existing process model repair techniques and discusses existing challenges.

Process Model Repair in Context

Process model repair sits in-between two process mining operations: process model discovery and conformance checking, cf. Fig. 1. On the one hand, discovery techniques use the information captured in an event log for creating a process model from scratch. On the other hand, repair techniques take a (current) model as a baseline for the creation of a new version of such model that reconciles differences between the current

Process Model Repair,

Fig. 1 Process model repair, conformance checking, and process discovery

model and a log. In both operations, discovery and repair, there is a common point of reference for measuring the quality of the resulting model, its similarity with respect to the log. In order to assess the similarity between a model and a log, four main quality measures have been proposed: fitness, precision, simplicity, and generalization (see Buijs et al. 2012 and van der Aalst 2011 for more details about these measures).

The reasons to repair a model, instead of discovering a brand new one, can be manyfold: the model can provide additional insights into the process, is normative, or is used as a reference model. Thus, while the repair operation modifies the behavior of a baseline model, the repaired version has to resemble as much as possible the baseline model. Then, the structural similarity between the repaired and the baseline model has been taken into account as another way to assess the quality of a repair. The structural similarity between process models has been widely studied in the literature, for instance, Dijkman et al. (2011, 2009) present different strategies for the computation of the similarity between models based on graph edit distance.

Process model repair is a multi-perspective operation which considers the different aspects mentioned above: fitness, precision, generalization, simplicity, and similarity. As discussed later in the chapter, some techniques have devoted their attention to maximize exclusively fitness at

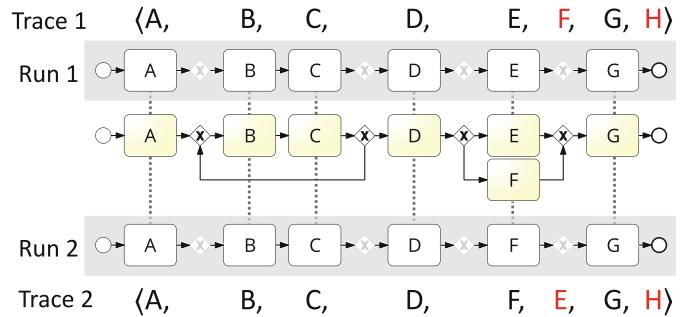

the cost of a negative impact in precision, while others have defined a set of repair patterns that aim at coping with the negative impact in precision of the repair at a cost of requiring human intervention.

Fitness-Based Repair

Fitness has been one of the main drivers for guiding the repair of a model. Intuitively, fitness measures the amount of behavior captured in a log that can be replayed by a given model; thus a model has perfect fitness iff it can replay every trace in the log. In the context of repair, given a model and a log, such that there exist some differences between them, a fitness-based repair modifies the model in such a way that it reconciles the existing differences and every trace can be replied in the resulting model.

The first process model repair technique given an event log was presented in Fahland and van der Aalst (2015). It is a fitness-based approach and uses three types of repair operations over the model: subprocess insertion, skip insertion, and cycle removal. This technique is divided into three steps; first an alignment between the observed and the expected behavior is computed. This alignment consists of finding for each trace in the log the most similar run of the process model, where the similarity is

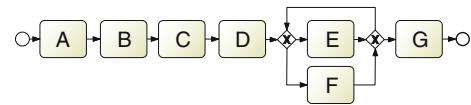

Process Model Repair,
Fig. 2 Alignment between
the behavior of a model
and a log

measured in terms of the events that can occur at the same execution state in both the trace and the run. This alignment is computed by a conformance checker. The second step finds the parts of the log that cannot be replayed by the model and gathers them into sub-logs. Finally, a model is discovered from each of the created sub-logs, which are then inserted into the original model. The repaired model has a perfect fitness and thus can fully replay the log.

Consider the example shown in Fig. 2 and a log with two traces: $\{\langle A, B, C, D, E, F, G, H \rangle, \langle A, B, C, D, F, E, G, H \rangle\}$, the central part of the picture depicts a process model in BPMN notation and its two possible *runs* (shaded areas), while the outer part displays the traces in the log *aligned* with the behavior of the model. The aligned traces show that in **Trace 1**, events *F* and *H* could not be matched with any activity occurrence in **Run 1**, whereas in **Trace 2**, events *E* and *H* could not be matched with any activity occurrence in **Run 2**. The repaired model produced by the technique in Fahland and van der Aalst (2015) is shown in Fig. 3. Observe that, in the repaired model, activities *B* and *C* cannot be repeated and activities *E* and *F* can occur any number of times one after the other.

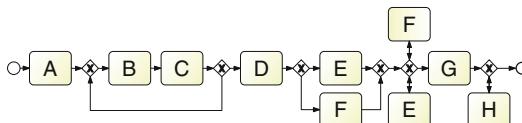

Dees et al. (2017) refine the technique presented in Fahland and van der Aalst (2015) by considering key performance indicators (KPI) when repairing the model. Prior the repair takes place, Dees et al. (2017) filter out the parts of the log that should be considered according to some specific KPI goals. Once the relevant parts of the log have been selected, the repair technique presented in Fahland and van der Aalst (2015) is

Process Model Repair, Fig. 3 Repaired process model by Fahland and van der Aalst (2015)

applied. The approach presented in Dees et al. (2017) is the first effort to integrate additional information to control-flow data while repairing a model.

Polyvyanyy et al. (2016) present a repair approach that detects the tasks that have to be inserted or deleted from the model in order to maximize fitness. The authors acknowledge the importance of other metrics in addition to fitness, though the identification of techniques to improve on such metrics during repair is left to future work. During the repair, this technique uses only two operations to modify the model: insertion of new tasks in a self-loop and creation of new paths for skipping a single task. In order to control the type of changes that can be performed over the model, this approach allows users to assign costs to the repair operations applied over specific events and, additionally, to specify the budget for the overall repair of the model. Thus, a model is repaired in such a way that it maximizes fitness, but the sum of the cost of all the operations over the events does not exceed the specified budget. The first step during the repair is to compute the alignment between the behavior of the model and the behavior of the log, and then finding the operations to be applied over the model. The repaired version of the running example (Fig. 2) by the technique in Polyvyanyy et al. (2016) is shown in Fig. 4.

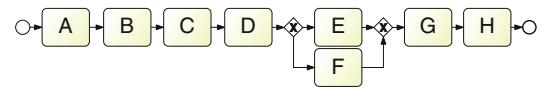

Process Model Repair, Fig. 4 Repaired process model by Polyvanyy et al. (2016)

Observe that the changes performed by the approaches above have a positive impact on fitness and on the similarity with the original model; however they affect other aspects. Specifically, the models in Figs. 3 and 4 contain additional behavior that is neither allowed in the original model nor observed in or implied by the log, which affects negatively the precision of the model. For example, in both repaired models, tasks *E* and *F* can be repeated any number of times, and similarly for task *H* in Fig. 4, however, the log does not contain any repetition of any task.

Generalized Repair

The approaches mentioned in the previous section have devoted their attention to the modification of the model while taking the fitness as the main driver. However, the choice of maximizing fitness in the repaired model comes with the assumption that all the observed behavior in the log is desired and shall be integrated into the model (positive deviances). The last is not always true since a log can be noisy, that is, it can contain undesired behavior or lack of relevant behavior that was not captured in the log (e.g., it can contain incomplete traces). In this context, Rogge-Solti et al. (2016) proposed a generalized conformance checking framework that combines three operations: conformance checking, process model repair, and inconsistency detection in the log.

The generalized conformance checking framework puts forward the idea of automatically repairing both the log and the model in one goal. The repaired log and model are as close as possible to those given as input, are fully fitting between them (i.e., the log has perfect fitness with the model), and are repaired according to

Process Model Repair, Fig. 5 Repaired process model by Rogge-Solti et al. (2016)

some levels of trust assigned to the model and the log given as input. The full trust in either the model or the log defines the ends of a spectrum. Specifically, if the log is fully trusted and not the model, then a process model discovery technique is applied, whereas, if the model is fully trusted and not the log, then a log is created by simulating the model.

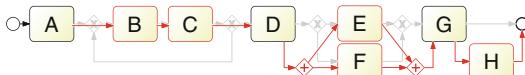

As an example, Fig. 5 displays the model – with the log $\{\langle A, B, C, D, E, G, H \rangle, \langle A, B, C, D, F, G, H \rangle\}$ – generated by the current implementation of the generalized conformance checking framework given the model and log in Fig. 2, and trust = ~ 0.5 for both, model and log.

Note that this technique does not seek to reconcile all the differences detected with respect to the log, as observed in the example above, but instead aims at integrating only the changes that lead to a model, similar to the original model, that respects the defined trust values.

P

Interactive and Incremental Repair

Different to the techniques presented so far, Armas Cervantes et al. (2017) introduce an alternative approach, which is interactive and incremental and that aims at supporting the users during the reconciliation of differences. The foundation of this approach is the visualization of the differences detected by a conformance checker, which offers a suggestion on how to reconcile an existing difference. The conformance checker used in this approach is the one presented in García-Bañuelos et al. (2015); it adopts true concurrency semantics – thus it is able to find differences involving concurrency – and explains the differences using predefined behavioral patterns. The differences detected by this conformance checker are then explained to the user by contrasting the behavior occurring in the log but not in the model

Process Model Repair, Fig. 6 Interactive and incremental repair: visualization of the differences

and vice versa. For instance, given the model and the log in Fig. 2, the conformance checker can diagnose that *In the model, the tasks E and F are mutually exclusive, while in the log they occur in parallel.*

The interactive and incremental repair translates every difference detected by the conformance checker into a graphical representation that suggest a way for reconciling such difference. Then, these visualizations are given to the users as recommendations on how to perform a repair. This approach gives the users full control on what and how to repair and does not make any assumption on how relevant certain differences can be for the users; instead, it ranks the detected differences according to the impact in the observed behavior. Specifically, a difference with high impact is the one involving highly frequent behavior in the log. Note that it is up to the user to decide what is the aspect they want to improve (fitness, precision, generalization, etc.) during the repair. Clearly, the user in charge of repairing of the model needs to have a deep understanding about the process, since the integration of negative deviances would be undesired.

Figure 6 shows the visualizations provided to the user for the running example depicted in Fig. 2. In this graphical representation, the elements in red have to be inserted or are those affected by the difference, whereas the elements in gray have to be deleted.

Future Directions

The presented techniques range from fully automatic approaches, where every difference between the model and the log is fixed, to interactive and incremental approaches, where the users ultimately choose what and how to apply a repair. A future direction is to explore options

for balancing automatic and manual operations, e.g., by considering compliance rules attached to the model. For instance, a difference could be automatically reconciled in the model iff the repair does not violate any of the given compliance rules; otherwise, the differences can be presented to the users, so that they can decide how to tackle the issue.

Another future direction, for both automatic and nonautomatic approaches, is to consider a balance of the various quality aspects (fitness, precision, generalization, simplicity, and similarity to the original model) during the repair. Finally, existing techniques can be extended by considering other data – such as KPIs as in Dees et al. (2017) or resources – in addition to control-flow information for repairing a model according to predefined business goals.

Definitions

Python programming language is an open-source, portable, high-level general-purpose programming language. It features an interpreter which provides interactive environment, dynamic-type system, as well as automatic memory management. Being object oriented in nature, it is widely used and provides a large and comprehensive library for real-world applications. Python 2 and Python 3 (<https://www.python.org/downloads/>) are two versions of Python interpreters being presently used. Python 3 is not back-compatible with Python 2, but it is gaining ground among developers and will ultimately replace Python 2 entirely. Python gained popularity among data scientist due to availability of easy-to-use libraries and ease of working with variety of file format in both local and remote locations.

High-Level Programming

Python is a general-purpose high-level programming language. It provides easy access to library (called *modules* here (<https://docs.python.org/3/py-modindex.html>)) functions for performing the low-level tasks. Python code is converted to byte code which in turn is interpreted byte by byte by the Python interpreter (<https://docs.python.org/3/tutorial/interpreter.html>). This makes the system portable as Python interpreter converts Python code (with few or no modifications) as per target processor on a target machine. The interpreter itself is quite configurable, which gives power to developer to customize the same as per project requirements.

Interactive Environment

Python interpreter provides two modes of operations: *shell mode* and *program mode*. In *shell*

mode, a REPL (Read-Evaluate-Print-Loops) is provided which:

- Reads a Python expression typed by a user.
- Evaluates Python expression.
- Prints out the return value after evaluation.
- Loops back and does it all over again.

REPL-based workflow is useful for interactive development in data science since it shortens the overall development time by providing facility for easier debugging. In addition to allowing quick and easy evaluation of Python statements, it also showcases a searchable history (press up and down keys) and tab completion, defining key bindings for ease of use and easy access to help documentation.

In *program mode*, one can define a Python program via a text editor of user's choice and run by simply invoking the Python interpreter and feeding the program file. A variety of IDE (Integrated Development Environments) provides rich feature of syntax highlighting and file management in this regard. IPython and IPython notebook environments also provide rich feature to teach Python effectively where code, textual and graphical contents, can be integrated within a single environment (a browser in the case of a notebook). Since many programming language kernels are now supported here, the name has been changed to Jupyter Notebook. This facility also provides easier way for teamwork where Jupyter Notebooks can be deployed on server to work collectively in an interactive manner.

Object-Oriented Programming

Most of small Python programs are procedural in nature, i.e., a set of procedures were defined to compute a problem, and flow of information was controlled within these procedures to obtain a desired output. On the other hand, larger Python programs are framed under an object-oriented programming (OOP) framework which deals with data as an object on which different

methods act, to produce a desired result. All computable entities are treated as an object whose nature is defined via functions called methods. A class of objects can be clubbed and defined together to create an environment similar to a physical one to define an easy to understand correspondence to real-life situations. This is critical for data science because different data can be treated as different objects as per requirements which give flexibility as well as intuitive understanding of physical features represented by the data.

Multipurpose

OOP-based architecture and open-source nature of Python enabled developers from a variety of domains and enriched Python ecosystem with their fields of expertise. One can define a module (a set of classes) specific for different domains of studies. Some of them are mentioned in Table 1.

Big data workflow usually employs modules related to networking, database management, machine learning, statistics, plotting, as well as making GUI for final products. The Pandas module (<https://pandas.pydata.org/>) is used extensively by Big Data community in general as an alternative to R. Python provides a good option for such a workflow which can be stitched together with ease.

Extensible

Instead of providing all functionalities in core Python program, it was designed to be extensible, i.e., user can choose to have functionality as per requirements. For example, if somebody needs to work on statistical problems, then one can simply use that particular module, ignoring others!

Python programs can be easily embedded in programs written in programming languages like Julia, C, C++, R, etc. On the other hand, other programming language codes can also be embedded into Python. For example, the modules cython and jython are used to embed C and Java codes. This has enabled the use of a lot of legacy code written in other languages and already optimized for speed and stability. This

Python, Table 1 List of areas and corresponding Python modules

Field of study	Name of Python module
Scientific computation	scipy, numpy, sympy
Networking	networkx
Cryptography	pyOpenSSL
Game development	PyGame
Graphic user interface (GUI)	pyQT
Mobile app	kivy
Machine learning	scikit-learn, tensorflow
Statistics	pandas
Image processing	scikit-image
Plotting	Matplotlib
Database	SQLAlchemy
HTML and XML parsing	BeautifulSoup
Natural language processing	nltk
Testing	nose

avoids replication of efforts and increases productivity of an organization tremendously. This is critical for a data scientist since legacy codes in tools like R and C/C++ have already been optimized and hence need not be rewritten. Python can compete both as a stand-alone option and the one where other packages can be embedded in the overall workflow (Louridas and Ebert, 2013).

Minimalistic

Minimalistic design philosophy emphasizes code *readability* as a priority for language design. It provides a syntax structure that allows programmers to express concepts in fewer lines of code compared with other high-level languages. Python features a dynamic-type system where Python interpreter guesses the *type* of an object by its definition, which avoids a user's need to define the same explicitly. Indentations are used to define a block of statements for loops and functions instead of enclosing them in braces like in C/C++. Writing loops and functions is intuitive in nature. These results accelerated pace of development and ease of understanding. Some example below can highlight these features. If one wishes to print a string "Hello World," then one simply writes a Python expression as:

```
>>>print ("Hello World")
```

Even looping over a set of numbers can be written quite intuitively. For example, generating square roots of first ten numbers can simply be defined as:

```
1 >>>import numpy as np
2 >>>num = np.arange(1:11)
3 >>>for i in num:
4     answer=np.sqrt(num)
5     print (answer)
```

Data science needs such a design to define complex problems in an easier manner. Also different parts of a problem can be designed with different team members which can be stitched together within a single Python code. Minimalistic design feature enabled fewer lines of codes and hence easier understanding.

P

Data Types

Python provides a rich ecosystem of data types as shown in Table 2. Note that some data structures are defined in core Python program, whereas others are defined in modules, and hence they can be accessed by adding module name succeeded by a dot operator. Big data applications need ability to define classes of objects with flexible and easier definitions and operations. Table 2 lists some such objects which are used frequently.

Python, Table 2 List of areas and corresponding Python modules

Data type	Features
Integers	<code>int()</code>
Floating point numbers	<code>float()</code>
Complex numbers	<code>complex(a,b)</code> or <code>a+jb</code>
Immutable list = Tuple	<code>tuple()</code>
Heterogeneous list	<code>list()</code>
Array of numbers	<code>numpy.ndarray()</code>
Sets	<code>set()</code>
Key-value pairs	<code>dict()</code>
1D tabular data	<code>pandas.Series()</code>
Multidimensional tabular data	<code>pandas.DataFrame()</code>
Tensors	<code>tensorflow.Tensor()</code>

User-defined data structures can be defined using `Class` object definition and defining associated methods which imply associated properties. The ability to do so with ease is one of the major forces behind widespread utility of Python for big data applications.

Summary

Python is among the world's most preferred language among developers due to its open-source, flexible, portable, and user-friendly architecture. It is used by school students (Elkner, 2000; Grandell et al., 2006) as well as computer scientists for both simple and complex calculations (<https://ganga.web.cern.ch/ganga/>) with equal ease of effort to define a problem (Blank et al., 2004). With ever-increasing rich library of modules, it will continue to dominate the computing world in the near future too. Big data analytics community has embraced Python (Cielen et al., 2016; McKinney, 2012) for ease of

use and extensible nature as well as other features defined above.

Query Optimization Challenges for SQL-on-Hadoop

Mohamed A. Soliman
Datometry Inc., San Francisco, CA, USA

Definitions

In database management systems, the query optimizer is the component responsible for mapping an input query to the most efficient mechanism of executing the query, called query execution plan. Query execution is a resource-intensive operation that consumes memory, I/O, and network bandwidth resources of the underlying database management system. Query optimizer builds a space of plan alternatives capturing the different ways of executing an input query, such as different orderings of joins among the tables referenced by the query. Each plan alternative is assessed using a cost model that computes a cost estimate reflecting a prediction of the plan's wall clock running time. The optimizer picks the most efficient execution plan according to such cost estimates.

Overview

The job of a query optimizer is to turn a user query into an efficient query execution plan. The optimizer typically generates the execution plan by considering a large space of possible alternative plans and assigning an estimated cost to each alternative in order to pick the cheapest one. The art of query optimization is a combination of technically challenging problems (e.g., plan enumeration, cost estimation, statistics derivation, property enforcement, and join ordering); some of them are known to be NP-hard.

Query optimizer is one of the most performance-sensitive components in a database system. Differences in query plans may result in several orders of magnitude of difference in query performance, significantly more than any other contributing factor. Big data has triggered a renewed interest in query optimization techniques as a set of principled methods that could, when combined with scalable hardware resources and robust execution engines, make analyzing and processing petabytes of data finally possible. The increased amounts of data that need to be processed in today's world stress on the importance of building an intelligent query optimizer at the core of any query engine.

The impact of having a good optimizer on query performance is known to be substantial. The extensive research done by the database community in query optimization over the past decades provides a plethora of techniques that

can be leveraged and adopted in multiple big data processing environments such as Hadoop and the Cloud.

This article presents a number of query optimization research problems and technical challenges. The architectures of example big data query optimizers are described. The main similarities and differences of discussed optimizers are highlighted, and the technical problems tackled by each optimizer are illustrated.

Technical Challenges

Building a query optimizer is not an easy undertaking. It takes years of hard work to put together an industry-grade query optimizer that can be relied on in production settings. The amount of work devoted to the design and implementation of a new query optimizer is usually a considerable share of the effort needed to build a data management platform. This section gives an overview of some of the technical challenges involved in the design of query optimizers in big data query engines.

Modular Design

Building query optimizer as a complex monolithic software component does not allow adapting the optimizer design to the changing processing environments of big data. New data formats, storage structures, and query execution techniques are being constantly adopted in big data domains. The optimizer design needs to be modular to be easily pluggable in such evolving data management platforms. A crucial interface to query optimization engine is metadata acquisition. The optimizer makes extensive use of metadata (e.g., table/index definitions, statistical summaries such as histograms, and synopses) during plan enumeration, transformation rules, cardinality derivation, and cost computation. Using a highly extensible abstraction of metadata and system capabilities is important to allow query optimizer to deal with new data types and processing engine characteristics. Designing the optimizer's cardinality and cost models as pluggable components is important to allow

extending the optimizer with new advanced statistical models and cost estimation techniques.

Extensibility

Having all elements of a query and its optimizations as first-class citizens impacts optimizer architectures to a great extent. When an optimizer is designed based on a strict set of optimizations and query elements, adding new optimizations becomes technically hard. This often leads to resorting to multiple optimization phases, where the decisions made in earlier phases are revisited in later phases.

One example of new requirements that were triggered by big data processing environments is data distribution. In big data environments, scalability is realized by distributing data across many machines in a computing cluster. Optimizers ported from older database systems, or the ones that adopted older designs, typically handle data distribution by adding a plan parallelization phase, where data distribution is considered after the fact when some optimization decisions have been already made.

Multiphase optimizer design impacts the quality of final query plan since the available information does not impact all optimizer's decisions. Multiphase optimizers are notoriously difficult to extend as new optimizations or query constructs often do not match the predefined phase boundaries.

Addressing this challenge by abstracting query elements, data properties, and query optimizations as first-class constructs that optimizer treats similarly can avoid the problems of multiphase optimization where certain constructs are dealt with as an afterthought.

Exploiting Multi-core Architectures

Query optimization is probably the most CPU-intensive operation that a query engine performs. The space of query plan alternatives is combinatorial by definition. There are pressing needs for efficient exploration and pruning of the plan space in order to produce high-quality execution plans. Exploiting multi-core architectures allows optimizers to scale. By dividing the optimization

tasks into a set of work units, using multiple CPU cores for query optimization becomes possible.

A crucial challenge in this respect is formulating and capturing dependencies among optimizer's work units and designing a work unit scheduler that assigns optimization tasks to processing cores and efficiently gathers the computation results of these units to generate the optimization plan space.

Testing Optimizer Accuracy

Evaluating the accuracy of query optimizers objectively is a difficult problem. Benchmarks developed for assessing the query performance test the system as a whole end to end. However, no benchmarks are currently available to test a query optimizer in isolation. Being able to compare the accuracy of optimizers across different products independently is highly desirable.

The most performance-critical element in a cost-based optimizer is probably the accuracy of its cost model as it determines how to prune inferior plan alternatives. Typically, the cost units used in the cost model and displayed with the final plan do not reflect the anticipated wall clock time but are used only for comparison of alternative plans pertaining to the same input query. Comparing this cost value with the actual execution time does not give definitive conclusions about the accuracy of the cost model.

Optimization results are highly system-specific and therefore defy the standard testing approach where results are compared to a reference or baseline to check if the optimizer finds the “correct” solution. The optimal query plan for System A may widely differ from that for System B because of implementation differences in the query executors and the optimizers. These differences can lead to choosing radically different plans. Building a testing infrastructure for evaluating query optimizers is an important research problem.

Examples of Query Optimizers in Big Data Environments

This section presents example optimizers that are effectively used in production settings in different

big data management platforms. The main design principles behind these optimizers are given. The technical challenges in the previous section are also discussed in the context of each optimizer.

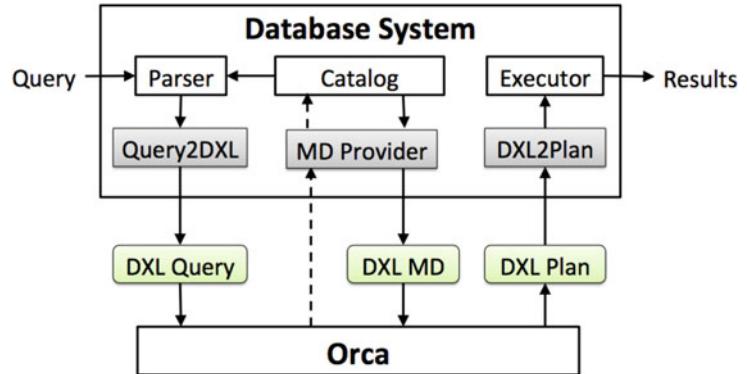

Orca

Orca (Orca Open Source 2018; Antova et al. 2014; El-Helw et al. 2015; Soliman et al. 2014) is the query optimizer of Pivotal’s data management products, including the massively parallel processing database system Greenplum (Pivotal 2018a) and the SQL-on-Hadoop database system HAWQ (Pivotal 2018b). While many query optimizers are tightly coupled with their host systems, a unique feature of Orca is its ability to run outside the database system as a stand-alone optimizer. This ability is crucial for supporting query engines with different computing architectures (e.g., massively parallel processing (MPP) and Hadoop) using one optimizer. It also allows leveraging the extensive legacy of relational optimization in new query processing paradigms. Furthermore, running the optimizer as a stand-alone product enables elaborate testing without going through the monolithic structure of a database system.

Figure 1 shows the interaction between Orca and an external database system. The database system needs to include translators that consume/emit data using Data eXchange Language (DXL), which is an XML-based language that is used to define an interface for accessing Orca. The Query2DXL translator converts a query parse tree into a DXL query, while the DXL2Plan translator converts a DXL plan into an executable plan. The implementation of such translators is done completely outside Orca, which allows multiple systems to interact with Orca by providing the appropriate translators.

The input to Orca is a DXL query. The output of Orca is a DXL plan. During optimization, the database system can be queried for metadata (e.g., table definitions). Orca abstracts metadata access details by allowing the database system to register a metadata provider (MD provider) that is responsible for serializing metadata into DXL before being sent to Orca. Metadata can also be

Query Optimization Challenges for SQL-on-Hadoop, Fig. 1
 Interaction between Orca and database system (Soliman et al. 2014)

consumed from regular files containing metadata objects serialized in DXL format.

The design of Orca is based on the Cascades optimization framework (Graefe 1995). The space of plan alternatives generated by the optimizer is encoded in a compact in-memory data structure called the Memo. The Memo structure consists of a set of containers called groups, where each group contains logically equivalent expressions. Memo groups capture the different sub-goals of a query (e.g., a filter on a table or a join of two tables). Group members, called group expressions, achieve the group goal in different logical ways (e.g., different join orders). Each group expression is an operator that has other groups as its children. This recursive structure of the Memo allows compact encoding of a huge space of possible plans.

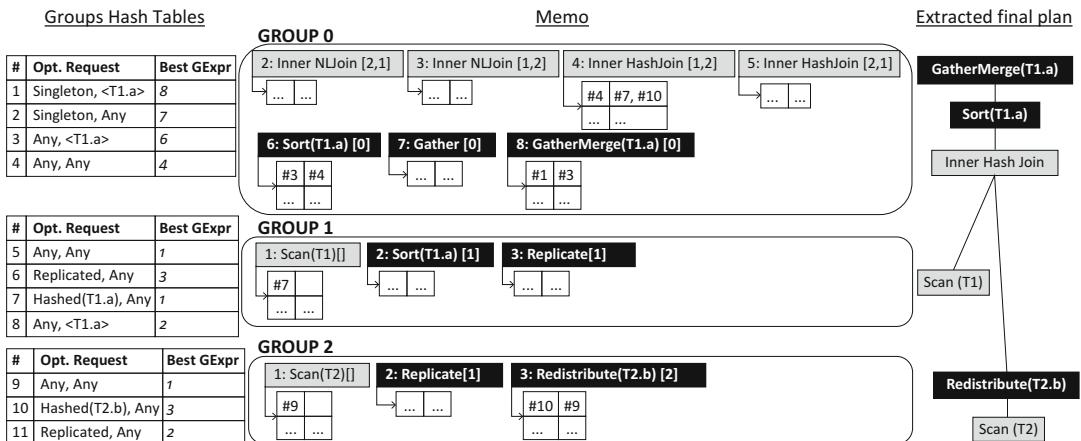

Orca optimizes queries in top-down fashion by computing optimization requests in the Memo. Each optimization request specifies physical properties (e.g., data distribution and sort order) that need to be satisfied. A Memo group is optimized under a given optimization request by finding the best plan, rooted at the group, that satisfies the required properties at the least cost.

Figure 2 shows how Orca processes optimization requests in the Memo for a simple join query between two tables T1 and T2 based on the join condition ($T1.a = T2.b$). In this example, the query results are required to be sorted on column T1.a. Assume that relation T1 is hash-distributed on column T1.a and relation T2 is hash-distributed on column T2.a. The initial op-

timization request is req. #1: (Singleton, T1.a), which specifies that query results are required to be gathered to a single node (typically the master node) based on the order given by column T1.a. The group hash tables are shown, where each request is associated with the best group expression that satisfies it at the least estimated cost. The black boxes indicate enforcer operators that are plugged in the Memo to deliver sort order and data distribution:

- Gather operator gathers results from all nodes to the master node.
- GatherMerge operator gathers sorted data from all nodes to the master node while keeping the sort order.
- Redistribute operator distributes tuples across nodes based on the hash value of given argument.
- Sort operator enforces a given sort order to the partition of tuples residing on each node.

Figure 3 shows the detailed optimization of req. #1 by InnerHashJoin[1,2], which is a hash-based algorithm for joining two relational inputs given by groups 1 and 2. For the join condition ($T1.a = T2.b$), one of the alternative plans is aligning child distributions based on join condition so that tuples to be joined are colocated. This is achieved by requesting Hashed(T1.a) distribution from group 1 and Hashed(T2.b) distribution from group 2. Both groups are requested to deliver any sort order.

Query Optimization Challenges for SQL-on-Hadoop, Fig. 2 Processing optimization requests in Orca (Soliman et al. 2014)

To satisfy a hashed distribution requirement, a hash value is computed for each tuple and used it to choose a node where the tuple is sent to. This allows parallel query execution on different nodes/machines. After child best plans are found, InnerHashJoin combines child properties to determine the delivered distribution and sort order. Note that the best plan for group 2 needs to hash distribute T2 on T2.b, since T2 is originally hash distributed on T2.a, while the best plan for group 1 is a simple scan, since T1 is already hash-distributed on T1.a.

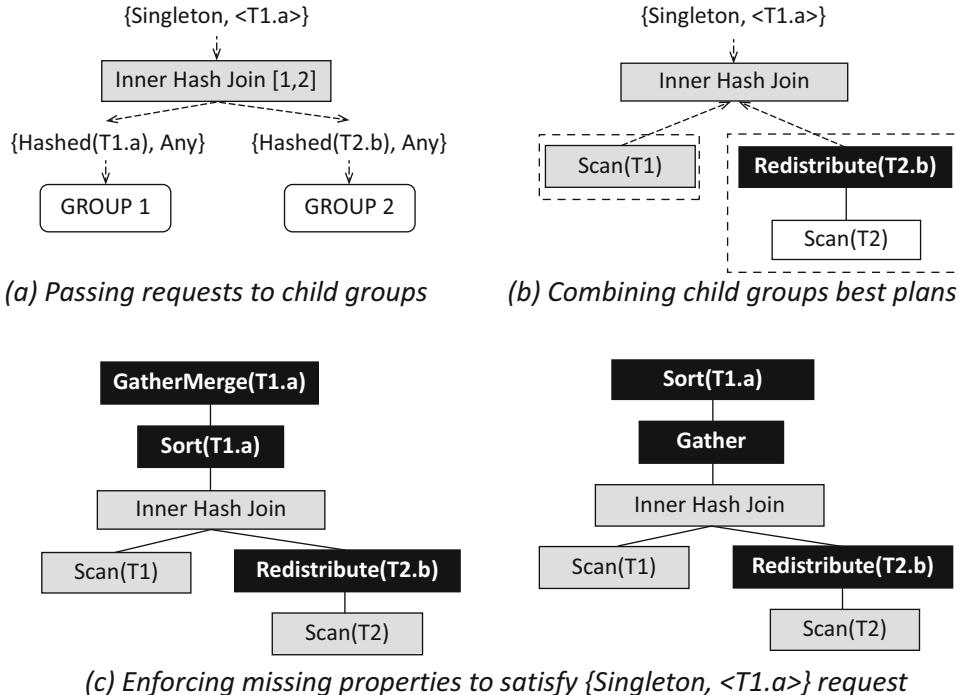

When it is determined that delivered properties do not satisfy the initial requirements, unsatisfied properties have to be enforced. Property enforcement in Orca is a flexible framework that allows each operator to define the behavior of enforcing required properties based on the properties delivered by child plans and operator local behavior.

Enforcers are added to the group containing the group expression being optimized. Figure 3c shows two possible plans that satisfy req. #1 through property enforcement. The left plan sorts join results on different nodes and then gather-merges sorted results at the master node. The right plan gathers join results from different nodes to the master node and then sorts them. These different alternatives are encoded in the Memo, and it is up to the cost model to differentiate their costs.

Finally, the best plan is extracted from the Memo based on the linkage structure given by optimization requests. Figure 2 illustrates plan extraction in Orca. The local hash tables of relevant group expressions are shown. Each local hash table maps incoming optimization request to corresponding child optimization requests. The best group expression of req. #1 is first looked up in the root group, which leads to GatherMerge operator. The corresponding child request in the local hash table of GatherMerge is req #3. The best group expression for req #3 is Sort. Therefore, GatherMerge is linked to Sort. The corresponding child request in the local hash table of Sort is req. #4. The best group expression for req. #4 is InnerHashJoin[1,2]. Sort is thus linked to InnerHashJoin. This procedure is followed to complete plan extraction leading to the final plan shown in Fig. 2.

Catalyst

Catalyst (Armbrust et al. 2015) is the query optimizer of SparkSQL, which is used to turn SQL queries into Spark execution plans. Many constructs in Catalyst are represented using tree data structures, including logical expressions, intermediate expression, and physical query execution plans. The optimizer design is based on decoupling the optimization phases which gives

Query Optimization Challenges for SQL-on-Hadoop, Fig. 3 Plan generation in Orca (Soliman et al. 2014)

room for including further optimizations as the design evolves.

The design of Catalyst is based on a query rewrite engine that runs batches of transformation rules. Each transformation rule converts an input tree to an equivalent output tree. Transformation rules are partitioned into batches. Batches are run sequentially, and rules within each batch are also run sequentially. The rule engine terminates when reaching a fixed point, which means that applying further transformations would not change the input expression anymore, or when a maximum number of iterations is reached. Query optimization in Catalyst takes place in a number of sequential phases, as depicted in Fig. 4.

The different phases that Catalyst optimizer goes through to produce the final query execution plan are next discussed. Figure 5 shows an example query which returns the *name* attribute of the Hive table *people* based on an equality condition applied to the *location* attribute.

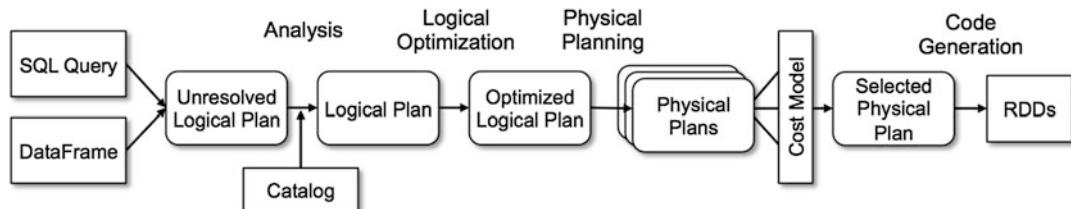

Query parsing and metadata lookup. Since the example query references a Hive table, a

HiveQL-based parser is used to generate an abstract syntax tree for the incoming query. Figure 5 shows the tree representation. The abstract syntax tree is preprocessed by resolving table names referenced in the query by looking up the MetaStore to obtain table definitions. A MetaStoreRelation is created for the unresolved relation in the query after looking up the MetaStore.

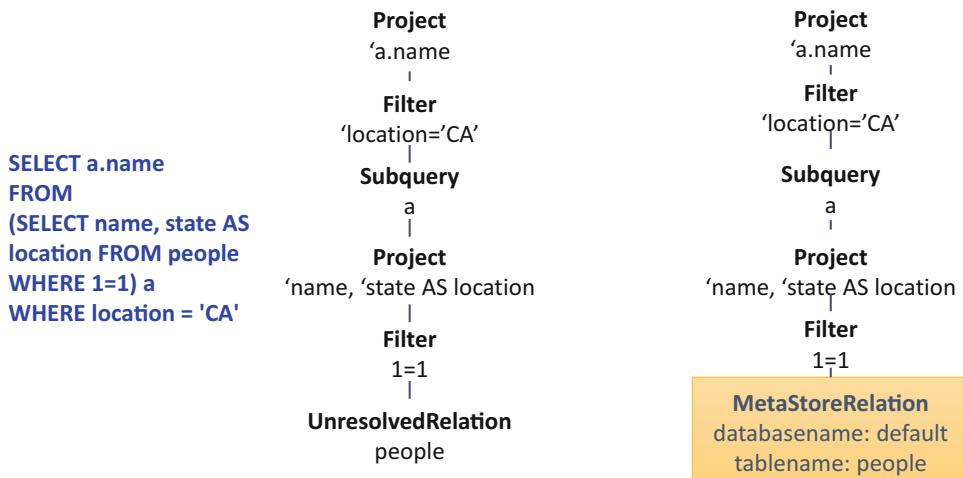

Resolving references. A globally unique identifier is assigned to each attribute (column) referenced in the query tree. Then, derivation of data types of every data item in the query tree takes place. Figure 6 shows unique numerical identifiers assigned to columns in the query tree.

Logical planning. Multiple logical rewrites are conducted to simplify the input query tree. These rewrite operations include the following:

- Removing redundant query operators.
- Constant folding, where inlined constant expressions are reduced to simple atomic values.

Query Optimization Challenges for SQL-on-Hadoop, Fig. 4 Query optimization phases in SparkSQL (Armbrust et al. 2015)

Query Optimization Challenges for SQL-on-Hadoop, Fig. 5 Query example in SparkSQL (Armbrust et al. 2015)

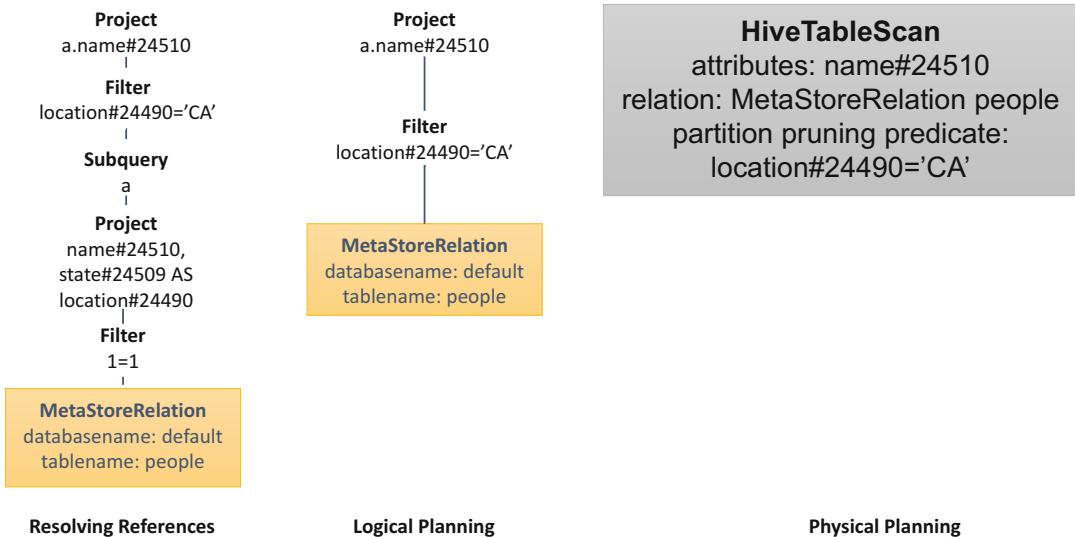

- Filter simplification, where trivial filters are removed and subtrees that are known to return no results are pruned.
- Filter push down so that filtering operations are applied as early as possible.
- Eliminate unused column references that are not needed to compute the final query answers.

Figure 6 shows the transformed query tree after applying the previous logical rewrites. For example, the Filter operator has been pushed down, while the Subquery operator was eliminated because of being a redundant operator.

Physical planning. In this phase, the optimized logical plan is transformed into a number of possible physical plans. This is done by recognizing operators in the logical plan that can be directly transformed into physical counterparts.

For example, a filter on a MetaStore relation can be transformed into HiveTableScan. In addition, a list of strategy objects, each of which can return a list of physical plan options, is used to transform logical operators to equivalent physical ones. Examples of strategy objects include HashJoin and NestedLoopJoin strategies. If a given strategy object is unable to plan all of the remaining operators in the tree, it creates a placeholder to be filled by other strategy objects. Figure 6 shows the final physical plan, which is reduced to a simple HiveTableScan with an embedded filter.

Plan parallelization. In this phase, data exchange operators are plugged into the generated physical plans to establish the required data distributions. Distribution requirements could arise from operator local requirements or from query-specific requirements. Physical operators may not be able to establish data distributions on their

Query Optimization Challenges for SQL-on-Hadoop, Fig. 6 Query example in SparkSQL (Armbrust et al. 2015)

own. In this case distribution enforcers are used to guarantee delivering the required data distribution.

Impala

The query optimizer of Impala (Kornacker and Erickson 2012) generates execution plans by following a two-phase approach:

- Phase 1 (single-node planning): In this phase, a query plan that runs on a single node (i.e., without considering data partitioning in the Hadoop cluster) is generated.
- Phase 2 (plan parallelization): In this phase, a parallelized query plan that processes distributed data in the cluster is generated.

In the first optimization phase, the query parse tree is translated into a non-executable single-node plan tree. The single node plan consists of different types of operators including table scan, join, aggregation, sort, and analytic evaluation functions. In this phase, filters specified in the given query are pushed down to be applied as close as possible to data sources. This is important to early-prune parts of the data that are not needed to compute the final query answer. New

filters could also be inferred from existing filters to prune data more aggressively.

Another important optimization that takes place in this phase is join ordering, where an efficient evaluation order of relational joins is identified. Heuristics are typically used to avoid exhaustive enumeration of the join orderings space. In the second optimization phase, the single-node plan is turned into a distributed (parallel) execution plan. The optimization objective of this phase is to minimize data movement and maximize scan locality.

Data movement is controlled by adding Exchange operators between plan nodes and by adding extra non-exchange plan nodes to minimize data movement across the network (e.g., local aggregation nodes). During this second phase, the join strategy for every join node is decided, including broadcast (one input of the join is replicated on all nodes) and partitioned/hashed (the two join inputs are partitioned across nodes using the join expression so that tuples that would join together reside on the same node).

All aggregations are executed as a local aggregation followed by a merge aggregation operation. The local aggregation output is partitioned on the grouping expressions, and the merge aggregation is done in parallel on all nodes. Sort is

parallelized similarly using a local sort followed by a single-node merge operation.

At the end of the second phase, the distributed plan tree is split into a set of plan fragments at the boundaries given by the exchange operators. Each plan fragment constitutes a unit of execution encapsulating a portion of the plan tree that operates on the same data partition on a single machine.

Apache Calcite

The Calcite project (Apache Calcite 2018) provides a Java-based SQL parser, optimizer, and data management framework that allows users to parse, optimize, and execute queries on a variety of data sources consumed using third-party connectors. A query is represented using a tree of operators-based relational algebra constructs. The operator tree is generated automatically by parsing SQL query. It can also be built manually using a set of given Java APIs.

Transformation rules are used to modify a relational algebra expression into an equivalent expression with the same semantics. This is needed to extend the search space of the optimizer while looking for the best execution plan of a given query. Transformations are guided by a cost model that performs the transformation if it yields a plan alternative with small cost according to the underlying cost model. The optimization framework is extensible allowing users to add new operators, transformation rules, and cost models.

Calcite provides two planner engine implementations: a volcano-style planner implementation that uses dynamic programming to exhaustively search the plan space and rule-based planner that builds the plan space by applying a fixed set of transformation rules.

Future Directions for Research

Despite a plethora of available commercial and open-source query optimizers, the effort needed to equip a data management platform with a scalable and sophisticated query optimizer remains considerable. Optimizer design remains to a large

extent tightly coupled with data management system components. Building a generic query optimization as service is still an open problem. Some efforts have been done toward this direction by abstracting optimizers interface and providing optimizer builder SDKs.

Big data applications and use cases are spreading into different environments and platforms including on-premises massively parallel processing systems and Hadoop ecosystems as well as public and private Cloud platforms. In such hybrid and rapidly changing environments, building query optimization techniques that are able to optimize queries across heterogeneous computing platforms is an important future direction of research.

Providing virtualized access to big data sources is gaining more traction with the wide adoption of the Cloud and the need to query data sources hosted by disparate environments. Performing query optimization within data virtualization layer poses new challenges regarding abstracting the characteristics and capabilities of the underlying data sources and seamless cross-optimization of queries against different query processing engines without disrupting existing application workflows.

Query Processing – k NN

Jianzhong Qi and Rui Zhang
The University of Melbourne, Melbourne, VIC, Australia

Synonyms

K Nearest Neighbor Query; k NN Query

Definitions

Consider a set of n data objects $O = \{o_1, o_2, \dots, o_n\}$ and a query object (user) q . Each object including the query object is associated with a d -dimensional vector representing its coordinate in a d -dimensional space ($d \in \mathbb{N}_+$). Given a query parameter k ($k \in \mathbb{N}_+$), the k nearest neighbor (k NN) query computes a size- k subset $S \subseteq O$ that contains the data objects that are the nearest to q :

$$\forall o_i \in S, o_j \in O \setminus S : \text{dist}(q, o_i) \leq \text{dist}(q, o_j)$$

Here, $\text{dist}(\cdot)$ is a function that returns the distance between two objects. A variety of distance functions have been considered in the literature, such as *Euclidean (L_2) distance*, *Manhattan (L_1) distance*, *Chebyshev (L_∞) distance*, spatial network distance, and *general metric distance*.

k NN query processing in the spatial data management context has focused on two- or three-dimensional Euclidean space and spatial network space.

Overview

The rapid growth of *location-based services* (LBS) has accumulated a massive amount of spatial data such as mapping data and user trajectories. Popular LBS such as Google Maps are serving millions of users who issue queries such as *finding Alice her nearest petrol stations*, which is a typical example of k NN queries. Most k NN algorithms use *spatial indices* over the data objects to help prune the unpromising search space and obtain high query efficiency. When the amount of data becomes too large to be indexed or queried on a single machine, parallelism needs to be exploited to overcome such limitations. This raises new challenges of k NN queries in parallel index management and query processing.

Key Research Findings

We start with a brief review of two classic k NN algorithms and then focus on the discussion of recent developments on k NN algorithms that use parallelism to manage the growing amount of data.

Traditional k NN Algorithms

The two arguably most popular k NN query algorithms are the *best-first* (Hjaltason and Samet 1995) and the *depth-first* (Roussopoulos et al. 1995) algorithms. These two algorithms rely on an tree index (e.g., R-trees Guttman 1984) over the data set O . They traverse the tree index starting from the tree root to find data objects nearest to q . During the traversal, the distance to the

k th NN among the data objects already visited is used to facilitate the pruning of unpromising tree branches that do not index nearer data objects. When a tree node N is visited, the best-first algorithm inserts all child nodes of N into a queue Q prioritized by an estimated distance between each child node and q . The next node to be visited is the one in Q with the smallest estimated distance to q . The depth-first algorithm simply visits the first child of each node before visiting the sibling nodes. While these two algorithms have shown high empirical query efficiency due to the pruning power of the tree indices, they are difficult to be parallelized because of the backtracking procedure in traversal.

Parallel k NN Algorithms

Parallel k NN query algorithms that suit popular parallel computation models such as *MapReduce* (Dean and Ghemawat 2008) have been developed to handle data beyond the processing capability of individual machines. Such algorithms partition the data space with a grid (a.k.a. *tiling*, cf. Fig. 1) so that data objects in different grid cells can be examined in parallel. A two-stage procedure is used in query processing. In the first stage, the cell C_q that contains the query object q is identified, and k NN is computed over the data objects in C_q (e.g., the 2NNs in Fig. 1 are o_3 and o_4). In the second stage, the cells adjacent to C_q are examined to find data objects that may be nearer to q than the k th

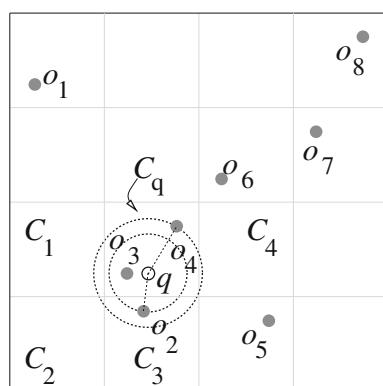

NN already found (e.g., cells C_1 , C_2 , C_3 , and C_4 , which are within the circle defined by the second NN o_4 ; o_2 is found to be the new second NN). This step may be repeated over more cells adjacent to the cells examined, until the nearest data object in these adjacent cells is farther away than the k th NN already found.

Hadoop-Based k NN Algorithms

Hadoop is an open-source implementation of the MapReduce computation model. The MapReduce model processes a task (a MapReduce job) in two phases: *Map* and *Reduce*. The Map phase assigns data to different machines in a cluster, while the Reduce phase runs computation on each machine. The data storage component of Hadoop named *Hadoop Distributed File System* (HDFS) is an implementation of the *Google File System* (Ghemawat et al. 2003). HDFS is optimized for large data blocks (e.g., 64 MB per block). Hadoop-based k NN algorithms need to design indices following this block size.

Aji et al. (2012) propose a k NN algorithm based on MapReduce with an assumption that the number of data objects is relatively small and the entire data set can be replicated to each machine for query processing. They focus on efficient processing of a large number of k NN queries at the same time, which is done by a single MapReduce job. In the Map phase, the query objects are partitioned with a grid and assigned to different machines according to their grid cell id. In the Reduce phase, the data set is replicated to each machine, upon which a local index (e.g., an R-tree) is built. The queries are then processed on each machine independently.

SpatialHadoop (Eldawy and Mokbel 2013) is a MapReduce framework for spatial query processing. It employs a two-level index structure that consists of a *global index* and a *local index*. The global index is built by partitioning the data space such that every partition can fit in a block in HDFS. Grid-based and R-tree-based indices are implemented in SpatialHadoop. A grid-based index simply partitions the data space with a uniform grid. An R-tree-based index creates an R-tree on a sample of the data set, where the leaf nodes are used to partition the data space.

Query Processing – k NN, Fig. 1 Grid-based k NN computation

Minimum bounding rectangles (MBR) of the partitions are stored in the global index which is kept in the main memory of the master node of the cluster. A local index is built on every partition and kept in HDFS. k NN queries are processed with the two-stage search space expansion procedure as described earlier. First, the partition containing the query object is identified using the global index, where a k NN query is computed using the local index. Then, adjacent partitions are explored until no more NNs can be found.

AQWA (Aly et al. 2015) builds a global index using the k-d tree (Bentley 1975) to create the data partitions where every partition is stored in HDFS as a block. The k-d tree is stored in the main memory of the master node. Additionally, the master node keeps a count of data objects for each partition. This enables processing a k NN query with only one MapReduce job as follows. The partitions nearest to the query object q that together contain at least k objects can be identified from the k-d tree index and the data counts. The farthest point of these partitions from q defines a circle centered at q . Only partitions within this circle needs to be fetched for query processing, which can be done by a single MapReduce job.

HBase-Based k NN Algorithms

HBase is an open-source *key-value* store (*NoSQL* database) built on top of HDFS. It hides the underlying block storage from users, and hence k NN algorithms based on it do not have to consider how to organize the data in blocks.

MD-HBase (Nishimura et al. 2011) is a multidimensional data store built on HBase. This system stores the *Z-order* (Orenstein and Merrett 1984) value of a data object together with the data object itself as a key-value pair in HBase. The key-value pairs are partitioned by the key range, and every partition is stored as a *region*. Data in HBase is indexed with a B^+ -tree-like index structure, where the key range of a region is stored in an index layer called the *META* layer. MD-HBase uses the longest common prefix of the keys (in the binary form) in a region as the index key of

the region. k NN queries are processed following a search space expansion procedure. At start, the region with an index key that shares the longest common prefix with the Z-order value of the query object q is identified, and an initial k NN answer is computed from the region. The k th NN found defines a distance from q where the search should expand to. This procedure repeats until no new k NN objects can be found in the expanded search space.

The *KR⁺ index* (Hsu et al. 2012) follows a similar k NN query procedure to that of MD-HBase but uses an R^+ -tree (Sellis et al. 1987) to group the data objects and Hilbert-order (Lawder and King 2001) values of the MBRs of the tree leaf nodes as index keys.

HGrid (Han and Stroulia 2013) uses another index key formulation, which is based on a two-level grid structure. The first level uses a coarse grid where the grid cells are indexed by the Z-order values. The second level further partitions each first-level grid cell with a regular grid where the cells are indexed by their row and cell numbers. The key value of a data object is formed by a concatenation of the index keys of the first and second level cells that this object locates at. HGrid has a slightly different k NN algorithm. The algorithm starts by estimating a region that may contain sufficient data objects to form a k NN answer based on the data density. Then, an initial k NN answer is computed from this region, and the search space expansion strategy is used to refine the answer.

COWI and *CONI* (Cahsai et al. 2017) build a quad-tree (Finkel and Bentley 1974) over the data set where the leaf node numbers are used as the index keys of the data objects. COWI stores the non-leaf levels of the quad-tree index in the memory of a master machine. The index also contains the number of data objects in each leaf node, which is used to help query processing in a way similar to that of AQWA. CONI considers the case where the quad-tree is too large to be held in memory. It stores the tree as a separate table in HBase. At query time, the tree index is accessed first to determine the leaf nodes that may be relevant for query processing.

Spark-Based k NN Algorithms

Spark provides an in-memory computation cluster framework to handle massive data. A set of data to be processed is modeled as a *resilient distributed dataset* (RDD). RDDs are stored in partitions across machines in the cluster.

GeoSpark (Yu et al. 2015) encapsulates RDDs with an abstraction named the *spatial resilient distributed dataset* (SRDD) to store spatial data. An SRDD is partitioned using a uniform grid. Local indices such as quad-trees may be created for data objects in the partitions. k NN query processing on GeoSpark is done by following the grid-based search space expansion strategy as discussed earlier.

Simba (Xie et al. 2016) uses both global and local indices. It creates a new RDD abstraction called the *IndexRDD* to store a local index (e.g., an R-tree) together with the data objects in each partition, while the partitions are created by the *STR* algorithm (Leutenegger et al. 1997). The global index (e.g., an R-tree) is created over the partitions and held in-memory in the master node for fast query processing. k NN queries on Simba also follow the search space expansion strategy but vary from the standard procedure slightly by fetching multiple partitions at start instead of only the partition containing the query object. The k th NN from the fetched partitions is used to define the search space to be explored next.

Examples of Application

k NN queries have a large variety of applications in different fields such as spatiotemporal databases, location-based services, and data mining, just to name but a few. In spatial data management, a typical application is in digital mapping, e.g., Google Maps, where k NN queries may be used for finding the nearest *points-of-interest* (POI) for query users. A closely related application is in ride sharing, e.g., Uber, where k NN queries may be used to find the nearest cars for car riders. Another application is in augmented reality gaming, e.g., Pokémon GO, where k NN queries may be used to find the nearest gaming objects of game players.

Future Directions for Research

The techniques discussed above consider stationary data objects whose locations do not change over time. With the growing popularity of smart mobile devices, location-based services for moving data objects (users) become prevalent, which call for efficient k NN algorithms over massive sets of moving objects (Nutanong et al. 2008; Wang et al. 2014; Li et al. 2014, 2016; Gu et al. 2016) and streaming location data (Koudas et al. 2004). Simply recomputing the query whenever there is an object location update may be infeasible due to the larger number of objects and updates. Keeping the query result updated under such constraints is a challenging task.

k NN queries in higher-dimensional spaces (Jagadish et al. 2005) is another challenge. As a major application domain, data mining requires k NN computation over feature spaces that may have thousands of dimensions. The techniques discussed are inapplicable, because they use spatial indices for low-dimensional spaces. Approximate k NN algorithms are in need to cope with the high processing costs in high-dimensional spaces.

Query Processing: Computational Geometry

Amr Magdy

University of California, Riverside, California,
USA

Definitions

Computational geometry studies computational algorithms on computer objects that are modeled as geometric shapes, e.g., points, lines, polygons, and surfaces.

Overview

Geometry has been used for decades to model computer objects with geometric shapes in two- and three-dimensional spaces, e.g., points, lines, polygons, and surfaces. Naturally, different applications that use these objects need to develop algorithms that process and query the geometric shapes for different scenarios and operations. This has started the evolution of computational geometry field that focuses on designing efficient algorithms for different operations and queries on geometric objects. These algorithms are used in several application domains such as computer graphics, computer-aided design and manufacturing (CAD/CAM), geographic information systems (GIS), and robotics motion planning and visibility problems. Part of these application domains intersect with the big data literature due to the large volume of data and/or the large frequency of operations, depending on the application. For example, OpenStreetMap geographic data contains over 6 billion objects, while computer graphics applications perform a plethora of operations every second. Such high-intensive computation necessitates efficient and scalable algorithms for computational geometry operations and queries. In this article, we highlight the main contributions of the research community in the field and give pointers for more comprehensive readings and future directions.

The existing big data literature focus on a set of computational geometry query operations in the two-dimensional (2D) space. 2D computational geometry is mainly abstracting different applications into query operations on three basic geometric objects: points, line segments, and polygons (Fig. 1a). Polygons can be regular shaped, e.g., rectangular search range, or arbitrarily shaped, e.g., country boundaries. In this section, we define common 13 query operations on 2D geometric objects that are used in different applications (de Berg et al. 2008; Lee and Preparata 1984). These operations can be categorized into four types: point operations, line operations, polygon operations, and hybrid operations. All operations assume Euclidean space and Euclidean distance.

(1) **Point query operations:** these operations are performed on a set of input points, while the output can be either a set of points or polygons.

Definition 1 (Closest pair) Given a set of input points P , the *closest pair* operation finds two points $\{p_1, p_2\} \subseteq P$ so that $distance(p_1, p_2) \leq distance(p_i, p_j), \forall p_i, p_j \in P, i \neq j$. So, p_1 and p_2 are the closest pair of points in P out all possible pairs without repetition.

Definition 2 (Farthest pair) Given a set of input points P , the *farthest pair* operation finds two points $\{p_1, p_2\} \subseteq P$ so that $distance(p_1, p_2) \geq distance(p_i, p_j), \forall p_i, p_j \in P, i \neq j$. So, p_1 and p_2 are the farthest pair of points in P out all possible pairs without repetition.

Definition 3 (Convex hull) Given a set of input points P , the *convex hull* operation finds a subset of P that contains vertices of the smallest convex polygon that contains *all* points in P . Convex polygons have all interior angles measuring less than 180° .

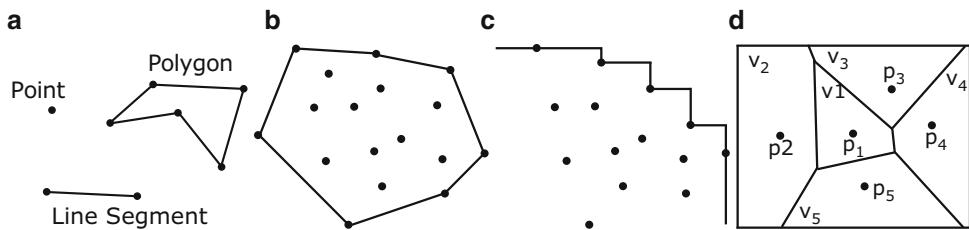

Figure 1b shows an example of the convex hull operation output. The operation output is the set of points on the polygon perimeter ordered in a clockwise direction.

Q

Definition 4 (Skyline) Given a set of input points P , the *skyline* operation finds a subset $P_d \subseteq P$, where $P_d = \{p_i \in P, p_i \text{ is not dominated by } p_j, \forall p_j \in P, i \neq j\}$. A point p_i dominates point p_j if and only if $p_i.x \geq p_j.x$ and $p_i.y \geq p_j.y$, where x and y are the 2D coordinates in the Euclidean space.

Figure 1c shows an example of the skyline operation output. The output is the set of points that represent vertices of the line segments in the figure.

Definition 5 (Voronoi diagram) Given a set of input points P , the *Voronoi diagram* operation finds a set of Voronoi partitions V , such

Query Processing: Computational Geometry, Fig. 1 Geometric basic objects and point query operations. (a) Geometric objects. (b) Convex hull. (c) Skyline. (d) Voronoi diagram

that $|V| = |P|$ and each partition v_i has a distinct seed point $p_i \in P$, $1 \leq i \leq |P|$. A Voronoi partition v_i with a seed point p_i is an area in the Euclidean space R^2 where $v_i = \{p_x \in R^2, \text{distance}(p_x, p_i) \leq \text{distance}(p_x, p_j), \forall p_j \in P, i \neq j\}$. This makes each Voronoi partition v_i a union of all points in the Euclidean space where p_i is the nearest point among all points in P .

Figure 1d shows an example of a Voronoi diagram for a set of five points $P = \{p_1, p_2, p_3, p_4, p_5\}$. The figure shows corresponding five Voronoi partitions $V = \{v_1, v_2, v_3, v_4, v_5\}$. All points in the partition v_1 , for example, have p_1 as their nearest neighbor among all points in P and similarly v_2 with p_2 and so on.

(2) **Line query operations:** this operation is performed on a set of input line segments, while the output is either a Boolean value (true or false) or a set of line segments.

Definition 6 (Line segment intersection) Given two input line segments L_1 and L_2 , the *line segment intersection* operation finds whether or not L_1 and L_2 intersect.

(3) **Polygon query operations:** these operations are performed on a set of input polygons, while the output is another set of polygons.

Definition 7 (Polygon intersection) Given two input polygons A and B , the *polygon intersection* operation $A \cap B$ finds a polygon that represents the common area of A and B .

Figure 2a shows an example of polygon intersection operation. The gray-shaded area shows the output intersection polygon.

Definition 8 (Polygon union) Given two input polygons A and B , the *polygon union* operation $A \cup B$ finds a polygon that represents the unity of both A and B areas.

Figure 2c shows an example of polygon union operation. The gray-shaded area shows the output union polygon.

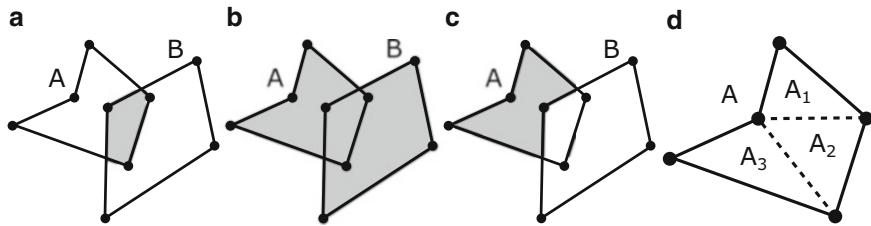

Definition 9 (Polygon difference) Given two input polygons A and B , the *polygon difference* operation $A - B$ finds a polygon that represents the area of A that is not part of B .

Figure 2c shows an example of polygon difference operation. The gray-shaded area shows the output difference polygon.

Definition 10 (Polygon triangulation) Given an input polygon A , the *polygon triangulation* operation finds a set of disjoint triangles $\{A_1, A_2, \dots, A_n\}$ such that $A = A_1 \cup A_2 \cup \dots \cup A_n$.

Figure 2d shows an example of polygon triangulation operation. The polygon A is decomposed into three triangles: A_1 , A_2 , and A_3 . The output triangles are disjoint and their union covers the whole area of polygon A .

(4) **Hybrid query operations:** these operations are performed on an input hybrid set of points, line segments, and/or polygons, while

Query Processing: Computational Geometry, Fig. 2 Polygon query operations. (a) Intersection. (b) Union. (c) Difference. (d) Triangulation

the output is either Boolean true or false or another hybrid set of points, line segments, and/or polygons.

Definition 11 (Point in polygon) Given a point p and a polygon A , the *point in polygon* operation finds whether or not p lies inside the perimeter of A .

Definition 12 (Range search) Given a set of points P and a rectangular polygon R , the *range search* operation finds a set of points $P_R \subseteq P$ such that $P_R = \{p_i \in P, p_i \text{ lies inside } R\}$.

Definition 13 (Simplex range search) Given a set of points P and a 2D simplex polygon, i.e., triangle, T , the *simplex range search* operation finds a set of points $P_T \subseteq P$ such that $P_T = \{p_i \in P, p_i \text{ lies inside } T\}$. In 2D, this operation can be referred as *triangular range search* because a 2D simplex is a triangle.

Key Research Findings

This section gives a brief overview on traditional computational geometry structures and query processing. Then, it highlights query processing techniques on big geometric data in modern big data systems.

Traditional Query Processing

This section highlights the major families of algorithms and data structures that are traditionally employed to solve and speed up computational

geometry query operations in different applications.

(1) **Plane sweep algorithms** (or *sweep line algorithms*): A family of algorithms that use a conceptual sweep line to solve various problems in Euclidean space. The main idea is to imagine a straight line, mostly a horizontal or a vertical line, moved across the plane and stops at certain discrete points that correspond to the input set of points or line segment vertices. Then, geometric operations are performed on geometric objects that either intersect or are in the immediate vicinity of the sweep line whenever it stops. The final solution is available once the line has passed over all the input objects. This family has a variety of algorithms to solve points closest pairs (Bartling and Hinrichs 1992), polygon intersections (Nierergelt and Preparata 1982), convex hull (Andrew 1979), and Voronoi diagrams (Fortune 1987).

(2) **Multidimensional trees**: A family of tree data structures that are used to index multidimensional data, e.g., 2D or 3D, including points, line segments, and polygons. They are used to support efficient range search query operation. Three major tree structures in this family are kd-trees, quadtrees, octrees, and their different variations. Kd-tree (Bentley 1975) is a binary tree that index k-dimensional data points. Every non-leaf node is dividing the space into two halves through a hyperplane perpendicular to one of the k-dimensions. Points to the left of this hyperplane are indexed by the left subtree of that node and points right of the hyperplane are indexed by the right subtree. For example, if for a particular node splits the x-axis, all points in the subtree with a smaller x value will appear in the left subtree and all points with larger x value

will be in the right subtree. Quadtree (Samet 1984) is a more generic structure and has several variations that can index points, line segments, and/or polygons. A quadtree is a four-ary tree and consists of multiple levels, each level covers the whole indexed space, and level i has 4^i nodes. Level 0 consists of one (4^0) root node that covers the whole space. Then, at level 1 the root node is divided into four children nodes of equal areas, and each of the children nodes are divided into four equal nodes at level 2 and so on. Each tree node has a maximum capacity of m objects, so a node is divided only if has more than m objects. Quadtree is mainly indexing two-dimensional data. Octree (Meagher 1982) is the corresponding three-dimensional version where each node is divided into eight children nodes in the three-dimensional space. Both quadtrees and octrees are used heavily in different operations for computer graphics applications. In addition, quadtrees are used to index and query location data in geographic information systems and location-based services.

(3) **Point in polygon:** A point in polygon query can be processed through two algorithms: *crossing number* and *winding number* algorithms. The crossing number algorithm, also known as ray casting, counts the number of intersections of the query polygon sides with an infinite line starts from the query point and continues to infinity. If the crossing number is even, then the point is outside the polygon; otherwise, it is inside. This algorithm, however, is considering only simple polygon where there is no self-intersection among the polygon sides and might fail in complex polygons. To overcome this, the winding number algorithm, as its name suggests, calculates the winding number (a known concept in mathematics) of the polygon around the point. If this number is zero, then the point is outside the polygon; otherwise, it is inside. The winding number is mainly counting the number of cycles the polygon sides are winding around the point. Calculating this number is performed through summation of angles between the query point and end points of the query polygon sides. Then, the winding number is the nearest multiple of 360° .

(4) **Line segment intersection:** It is straightforward to efficiently find intersection of two line segments based on geometry laws. However, if a large number of line segments are involved in the query, the query becomes increasingly expensive. This query is processed by a sweep line technique where the algorithm tracks which line segments are intersecting with the sweep vertical line at each point along the axis using a dynamic data structure based on binary search trees. This phase eliminates the majority of unnecessary checks on segment pairs. Then, a significantly smaller number of checks are performed on segment pairs that are potentially intersecting.

(5) **Skyline:** Skyline has a variety of query processing techniques and variations (Kalyvas and Tzouramanis 2017). Several divide and conquer algorithms have been proposed to tackle this query. The algorithm is dividing the input data into smaller subsets, so each subset fits in main memory. Then, the skyline of each subset is computed efficiently. Finally, the global skyline is computed by merging local skylines of each subset. One way of efficient skyline computation is using multidimensional trees, e.g., R-trees or quadtrees, to early prune points that do not contribute to the final skyline and eliminate redundant dominance checks.

Computational Geometry on Big Data

Scaling computational geometry operations on big volume data has been developed over two main stages that overlap in time, both exploiting parallel computing environments to speed up computational geometry operations. The first stage is exploiting multicore architectures (Akl and Lyons 1993; Aggarwal et al. 1988; Liknes et al. 2014; Miller and Stout 1988; McKenney et al. 2017) with shared-memory parallel computation model, while the second stage is exploiting distributed big data systems (Eldawy et al. 2013; Puri et al. 2017; Vlachou et al. 2008; Zhang et al. 2016) with shared-nothing computation model. This section highlights query processing techniques in both stages.

Geometric query processing in multicore environments. Multicore environments have been

exploited in parallel query processing techniques to support efficient computational geometry operations on large datasets that fit in main memory. These techniques have adapted a generic framework that work in three stages: (a) divide the input data into smaller subsets, (b) compute the geometric operation on each subset in parallel efficiently, and (c) combine the results of the subsets to get the final output on the whole dataset. The details of each stage depend on the geometric operation and the optimizations of the underlying algorithm. We elaborate on this framework through two examples of computing *convex hull* and *closest pair* in parallel multicore environments. It is noteworthy that the presented examples are not the only parallel algorithms for these operations; however, they show instances of the described generic framework.

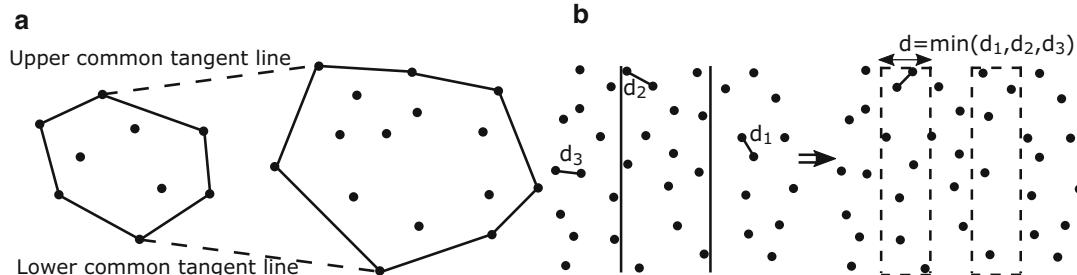

Example 1 (Convex Hull) One way to compute the convex hull of a set of points through the above framework is to divide the input data into smaller subsets that are linearly separable. Then, the convex hull on each subset is computed and combined to get the convex hull of bigger sets out of smaller ones through upper and lower common tangent lines. Figure 3a shows an example of merging convex hull polygons of two sets of points to get the convex hull polygon of the combined set. Given the two polygons, the algorithm finds two line segments, namely, upper common tangent line and lower common tangent line, as depicted in the figure. These two lines represent upper and lower envelopes for all points on the two convex polygons. Then, the algorithm

removes all points between these two lines and keeps the other points as the final convex hull.

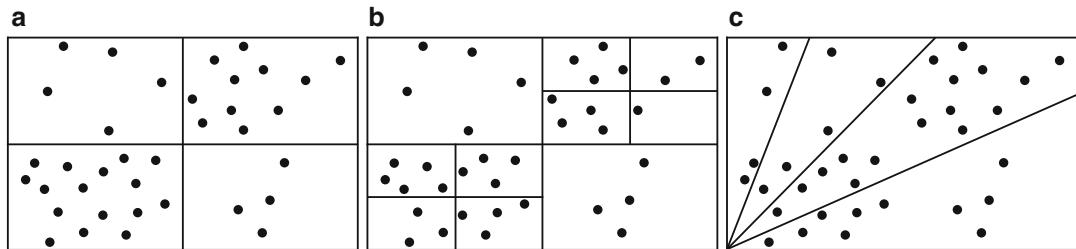

Example 2 (Closest Pair) Figure 3b shows an example of a parallel closest pair algorithm. The algorithm divides the input points into linearly separable subsets S_1 , S_2 , S_3 and computes the local closest pair in each subset with corresponding closest distances d_1 , d_2 , and d_3 , respectively. Then, to compute the global closest pair, a buffer zone of width d is considered around the partition lines of the three subsets, where $d = \min(d_1, d_2, d_3)$. The points in this buffer zone are checked for the closest points to ensure getting the global closest pair.

In addition to convex hull and closest pair, parallel algorithms in multicore environments exist for different geometric operations including polygon triangulation, Voronoi diagrams, line segment intersections, minimizing a circumscribing triangle, and recursive data structures for three-dimensional queries (Aggarwal et al. 1988; Akl and Lyons 1993).

Geometric query processing in big data systems. With the increasing volume of datasets, fitting data in main memory is no longer a possibility for several applications. For example, OpenStreetMap geographic data contains over 6 billion objects, which need to be processed in disk-based environments to accommodate such large volumes. For that, new techniques have been developed to exploit the recent advances in distributed big data systems such as MapReduce

Query Processing: Computational Geometry, Fig. 3 Examples of parallel operations in multicore environments. (a) Merging convex hulls. (b) Parallel closest pair

Query Processing: Computational Geometry, Fig. 4 Examples of different partitioning techniques. (a) Fixed grid partitioning. (b) Dynamic grid partitioning. (c) Angle partitioning

environments. These techniques mainly focus on batch analysis applications, e.g., geospatial analysis, rather than interactive querying applications, e.g., robot motion planning. Therefore, batch analysis environments such as MapReduce are suitable incubator to realize them.

Distributed geometric techniques in big data systems adopt the same three-stage generic framework that has been employed in multicore environments: divide input data, compute geometric operation locally, and merge local outputs to get the global one. However, the details of each stage are different due to the different computation environment and therefore the different performance optimization goals. For example, MapReduce-based techniques optimize for lower I/O and lower network communication, which were not the optimization goals in main memory environments. The main differences in MapReduce techniques compared to traditional parallel techniques come in two folds. First, the early focus of traditional techniques is to optimize the theoretical runtime complexity with later focus on experimenting actual runtime of the algorithms. On the contrary, MapReduce techniques mainly focus on optimizing the actual runtime with almost no focus on the theoretic bounds. Second, MapReduce techniques have different filtering and partitioning techniques that optimize for I/O and network communication costs in shared-nothing architectures. Figure 4 shows three examples of different partitioning techniques: fixed grid partitioning, dynamic grid partitioning, and angle-based partitioning. The pros and cons of each partitioning technique are studied in the literature.

Examples of Application

Computational geometry algorithms are used in several application domains such as computer graphics, computer-aided design and manufacturing (CAD/CAM), geographic information systems (GIS), and robotics motion planning and visibility problems (de Berg et al. 2008; Lee and Preparata 1984). For example, in GIS applications, 2D computational geometry structures and algorithms are heavily used for range search queries, point in polygon operations, and nearest neighbor search.

Future Directions for Research

The presented techniques in this entry have not exploited the recent advances in both hardware technologies, e.g., GPUs, and software systems, e.g., Apache Spark and Apache Flink. The advances in GPU technology have recently attracted emerging efforts to exploit them in speeding up operations and applications in the geometric space (Chen and Chen 2016; Sebastian et al. 2014). However, these efforts form few steps in a promising research direction that might be expanded to fill more gaps. One of such gaps is the lack of holistic systems that gather the scattered techniques and exploit GPU infrastructures to develop end-to-end solutions. In addition to the new hardware, the recent advances in software systems have not yet exploited in the field of computational geometry. The current literature depends on Hadoop MapReduce as the underlying distributed framework to handle disk-

resident big data. However, the new in-memory processing frameworks such as Apache Spark and Apache Flink have not been exploited, yet, they provide much better interactive response compared to Hadoop-based frameworks.

Query Processing: Joins

Nikos Mamoulis

Department of Computer Science and Engineering, University of Ioannina, Ioannina, Greece

Q

Synonyms

[Parallel spatial joins](#); [Spatial joins](#); [Spatial joins in clusters](#)

Definitions

Given two collections R and S of spatial objects and a spatial predicate θ , the spatial join computes the pairs of objects (r, s) such that $r \in R$, $s \in S$, and $r \theta s$. Common spatial predicates are intersect, inside, and contains. For example, con-

sider a GIS application, where R is a collection of rivers and S is a collection of road segments. The spatial join of R and S finds the pairs of rivers and roads that intersect. If the spatial objects are points, the most common type of spatial join is the distance join, where θ is “*within distance ϵ from*”; here, ϵ is a given threshold. For example, assuming that R is the set of hotels on a city map and S is the set of restaurants on the same map, the distance join finds pairs of hotels and restaurants that are sufficiently close to each other (e.g., $\epsilon = 100$ m).

Overview

For objects with spatial extent, a common practice is to evaluate spatial joins (and queries in general) in two steps. During the *filter* step, the *minimum bounding rectangles* (MBRs) of the objects are compared, and if they do not satisfy θ , they are filtered out from consideration. During the refinement step, for each object pair that passes the filter step, θ is tested using the exact geometries of the objects.

A wide variety of spatial join algorithms have been proposed in the literature (Jacox and Samet 2007; Mamoulis 2009). Single-threaded spatial join techniques were first proposed for memory-resident data. Given the quadratic cost of a naive nested-loops approach, efforts were put into developing methods based on plane sweep, after sorting the data in one dimension (Preparata and Shamos 1985; Arge et al. 1998). These algorithms were later used as modules for joining larger datasets that do not fit in memory. In this case, the typical procedure is to partition one or both datasets with the help of a data structure, e.g., a spatial access method (Samet 1990), and then execute the join as a set of (independent) joins between partitions which can be accommodated in memory. Objects may already be indexed before join processing, as spatial indexes are also useful for other spatial queries, such as range selections and nearest neighbor search. As a result, spatial join algorithms have been proposed for both cases of non-indexed and indexed inputs.

Partitioning-based approaches may also improve the performance of in-memory joins, if the datasets are very large, in a similar manner as relational hash join algorithms. In the late 1990s, the research interest gradually shifted to parallel processing of spatial joins for shared-nothing and shared-memory architectures (Brinkhoff et al. 1996; Patel and DeWitt 2000). The developed approaches attempt to divide the problem into multiple independent smaller problems of similar cost, which are then processed in parallel. Finally, since the late 2000s, the focus is on processing of spatial joins in a distributed environment using the MapReduce or Spark frameworks (Eldawy and Mokbel 2015; Zhang et al. 2009; Xie et al. 2016) and on in-memory joins (Nobari et al. 2013).

Key Research Findings

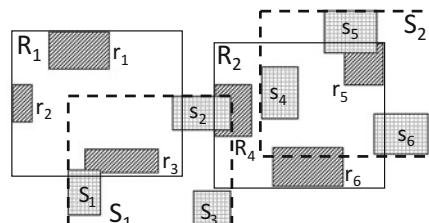

We will focus on the filter step of spatial intersection joins. Hence, the join inputs are considered to be two collections R and S of rectangles, and the objective is to find pairs (r, s) , $r \in R, s \in S$, such that r intersects s (i.e., r and s have at least one common point). Distance joins can be modeled as intersection joins, if we extend the objects in one of the inputs by ϵ in all dimensions and directions (Nobari et al. 2013).

For in-memory spatial join processing, plane sweep (Preparata and Shamos 1985) is a well-studied technique. The most commonly used version of plane sweep is suggested by Brinkhoff et al. (1993). The inputs R and S are sorted based on their lowest value in one dimension (e.g., the x -dimension). Then, the inputs are concurrently scanned (as in a merge join), and each encountered value can be considered as a stop position of a line that sweeps along the sorting dimension. For every encountered value (e.g., a lower x -endpoint $r.xl$ of a rectangle $r \in R$), the other collection (e.g., S) is *forward scanned* until an $s \in S$ whose $s.xl$ is *after* the upper x -endpoint $r.xu$ of r . All $s \in S$ found in the scan are guaranteed to x -intersect r , and a y -intersection test is performed on-the-fly. Other versions of plane sweep, based on maintenance of *active lists*

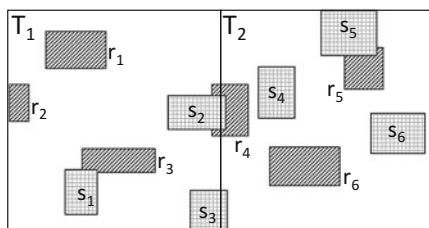

at every position of the sweep line, were studied in Arge et al. (1998).

Big spatial data may not fit in memory, and even if they do, it would be expensive to spatially join them using plane sweep. Given this, *data partitioning* has been used as a technique to break down the problem into numerous small problems each of which can be solved fast in memory. In a nutshell, objects are divided to groups based on their spatial proximity. A partition from R should then be joined with a partition from S if their MBRs intersect. Spatial join techniques which were proposed in the 1990s apply this approach. They can be classified into *single-assignment*, *multi-join* (SAMJ) methods or *multi-assignment*, *single-join* (MASJ) approaches (Lo and Ravishankar 1996). SAMJ methods partition the two datasets differently so that each object is assigned to exactly one partition, but a partition from R may have to be joined with multiple partitions from S . MASJ, on the other hand, may assign objects to multiple partitions, but each partition from R is joined with exactly one partition from S (which has exactly the same MBR). Figure 1a illustrates an example of SAMJ. The dark-gray rectangles belong to R , and they are partitioned to two groups R_1 and R_2 , while the light-gray rectangles belong to S , and they are divided into S_1 and S_2 . Group R_1 only needs to be joined with S_1 because its MBR is disjoint with that of S_2 . However, R_2 should be joined with both S_1 and S_2 . In Fig. 1b, MASJ is applied. The datasets are again partitioned to tiles T_1 and T_2 , and the data from R in each tile only have to be joined with the group of S in the same tile. However, objects $\{r_4, s_2, s_3\}$, which cross the borders of the two tiles, are replicated in both of them.

SAMJ is naturally applied when the two datasets are spatially indexed before the join by a separate spatial access method (e.g., a different R-tree for each input). The *R-tree join* (RJ) algorithm (Brinkhoff et al. 1993) takes as input two R-trees, which index R and S , respectively. RJ starts by finding all pairs of entries (e_R, e_S) one from each root node of the trees that intersect. For each such pairs, it recursively applies the same procedure for the nodes pointed by e_R and e_S , until pairs of leaf node entries (which

(a) multi-assignment, single-join (MASJ)

(b) single-assignment, multi-join (SAMJ)

Query Processing: Joins, Fig. 1 Two classes of partitioning techniques. (a) Multi-assignment, single-join (MASJ). (b) Single-assignment, multi-join (SAMJ)

correspond to intersecting object MBRs) are found. For example, if R_1 and R_2 (S_1 and S_2 , respectively) in Fig. 1a are the two children of an R-tree root that indexes R (S , respectively), then RJ would use their MBRs to determine that R_1 only needs to be joined with S_1 . To join each pair of nodes, plane sweep is used. RJ was later extended to a multiway join processing algorithm (Mamoulis and Papadias 2001) that applies to multiple R-trees.

One of the first MASJ approaches is *spatial hash join* (Lo and Ravishankar 1996). First, input R is read and partitioned to buckets, which are expected to fit in memory. The bucket extents are determined by sampling. The objects are divided to partitions that may spatially overlap each other, but each object goes into exactly one bucket. Dataset S is then partitioned to buckets that have the same extent as those for R , but an object from S is replicated to all buckets whose spatial extent overlaps. A 1-1 bucket-to-bucket join is then performed. The most popular MASJ approach is *partition-based spatial-merge join* (PBSM) (Patel and DeWitt 1996). PBSM divides the space by a regular grid, and objects from both join inputs are assigned to all tiles which spatially

overlap them. For example, in Fig. 1b, T_1 and T_2 could be tiles in a large rectangular grid that can be used to partition both R and S . We may have a huge number of tiles which have an uneven number of objects. In order to make the partitions as balanced as possible, we choose the number of tiles to be much larger than the number of partitions and then assign multiple tiles to each partition, such that the expected set of objects per partition fits in memory and the partitions are as balanced as possible. The assignment of tiles to partitions can be done in round-robin or by using a hash function. For example, assuming three partitions, tiles T_1, T_4, T_7 , etc. are assigned to partition 1; T_2, T_5, T_8 , etc. to partition 2; etc. In the join phase, for each partition, PBSM accesses the objects from R and the objects from S and performs their join in memory (e.g., using plane sweep). Since two replicated objects may intersect in multiple tiles (e.g., see r_4 and s_2 in Fig. 1b), duplicate results may be produced. In order to avoid duplicates, a join result is reported by a tile only if a prespecified reference point (e.g., the top-left corner) of the intersection region is in the tile (Dittrich and Seeger 2000).

Size separation spatial join (Koudas and Sevcik 1997) is a SAMJ algorithm that applies a hierarchical grid decomposition and avoids object replication. Objects are assigned to the smallest tile in the hierarchy that entirely contains them. All pairs of tiles that have an ancestor-descendant relation in the hierarchy are joined to each other. *Scalable sweeping-based spatial join* (Arge et al. 1998) divides the space to stripes according to one dimension and applies plane sweep at each stripe in the direction of the other dimension.

Join algorithms that apply on one indexed input (by an R-tree) take advantage of the index to guide the partitioning of the second (raw) input. One approach is to build a second R-tree using the existing tree to guide the MBRs of the top tree levels (Lo and Ravishankar 1998). Another approach is to use the existing R-tree to create bucket extents for hashing the raw input (Mamoulis and Papadias 2003) and then apply a hash join (Lo and Ravishankar 1996).

Early efforts on parallelizing spatial joins include extensions of the R-tree join and PBSM

algorithms in a distributed environment of single-core processors with local storage. Consider the case of joining two R-trees. Since overlapping pairs of root entries define independent join processes for the corresponding subtrees, these tasks can be assigned to different processors (Brinkhoff et al. 1996). Two tasks may access a common subtree; therefore, a virtual global buffer is shared among processors to avoid accessing the same data twice from the disk. An early approach in parallelizing PBSM (Zhou et al. 1997) asks processors to perform the partitioning of data to tiles independently and in parallel. Then, each processor is assigned one partition and processors exchange data, so that each one gets all objects that fall in its partition. The join phase is finally performed in parallel. A *partial spatial surrogate* approach (Patel and DeWitt 2000) replicates MBRs instead of entire tuples, while the exact object geometry is assigned to a single (home) node. In the join phase, each operator looks at the fragments of the declustered datasets residing on its local disks and joins them using any centralized spatial join algorithm.

Recently, the research interest shifted to spatial join processing for distributed cloud systems and multi-core processors. The popularity and commercial success of the MapReduce framework motivated the development of spatial join processing algorithms on clusters. The *spatial join with MapReduce* (SJMP) algorithm (Zhang et al. 2009) is an adaptation of the PBSM algorithm in this direction. Initially, the space is divided by a grid, and tiles are grouped to partitions in a round-robin fashion after considering them in a space-filling curve order. During the *map* phase, each object is assigned to one or more partitions based on the tiles it overlaps. Each partitioned object also carries the set of tiles it intersects. Each partition corresponds to a *reduce* task. The reducers perform their joins by dividing the space that corresponds to them into stripes and performing plane sweep for each tile. Duplicate results are avoided by reporting a join pair only at the tile with the smallest id where the two objects commonly appear. In the *Hadoop-GIS* system (Aji et al. 2013), spatial joins are computed in a similar fashion. The space

is divided by a grid to tiles, and the objects in each tile are stored locally at nodes in the HDFS. A *global index* that is shared between nodes is used to find the HDFS files where the data of each tile are located. The local data at each node are also locally indexed. Local joins are performed by each node separately, and the results are merged. The *SpatialHadoop* system (Eldawy and Mokbel 2015) follows a similar approach where a global index per dataset is stored at a Master node; however, different datasets may have different partitioning that could preexist before queries. If the two join inputs are partitioned differently, then two options exist: (1) use existing partitions and perform joins for every pair of partitions that overlap (they could be many) or (2) repartition the smaller file using the same partition boundaries as the larger file and apply MASJ. The cost of each of the two options is estimated, and the cheapest one is selected accordingly. Implementations of spatial joins using Spark, where the data, indexes, and intermediate results are shared in the memories of all nodes in a cluster, have also been proposed (You et al. 2015; Yu et al. 2015; Xie et al. 2016), with a focus on effective spatial indexing of the *resilient distributed datasets* (RDDs) that are generated during the process. Processing spatial joins in parallel with a focus on minimizing the cost of the refinement step was studied by Ray et al. (2014). During data partitioning, the exact geometries of objects are clipped and distributed to partitions (that may be handled by different nodes) in order to avoid any communication between nodes when object pairs whose MBRs intersect are refined.

In-memory joins were recently reconsidered, given that memories have become large and that applying plane sweep for big data inputs is too slow due to the large number of objects intersected by every position of the sweep line. Partitioning-based approaches, such as PBSM, can be used to break the problem into numerous small instances that can be solved fast (i.e., a divide and conquer approach). Algorithm *TOUCH* (Nobari et al. 2013) is a recent effort in this direction, designed for scientific applications that join huge datasets that have different density and skew. *TOUCH* first bulk-loads an R-tree for one

of the inputs using the STR technique (Leutenegger et al. 1997). Then, all objects from the second input are assigned to buckets corresponding to the non-leaf nodes of the tree. Each object is hashed to the lowest tree node, whose MBR overlaps it, but no other nodes at the same tree level do. Finally, each bucket is joined with the subtree rooted at the corresponding node with the help of a dynamically created grid data structure for the subtree. A comparison of spatial join algorithms for in-memory data (Nobari et al. 2017) shows that PBSM and *TOUCH* perform best and that the join cost depends on the data density and distribution.

Examples of Application

The amount of spatial data that are collected and need to be analyzed has exploded in the recent years, due to the wide use of mobile and sensing devices and the drop of equipment and telecommunication costs. The spatial join is a core operation in *spatial data management systems* (Güting 1994) and *geographic information systems* (GIS), which manage big amounts of spatial data. In GIS, for example, for a given map, we typically store different thematic layers (e.g., hydrography, road network) which may have to be joined in order to find pairs of elements (e.g., rivers and roads) that intersect.

Spatial joins are especially useful in scientific data analysis. For example, the *Sloan Digital Sky Survey* (Szalay et al. 2000) is a project that collects and analyzes multiple terabytes of sky data. Among the most useful operations for analyzing these data is the spatial join, which can be used as a component for clustering and other higher-level analysis tasks.

Spatial joins also find use in medical applications. For example, they can be used to facilitate the analysis of high-resolution images of human tissue specimens, which can lead to more effective diagnosis, prediction, and treatment of diseases (Aji et al. 2012). Another medical application of spatial joins is to determine neuron synapses in large spatial brain models, i.e., pairs

of neuron branches that are within very small distance to each other (Nobari et al. 2013).

Future Directions for Research

The refinement step of a spatial join can be much more expensive than the filter step if the objects have complex spatial extent. However, the focus of research has been on the filter step, and there is little work on optimizing the refinement step (Ray et al. 2014). Hence, there is room for improving the mechanisms for avoiding refinements wherever possible and for optimizing how refinements are implemented and scheduled in a distributed environment. Finally, for some classes of objects such as line segments, it might be more appropriate to directly use their geometric representation instead of approximating them by MBRs and design specialized join algorithms. In a recent work in this direction (McKenney et al. 2017), a multi-core spatial join algorithm based on plane sweep was designed for line segment collections.

Distance and nearest neighbor joins (Zhang et al. 2004) are evaluated by extending and adapting algorithms for intersection joins. Special algorithms that take into consideration the fact that such joins are typically conducted between point sets could be designed.

In most of the applications that manage spatial data, the data can be preprocessed and can easily fit in the memory of a single commodity machine. Therefore, it is questionable whether we need cloud computing algorithms for spatial joins. On the other hand, multi-core parallelism is gaining ground, so a promising research direction is to design good shared-memory parallel algorithms for spatial joins.

Queue Mining

Arik Senderovich
Mechanical and Industrial Engineering,
University of Toronto, Toronto, ON, Canada

Definitions

Queue mining is a set of data-driven methods (models and algorithms) for queueing analysis of business processes. Prior to queue mining, process mining techniques overlooked dependencies between cases when answering such operational

questions. To address this gap, queue mining draws from analytical approaches from queueing theory and combines them with classical process mining techniques.

Overview

Modern business processes are supported by information systems that record process-related events in event logs. *Process mining* is a maturing research field that aims at discovering useful information about the business process from these event logs (van der Aalst 2011). Process mining can be viewed as the link that connects process analysis fields (e.g., business process management and operations research) to data analysis fields (e.g., machine learning and data mining) (van der Aalst 2012).

This entry is focused on process mining techniques that aim at answering operational- or performance-type questions such as “does the executed process as observed in the event log correspond to what was planned?,” “how long will it take for a running case to finish?,” and “how should resource capacity or staffing levels change to improve the process with respect to some cost criteria?” (van der Aalst 2011, Chs. 7, 8). Throughout the entry, the term *operational process mining* is used to describe techniques that tackle such questions. Definition of process mining as well as other types of process mining methods, such as social network mining and process model visualization, is beyond the scope of this entry. Below, a historical background is presented. It comprises of existing techniques for operational process mining, along with queue mining methods that extend or improve these methods to accommodate inter-case dependencies.

Historical Background: Emergence of Queue Mining

Historically, process mining techniques overlooked dependencies between cases when conducting operational analysis. For example, state-of-the-art methods for predicting remaining times of running cases considered only historical

data of the case itself (van der Aalst et al. 2011), while the interactions among cases (e.g., through queueing for shared resources) were neglected. The independence assumption is plausible in processes where capacity always exceeds demand. However, in service processes, which are prevalent in numerous application domains (e.g., healthcare, banking, transportation), multiple customer-resource interactions occur, and customers often compete over scarce resources. Consequently, this understanding led to queue mining, which is a set of operational process mining solutions that consider case interactions when answering operational questions. In what follows, the entry surveys operational process mining, specifically, two main streams of work, namely, *model-based process mining* and *supervised process mining*.

Model-Based Process Mining. Early works on performance-oriented process mining were based on the enhancement of control flow models with further data-based information such as decisions, resources, and time (Rozinat et al. 2009). The work of Mărușter and van Beest (2009) extends this approach from modeling and analysis of an existing process to its improvement based on the discovered model. Due to the expressiveness of the discovered models, they can only be analyzed via simulation. Thus, these methods are referred to as simulation mining or model-based process mining, interchangeably.

To discover resource dependencies and roles in the business process, Song and Van der Aalst (2008) propose a method that is based on social network mining. Moreover, Burattin et al. (2013) discover roles and role handover by grouping activities and associating the resulting groups with resources.

In order to create unbiased models, one needs to consider several resource-related factors. For example, it is common to assume that resources work on an activity immediately as it is assigned to them. In reality, however, activities associated with different cases can be processed in batches, when enough work is accumulated. Discovering batch processing of work is key in creating accurate models. Previous work addressed the

discovery of batch processing when mining process models (Nakatumba and van der Aalst 2009; Martin et al. 2017).

Another aspect that can bias process models is related to assumptions on resource speedups and slowdowns when working on activities. In process models, it is often assumed that resources work in constant rates. Yet, previous research has shown that resources often increase and decrease their working rate, depending on stress levels (Wickens et al. 2015). In Nakatumba et al. (2012), the authors investigate the influences of varying processing rates on performance analysis and process discovery. Lastly, acknowledging that resources adhere to a predefined schedule and are not always present to work on activities should be considered when mining event logs for operational purposes (Liu et al. 2012).

The main benefit of model-based techniques is their ability to solve a large set of performance problems. For example, one can use simulation to predict waiting times and propose resource staffing. However, current simulation mining techniques overlook queueing effects by simulating process cases independently of each other and drawing waiting times (and other measures that stem from case dependencies) from fitted distributions. Furthermore, model-based mining techniques tend to overfit reality as it is observed in the event log, and therefore it was shown that simpler performance models often provide accurate results and are more efficient (Senderovich et al. 2015a). The expressiveness problem is partially addressed in Rogge-Solti and Weske (2015), where authors mine non-Markovian stochastic Petri nets (Haas 2002), which are simple formalisms that account for control-flow and exponential durations. In a queue mining technique proposed by Senderovich et al. (2015a), the best of both worlds is combined by a method for simulation mining that captures queueing effects and simplifies the resulting model. This simplification results both in improved efficiency (run-time complexity of the solution) and accuracy.

Supervised Process Mining. Another prevalent stream of work in process mining is the encoding

of event logs into well-established supervised learning methods. Examples for such methods can be found in van der Aalst et al. (2011), de Leoni et al. (2016), Polato et al. (2016), and Leontjeva et al. (2015). In these works, both the behavior and the operational aspects of the process are encoded: the former representing the control-flow perspective and the latter capturing activity durations and resources. While these approaches are often accurate in solving a given mining problem with respect to a set of performance measures observed in the event log (e.g., total time in process), it has two major drawbacks.

First, one cannot use these techniques for quantifying measures that are not directly observable in the log. For example, information that allows one to calculate resource utilization might be missing from the event log, and thus supervised approaches cannot be applied. Second, exploring process improvement directions and sensitivity of process parameters (e.g., durations and arrival rates) is impossible due to the lack of data that describes the effect of changing these parameters. In Gal et al. (2015) and Senderovich et al. (2015b), queue mining solutions bring together the benefits of model-based mining (or simulation mining) and supervised learning. Specifically, these solutions comprise machine learning methods (e.g., decision trees) and queueing models. This combination enables quantifying measures that were not observed in the event log due to the existence of the model. For measures that appear in the event log, one can get accurate solutions by exploiting the strengths of supervised learning (Hastie et al. 2001). Furthermore, one is able to obtain what-if reasoning based on the queueing model, without the need to acquire further data from the changed process. To summarize, queue mining:

- Integrates data-driven queueing models and their analysis into operational process mining (Senderovich et al. 2014, 2015a,b,c, 2016b; Gal et al. 2015).
- Links operational conformance analysis to performance improvement in business

processes (Senderovich et al. 2016b). Specifically, we develop a methodology for the detection of problematic areas in a process (e.g., due to synchronization or resource delays) and propose proper adjustments to queueing policies (selection of the next case to enter service) in these problematic parts.

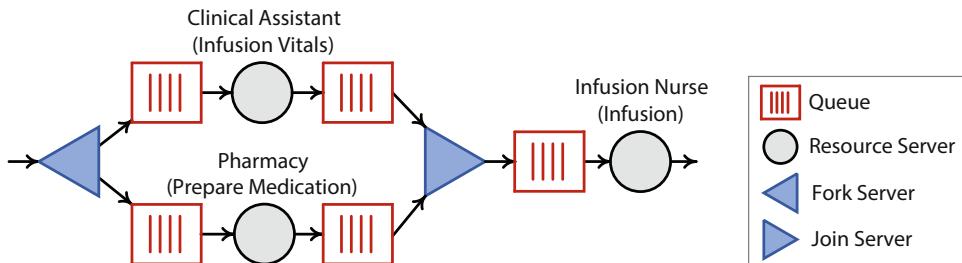

- Offers hybrid methods that combine supervised learning and model-based process mining techniques to improve the accuracy of answering operational questions (Senderovich et al. 2015b; Gal et al. 2015). This combination improves accuracy with respect to applying the two approaches separately.

The proposed queue mining methods were validated based on real-world applications and their corresponding datasets coming from various service domains. The details of these applications and datasets appear in section “[Examples of Applications](#).“ To conclude the overview, the entry offers an elaboration on queue mining basic ideas and methods.

Foundations of Queue Mining

Queue mining methods are based on process models that are referred to as queueing networks. An example of a queueing network appears in Fig. 1. The network depicts the queueing perspective for the patient flow in an outpatient hospital in Boston. The model contains servers (or resources), edges that correspond to routing, three resource queues (preceding resources), and two synchronization queues (succeeding resources). Queues are defined implicitly before and after their respective servers. The example, Fig. 1, contains three resource constructs as well as a fork and a join. The fork and join constructs correspond to AND gateways in control-flow models.

Discovery of a queueing network from an event log involves the identification of the network structure or control-flow (see van der Aalst 2011, Ch. 5 and the references therein), an estimation of routing probabilities (Senderovich et al. 2016b), and a characterization of server

Queue Mining, Fig. 1 Patient flow: an outpatient hospital in Boston

dynamics (Senderovich et al. 2015b). When a queueing network is discovered, one may employ numerous techniques from queueing theory to analyze performance based on the network (see Bolch et al. 2006 and the references therein). For example, one may use a queue-length-type predictor to estimate the expected waiting time in a station (Ibrahim and Whitt 2009; Senderovich et al. 2015b). These queue mining techniques are referred to as *model-based queue mining*.

second approach for the analysis is by using the resulting queueing network in combination with historical data (i.e., the event log) for constructing an improved supervised learning framework (Gal et al. 2015). The latter approaches are referred to as *supervised queue mining*. The two approaches clearly correspond to the ideas of *model-based process mining* and *supervised process mining*, respectively. Below, the entry briefly explains the two approaches based on a prediction operational problem.

Model-Based Queue Mining. Depending on the complexity of the resulting queueing network, we may apply different queueing analysis techniques ranging from simulation to tractable steady-state analysis (Bolch et al. 2006). If the model is a complex network of queues with concurrency and multiple customer classes, the analysis will rely mainly on stochastic simulation (Rubinstein 1986; Glynn and Iglehart 1988) or approximation techniques (Whitt 1983; Chen and Yao 2013). In contrast, for simple networks that do not present time fluctuations, one may apply closed-form results from, at

steady state, classical queueing theory (Kelly 1975; Bramson 2008; Jackson 1957).

Here we give an example of a discovered single-station single-class network with $G/M/s$ server dynamics, i.e., a general arrival process with i.id. inter-arrival times, i.id. exponentially distributed service times, and s independent homogeneous service providers. Further, the service policy is assumed first-come first-served; we propose methodologies for learning the policy from data and testing whether an assumed policy holds (Senderovich et al. 2014, 2015c).

Based on the resulting model, we may apply a well-known predictor named the queue-length predictor (QLP) (Whitt 1999). As its name suggests, it exploits the queue-length ahead of the customers whose delay time we wish to predict. The QLP was shown to work well with no abandonments. However, it fails when abandonments are prevalent (e.g., in call center scenarios) (Senderovich et al. 2015b). Further, queue-length predictors as well as other queueing theory techniques are mined, tested, and extended based on real-world call center data in Senderovich et al. (2015c).

Supervised Queue Mining. Supervised queue mining considers incorporation of queueing analysis into machine learning methods. Currently, the idea comprises two basic approaches: (1) feature enrichment and (2) model adaptation.

Approach 1: Feature Enrichment. In this approach, we define (feature) construction functions that transform event data into queueing features. These functions rely on the discovered

queueing model, which contains information that reflects dependencies among running cases. The resulting queueing features are assumed to better explain operational performance measures. Note that with this approach, the learning method (e.g., a linear regression) is used out-of-the-box.

To illustrate the approach, consider an event log with the following basic features: case identifier, activity, and timestamp. Applying a construction function that is based on the discovered queueing network to these features can result in new queueing features, e.g., waiting time of the head-of-the-line and current queue-length. Subsequently, these queueing features are plugged into a learning method of choice (e.g., linear regression, regression trees, and random forests). This substitution was found to significantly improve prediction accuracy in Senderovich et al. (2015b) and Gal et al. (2015).

Approach 2: Model Adaptation. An alternative approach to the aforementioned feature enrichment is an adaptation of the learning method itself, based on the discovered queueing network. For example, in Gal et al. (2015), a gradient tree boosting method that comprises multiple learners (decision trees) was extended (Friedman 2001). Every learner is built on top of the other iteratively. In Gal et al. (2015), the first predictor was based on a well-established result in queueing theory, which we refer to as the snapshot principle (Gal et al. 2015; Senderovich et al. 2015b). The other predictors were plain decision trees, which were constructed via boosting based on the initial queueing predictor. In Gal et al. (2015), it was shown empirically that the proposed method improves prediction accuracy both over the gradient tree boosting algorithm without the snapshot predictor and over the snapshot predictor when it is applied without a learning procedure.

As a concluding remark, it is worth mentioning that queue mining is limited neither to the discovery of a single queueing model nor to the application of a single technique for solving one operational mining problem. On the contrary, given a set of problems, one is advised to discover different queueing models for the different types of analysis. Our studies show

that, for time prediction, one would prefer a simple queueing model over complex simulation models. The former gives rise to accurate and efficient solutions. In contrast, for conformance checking, a complex queueing network is preferable, since it allows one to capture deviations in multiple dimensions, e.g., durations, resources, and customer classes. Therefore, queue mining can be viewed as a variety of solutions that can be combined to solve a set of operational mining problems.

Examples of Applications

In this part, the effectiveness of queue mining techniques is demonstrated on three real-world applications, namely, online delay prediction, root cause analysis, and process improvement. Furthermore, experiments that show the empirical value of queue mining were based on real-world data from three domains: banking (a bank's call center), transportation (city buses), and healthcare (an outpatient hospital).

Online Delay Prediction

The first problem that was addressed by queue mining was to predict delays of arriving cases, in real time. To this end, two sets of predictors were considered: learning-based and model-based.

The first set of predictors took traditional approaches to supervised learning as a starting point and extended the existing regression-based techniques for time prediction, e.g., (van der Aalst et al. 2011), to consider queues and system load. A second set of predictors originated from queueing theory (Hall 1991; Bolch et al. 2006) and leveraged properties of a queueing model, potentially under a widely known congestion law (the snapshot principle).

Further, queue mining studies have found that delay prediction is sensitive to classifications of cases. In a single-class setting, all cases are of a uniform type, and delay prediction relates to a single queue of cases. In a multi-class setting, in turn, cases are classified by a certain type that

influences how cases are enqueued. Hence, delay prediction relates to a specific case type.

By taking the above considerations into account, it was shown that queue mining techniques significantly improve delay prediction (Senderovich et al. 2015b). The experiments were conducted on several real-world datasets, and the developed methods yielded an improvement in various performance measures.

The results were extended to networks of queues with predefined and random routing in Gal et al. (2015) and Senderovich et al. (2016a), respectively.

Root Cause Analysis

The next application of queue mining was root cause analysis (RCA) (Senderovich et al. 2016b). The goal was to discover deviations between actual executions of scheduled business processes and the underlying schedule or plan that govern such processes. Example for such processes can be found in healthcare (appointment book is the schedule) and in public transportation (bus timetable is the schedule).

The proposed method comprises of two main steps. First, deviations in performance measures are quantified. For example, if waiting times were longer than the corresponding planned buffers, they are classified as a deviation. Clearly, these deviations must be tested statistically for their significance (Senderovich et al. 2016b).

Next, these deviations are connected to local deviations in the queueing network that arises from the data. The network's building blocks (arrival rates, service times, capacities, and service policies) are compared against the predefined counterparts from the schedule. For example, if 5 doctors were scheduled between 8:00AM and 9:00AM, and the number of doctors during that time has a distribution, the actual number that arrived to work (say 6) is compared to the median via a statistical test. If a deviation is found in these building blocks, then a root cause for waiting time discrepancies is announced.

The underlying assumption in this method is that deviations from schedule drive local differ-

ences in terms of performance measures (e.g., waiting times and queue lengths).

An example for a root cause analysis that was conducted on a real-world hospital's dataset is as follows. In a large cancer hospital in the United States, queue mining techniques were able to show that deviations in production policy of chemotherapeutic drugs in the pharmacy were a root cause for the delays in the process.

Process Improvement

The aforementioned root cause analysis detects parts of the process that fail to conform (conceptually or operationally) to a given schedule. Here, the focus switches is on how to handle the detected problems by introducing a methodology for process improvement, which combines data-driven analysis via the queueing network, and principles from scheduling research (Pinedo 2012).

Provided with the queueing network (see, e.g., Fig. 1) which corresponds to some underlying business process, one may aim at a local improvement of the service policy, given problematic areas. We assume that splits and joins have a single layer of resource nodes, a plausible assumption since multiple stages can be aggregated into such a construct (Senderovich et al. 2015a).

default, processes often operate under the earliest due date (EDD) first service policy per node, thus “optimizing” schedule-related performance measures (e.g., non-punctuality). Assuming that all cases are available at the beginning of the scheduling horizon, it is indeed optimal to use the EDD policy. However, when cases arrive into the system at different times (according to schedule), one can show that the EDD policy can be improved to achieve lower tardiness. Moreover, using queue mining, one can show that without losing punctuality, the proposed algorithms may also improve other performance measures such as flow time. This is achieved by considering synchronization delays in concurrent processing and by partially reordering EDD-ordered cases in a first-come first-served order.

Future Research Directions

Future research in queue mining can be divided into two categories with respect to the following dimensions: (1) model-based vs. supervised queue mining and (2) predictive vs. prescriptive analysis.

The first dimension corresponds to the representational choices of the underlying data and process. Model-based approaches can be extended with further components of queueing models. For example, the queueing networks can be enhanced with additional constructs, such as shared resources, which were not previously considered as part of queue mining. For supervised queue mining, future work may include a feature encoding method that would not assume any prior process knowledge. Specifically, queueing insights provide with natural metrics to measure distances between running cases. This allows for the abandonment of strict assumptions on the underlying queueing system. For example, the snapshot features can be considered special cases of more general temporal distance functions that measure proximity between sequences.

The second dimension addresses the questions that one wishes to answer with queue mining. Continuing the predictive direction, one could consider additional tasks beyond time prediction. For example, one may analyze the utilization profile of resources and aim at predicting the time that resources will return from breaks and other types of idle periods. For the prescriptive direction, a natural extension of queue mining would be to further advance into optimization of processes. For instance, having observed historical decisions (e.g., the ordering of customers waiting in queues) can an optimal decision-making policy be automatically devised from data. Although the task bears similarities to predictive analysis, it also differs in that the decision policy must also accommodate situations that were not observed in the data. Hence, a combination of statistical causal inference methods, and queueing modeling, must be considered. Consequently, queue mining would serve the bridge between statistical analysis, optimization, and process management

and mining. Lastly, one of the current topics considered in future work is the construction of a unified tool that brings all aspects of queue mining (modeling and analysis) in a software package. This would enable researchers and practitioners to add and use implementations of novel queue mining methods.

R

R Language: A Powerful Tool for Taming Big Data

Norman Matloff¹, Clark Fitzgerald², and Robin Yancey³

¹Department of Computer Science, University of California, Davis, CA, USA

²Department of Statistics, University of California, Davis, CA, USA

³Department of Electrical and Computer Engineering, University of California, Davis, CA, USA

It should be noted that Big Data can be “big” in one of two ways, phrased in terms of the classical $n \times p$ matrix representing a dataset:

- **Big-n:** Large number of data points.
- **Big-p:** Large number of variables/features.

Both senses will come into play later. For now, though, back to R. Some general information about the language will be presented first, as foundation for the Big Data aspects.

Overview

Definitions

The R language (R Core Team 2017; Chambers 2008; Matloff 2011) is currently the most popular tool in the general data science field. It features outstanding graphics capabilities and a rich set of more than 10,000 library packages to draw upon. (Other notable languages in data science are Python and Julia. Python is popular among those trained in computer science. Julia, a new language, has as top priority producing fast code.) Its interfaces to SQL databases and the C/C++ language are first rate. All of this, along with recent developments regarding memory issues, makes R well poised as a highly effective tool in Big Data applications. In this chapter, the use of R in Big Data settings will be presented.

In terms of syntax, R, along with Python, C/C++, and many others, is ultimately a descendant of ALGOL, and thus a programmer in one of those languages can quickly pick up at least a rough “reading knowledge” of R.

As with Python, R is an *interpreted* language, meaning it is not translated to machine code, unlike the C/C++ language. The interpreted nature of R brings up possible performance issues, a topic to be discussed in section “[Uniprocessor Performance Issues](#)”.

From a programming style point of view, R (to various degrees) follows the *object-oriented* and *functional programming* philosophies. Some computer scientists believe that they lead to clearer, safer code, and this has influenced the design of R. This in turn will have implications for all R users, as will be explained.

Vectors and matrices are similar to one- and two-dimensional arrays in C. A *list* is like a vector, but with possibly different modes. A *data frame* looks like a matrix, but its columns can be of different modes, e.g., numeric in some, character in others, and logical in still others. These structures are intrinsic parts of the R language, as opposed to add-ons in the case of Python.

Subsetting is a major operation in R. For instance,

```
> d <- data.frame(x=c(5,12,13), y=c(8,88,888))
> da <- d[c(1,3),]
> d
      x     y
1 5     8
2 12    88
3 13   888
> da
      x     y
1 5     8
3 13   888
> row.names(da)
[1] "1" "3"
```

Such information could be quite useful and is attained without adding an extra column in the data frame that may need to be excluded in subsequent statistical computations.

One of R's most lauded features is its ability to produce beautiful, highly expressive graphics, in a manner accessible to even nonspecialists. Base R graphics is used for simpler plots or for advanced applications operating at a more finely detailed level (Murrell 2011; Chang 2013). For higher-level applications, the **ggplot2** (Wickham 2016) and **lattice** (Sarkar 2008) packages are quite powerful and are widely used. Another notable graphics package is Plotly (Plotly Technologies Inc. 2015), which produces especially esthetically appealing figures. A quite usable R interface is available.

`m[c(1,4,5),]`

is the submatrix of the matrix **m** consisting of rows 1, 4, and 5 of that matrix.

A seldom cited but widely used and very handy feature of R is the ability to set names of various data elements. For an example of how this can be useful, suppose one has a large data frame, and then split it into chunks of rows according to some criterion. The original row names will be retained:

Uniprocessor Performance Issues

As mentioned, R is an interpreted language, which raises performance concerns. The chief remedy is *vectorization*, referring to the fact that vector operations should be used instead of loops.

Vectorization and R as a Functional Language

First, the functional language nature of R is reflected in the fact that, for instance, the `+` operator is actually a function. The expression `x+y`, for vectors `x` and `y`, is actually the function call `'+'(x,y)`. The key point is that function is written in C, not in R. (This should not be confused with the fact that R itself – meaning the R interpreter – is written in C.) Thus C-level speed is attained, which could be an issue for very long vectors.

By the way, `<-` is a function too. So, `z <- x + y` is actually

```
'<-'(z, '+'(x, y))
```

It turns out that many R expressions can be vectorized. For instance, the `ifelse()` function vectorizes the classical if–then–else construct:

```
> x <- 1:3
> y <- c(5, 12, 13)
> ifelse(y > 8, x, x+1)
[1] 2 2 3
```

Interfacing R to C/C++

But in some R applications, vectorization is not enough; the general speed of C must be obtained directly, i.e., entire R functions must be written in C. For instance, `dplyr`, a popular R package for manipulation of data frames, is written partly in C, and `data.table`, an extremely fast (but compatible) alternative to data frames (section “[Data Input/Output, etc. with data.table](#)”), is based largely on C++.

This is a standard approach in the use of scripting languages such as R and Python. Typically only a portion of one’s code requires high performance. It thus makes sense to write that portion in C/C++ while retaining the convenience and expressiveness of R/Python for most of one’s code.

R has two main functions, `.C()` and `.Call()`, for calling C/C++ functions from R code. They are fairly easy to use, and many R programmers use another popular R package, `Rcpp`, that aims to further simplify the R/C interface process (Eddelbuettel 2013).

Interfaces that allow R code and Python to call each other are also available, such as the `rpy2` package.

R and Big Data

The sheer size of Big Data calls for parallel computation, either on multicore machines or clusters. (Define a *physical* cluster to be a set of independent machines connected via a network. Later, *virtual* clusters will be introduced, which

will consist of a number of R invocations running independently. They may be running on a physical cluster, a multicore machine, or a combination of the two.)

Note carefully that the issue is not only one of computation time but also of memory capacity. The latter point is just as important as the former; an application may be too large for a single machine, but if the data is broken into chunks and distributed to the nodes in a cluster, the application might be accommodated.

A detailed treatment of parallel computation in R is given in Matloff (2015). An overview is presented here.

Memory Issues

Earlier versions of R, 2.x.x, set a limit of $2^{31} - 1$ bytes for object size. For modern 64-bit machines, this limited vectors, for instance, to about 250 million numbers, which was not sufficient in certain Big Data contexts. R 3.x.x changed this limit to about 2^{52} , more than enough for even the biggest of Big.

Thus the constraint faced by most people in the R community is not in R limitation on object size, but in the memory sizes of their machines. R stores all objects in memory, so memory size may be an issue in R applications in Big Data.

The bigmemory Package

One solution is the `bigmemory` package (Kane et al. 2013), which offers programmers a choice between storing objects in memory or on disk, with the latter option being attractive on machines with only moderate amounts of RAM. The key point is that from the programmer’s point of view, the data look like they are in memory.

Objects of class `bigmemory` must be of matrix type. A vector is represented as a one-row or one-column matrix and a scalar as a 1×1 matrix.

Recall that operators like `+` are actually implemented as functions. The array indexing operator `[` is another example of this. What `bigmemory` does is replace R’s `[` function by special-purpose C++ code that relays the requested data reference to either memory or disk, according to what the user’s code originally requested.

Another advantage of **bigmemory** among many of its users is that it provides a workaround to R’s “no side effects” policy, which comes from R’s status as a functional language. What this means is that a function call should not change any of its arguments.

For example, the statement

```
sort(x)
```

will *not* change **x**. It returns the sorted version of **x**, but **x** itself doesn’t change. If one wants that change, one needs to write

```
x <- sort(x)
```

Now consider the innocuous-looking statement

```
z[5] <- 8
```

As noted, assignment is a function call, in this to the function '`[<-`'. Under a no-side-effects policy, this would be implemented internally as

```
z <- '[<-'(z, 5, 8)
```

with the right-hand side returning a *new* copy of **z**. In a Big Data context, the creation of this new vector could be quite costly in execution time.

Recent versions of R try to avoid this to some extent, but by placing **z** in a **bigmemory** object, the problem is definitely avoided.

Other Ways to Circumvent Memory Size Problems

As noted, one solution to this problem is to exploit the fact that **bigmemory** can store an object on disk but have it appear to the programmer as if it were in memory. Two other methods are common:

- If one is running on a cluster, one can use the data in distributed form, with one chunk of the data at each cluster node. The chunks may fit into memory even if the full data does not.
- If the data is stored on disk in an SQL database, various R packages for interfacing to SQL are available, such as **RMySQL**.

In such settings, it may also be useful to then use a Software Alchemy approach; see sections “[Distributed Computation](#)” and “[Software](#)

[Alchemy](#)”. Or in the cases in which the application algorithm needs only sums, such as linear regression models, one can read in data chunk-by-chunk, updating the sums at each stage.

Threaded Code

The standard mechanism used for parallel computation by multicore programs in C/C++ is *threaded* code (Matloff 2015; Breshears 2009). Here several copies of one’s code run simultaneously, sharing global data. That latter trait is key. For many algorithms, efficient parallelization requires shared-memory computation. If one has a multicore machine (or a manycore coprocessor, such as the Intel Xeon Phi) and the problem can fit into available memory, threaded programming of some kind is needed.

Roughly, here is how threads work. Say, for instance, the threads are executing some iterative algorithm. At the end of each iteration, each thread will need to know the results of the executions of the various threads, as this will determine the course of action in the next iteration. Accessing shared variables for this kind of action is the essence of threaded programming.

Threads systems must have some form of “lock” variables to avoid *race conditions*. That term refers to a situation in which two threads attempt to change a certain variable at approximately the same time, possibly resulting in incorrect results. A lock variable assures that only one thread at a time can access the sensitive variable.

Threads in C/C++

Say one wishes to find the sum of a very long array **x** of length **n**, with four threads. Each thread would have an ID, 0, 1, 2, or 3, stored in the variable **myID**. Each thread would have its own running sum, stored in **mySum**. The code would look something like this:

```
parfor (i = 0; i < n; i++) {
  if (i % 4 == ID) mySum +
    = x[i];
}
// lock the lock (not shown)
tot += mySum;
// unlock the lock (not shown)
```

Here “parfor” means that all the threads would execute the loop simultaneously. (The variables **myID** and **mySum** would be local to each thread, while **tot** would be global to all.)

Typically one does not write threaded code directly, opting instead to use a higher-level interface to threads, the most widely used being OpenMP (Breshears 2009). Intel’s Threads Building Blocks (Reinders 2007) may produce faster code, but requires more programming skill (and patience), as it is more complex and uses C++ templates.

Threads in R

Scripting languages typically do not offer true threads programming. Python threads, for instance, must use something called the global interpreter lock, which prevents parallel execution of threads. Julia threads are, as of this writing, experimental.

R does not offer threading at all. However, one can still write threaded applications, in one of two ways:

- If one wants to limit one’s code to R, a quasi-threading environment is provided by the **Rdsm** package (Matloff 2015). It runs on top of the **bigrmemory** system discussed earlier, as well as atop the **parallel** package that is included with base R (section “[partools](#)”).

To see how this works, let’s again consider our earlier example. **Rdsm**, in creating a shared variable **z** – in memory, not on disk – will save on disk information as to where in memory **z** resides. If one then has multiple invocations of R running simultaneously, they can all access that same memory location, and thus share **z**, thus attaining the essence of threaded code.

In the array-summing example above, the programmer would call a **parallel** function, **splitIndices()**, to explicitly assign values of **i** to the various threads. Instead of an explicit loop, the code would be vectorized, looking something like this, using the built-in R function **sum()**:

```
myIndices <- splitIndices
(etc .)[[myID]]
```

```
mySum <- sum(x[1, myIndices])
# lock the lock variable
# (not shown)
totx[1,1] <- totx[1,1] + mySum
# unlock the lock variable
# (not shown)
```

Here **x** and **totx** are variables in shared memory.

- One can have one’s R code access C/C++ code that does threading, say using OpenMP. In the above array-summing example, the C code could be used without change. (The R system file **R.h** must be included.)

The **data.table** package is written largely in C++ and makes use of OpenMP.

Another important example is the Basic Linear Algebra Subroutines (BLAS) library. Lots of BLAS libraries exist, and when building R one has the option of using one other than what is included in the R source code. One that is very fast is OpenBLAS, which again uses OpenMP to run threads.

Message-Passing Parallel Code in R

In addition to the shared-memory world view seen above, another paradigm of parallel computation is *message-passing*. Here, instead of having different processes communicate via shared variables, they explicitly send information to each other.

This approach is generally used on clusters rather than multicore machines, though many users do use it on the latter as well. In either case, it must be kept in mind that a major source of speed-sapping overhead is the time spent sending the messages, especially in the cluster case. For this reason, these approaches are generally efficient only in settings in which the time between network accesses is long. This in turn means the application is such that a large amount of computation is done between network accesses, a situation known as *coarse-grained parallelism*.

It should be repeated, though, that for many large problems, memory size is the overriding constraint. In such cases, a message-passing approach on a cluster may be the only feasible solution.

The “parallel” Package

A workhorse of parallel computation in R is the built-in **parallel** package. Its main virtue is its conceptual simplicity; users can readily write their own **parallel** code after seeing a few examples.

The package was adapted from the previous user-contributed packages **snow** and **multicore**. The focus here will be on the former case, which implements *scatter/gather* operations.

As with **Rdsm** (and **ddr** below), there will be many independent invocations of R. When the

user starts R, let’s refer to that as the “manager” invocation. It launches new invocations of R, termed “workers.” One writes code to run on the manager that distributes data to the workers – the *scatter* phase – and sends the workers commands to execute on the data given them. They return results, which are *gathered* at the manager. The latter pieces them together to obtain the desired outcome.

Here is a simple example, again involving an array-summing operation, in parallel over the workers:

```
library(parallel)
cls <- makeCluster(2)
x <- c(5,12,13,8,88)
clusterExport(cls, 'x')
clusterApply(cls, 1:2, function(i) myID <- i)
clusterEvalQ(cls, library(parallel))
clusterEvalQ(cls, myIndices <-
  splitIndices(5,2)[[myID]])
Reduce(sum(clusterEvalQ(cls, sum(x[myIndices])))
```

All this runs on the manager. It first makes a virtual cluster of two workers, meaning two new invocations of R connected to the manager. It then creates an example vector **x** and “exports” it to the workers. (This is not very efficient, as each worker needs only part of **x**.) Next, it sets up an ID at each worker, by applying the given function to (1,2) at the workers. Then it loads the **parallel** package at each worker; the function **clusterEvalQ()** simply instructs each worker to execute the given code locally. Next it runs

```
clusterEvalQ(cls, myIndices
  <- splitIndices(5,2)[[myID]])
```

This instructs each worker to assign to **myIndices** as indicated. The call to **splitIndices()** returns

```
[[1]]
[1] 1 2

[[2]]
[1] 3 4 5
```

i.e., an R list whose first component is (1,2) and the other (3,4,5). The purpose of this is to have Worker 1 handle elements 1 and 2 of **x**, while Worker 2 will handle the rest. After execution of the above statement, the variable **myIndices** will have the value (1,2) at Worker 1 and (3,4,5) at Worker 2.

Finally, there is the **Reduce()** call. Inside is a call to **clusterEvalQ()**, which has each worker sum its portion of **x**. That call returns to the manager an R list consisting of the two sums, 17 and 109. **Reduce()** then repeatedly applies **sum()** to each element of that list, resulting in the full sum 126.

As can be seen, compared to the shared-memory paradigm, the programmer must do quite a bit of work just for this simple operation. This is typical of message-passing systems. Many programmers use the **foreach** package (Weston 2017) as a simpler, more convenient wrapper for **parallel** in situations in which the main goal is to parallelize a loop.

Rmpi

A major limitation of **parallel** is that communication is possible only between a worker and the manager. The **Rmpi** package (Yu 2014), based on the famous C/C++/FORTRAN message-passing library MPI (Nielsen 2016), is much more general, allowing direct communication from any worker to any other. For some applications, this can increase performance tremendously.

Rmpi is more complex to program (and to configure) and thus is too involved to present in further detail here.

Distributed Computation

One sees much in the press about the Hadoop and Spark frameworks. These have been proven quite effective on very large systems for simple tabulatory computations such as sums, counts, and data grouping. And they do have R interfaces for them, e.g., **sparklyr** (Luraschi et al. 2017).

However, a major drawback to these frameworks is that one essentially must do a global sort after each operation, whether needed or not, potentially quite a drain on speed. Though Spark is a major improvement over Hadoop, neither is well-suited to the more complex statistical and data-wrangling operations typical in data science. Here two alternatives are presented.

Both of the packages in this section operate with distributed data. For instance, say **z** is a data frame with 10 million rows, and one has 4 workers in a cluster in the above sense. One could store 2.5 million rows at each worker, and to the degree possible and as long as possible, the data is

```
clusterEvalQ(cls, convert factors to dummy variables)
clusterEvalQ(cls, replace NA values by means)
clusterEvalQ(cls, remove outliers, say by a "3 sigma" rule)
calm(cls, regression formula)
```

That last function call implements Software Alchemy, to be explained in section “[Software Alchemy](#)”. It runs the R **lm()** linear model function at each cluster node and combines the results to obtain the overall estimated regression coefficients.

kept distributed in that manner, over the course of many data and statistical operations. In the above scatter/gather terms, one scatters but then avoids gathering for as long as possible. The goal, of course, is to avoid costly network communication delays. Informally let’s call this policy “Leave It There” (LIT).

LIT is a very simple idea, yet a very powerful one.

partools

Both Hadoop and Spark are typically run on distributed file systems. The **partools** package (Matloff et al. 2017a), which runs on top of **parallel**, is predicated on the view that this is the best approach, but that the operation structures of Hadoop and Spark, with frequent network communication and disk read/writes, are unsuited for statistical/data science applications.

Again, consider a simple example of four workers. One might store the data in four files, **x.1**, **x.2**, and so on. The manager code would execute something like

```
file.read(c1s, 'x', 'x', 1)
```

Here **cls** is the name of the virtual cluster; the basename of the distributed file is “**x**”; and one wishes the distributed data frame at the virtual cluster nodes to also be named “**x**.”

Execution of the distributed program proceeds mainly with manager calls to **clusterEvalQ()**, instructing the workers to perform certain tasks. For instance, in a linear regression problem, the code at the manager might look like this:

R

Note that the data, even after various operations have been performed, is *still* distributed, available for further distributed operations, again following the LIT philosophy. And at the end of the session, the user can save the modified distributed data frame to a distributed file.

Numerous utility functions are available, including ones to convert data between distributed and monolithic forms: **distribsplit()**, to convert a monolithic data frame to a distributed one, and **distribcat()**, to go in the opposite direction.

The package also includes a number of statistical and tabulatory functions to do non-LIT operations, such as **distribagg()**, which performs the R **aggregate()** function at each node and then combines appropriately.

In addition, **partools** offers direct point-to-point communication between cluster nodes, which greatly extends the ability to write fast parallel code. One of the applications of that facility is an implementation of the Hyperquicksort distributed sorting algorithm.

```
library(ddR)
chunk <- 2
nc <- 5
n <- chunk * nc
x <- as.darray(matrix(rnorm(n)), psize = c(nc, 1))
y <- as.darray(matrix(rnorm(n)), psize = c(nc, 1))
setMethod("-", signature(e1 = "ParallelObj",
                        e2 = "ParallelObj"),
           function(e1, e2) {
             dmaply(`-`, e1, e2, output.type = "darray",
                   combine = "cbind")
           })
delta <- x - y
as.vector(collect(delta))
```

The package uses R’s S4 object-oriented programming model to define operations on distributed objects, in this case subtraction. The S4 function **setMethod()** is shown above to define subtraction between two objects of class **ParallelObj**, creating a third object of that class.

Software Alchemy

Real-world Big Data applications on parallel platforms tend not to be “embarrassingly parallel,” due to inter-process communication costs. This can severely limit potential speedup.

ddR

In designing a package for distributed computation, one desirable trait would be (at least near) compatibility with existing serial code, enabling software reuse. The **ddR** package (distributed data in R) satisfies this criterion, defining distributed versions of some R data structures, including arrays, lists, and data frames. Several algorithms have been implemented in this framework, such as generalized linear models and random forests. The package runs on top of **parallel** or another HP product, **distributedR**.

Here is an example of **ddR** code to initialize and subtract two distributed matrices.

Fortunately, for statistical/machine learning applications, this frequently can be resolved by a method also known as “Software Alchemy” (SA) in Matloff (2016). Here the data is divided up into chunks which are distributed to each available cluster node, and one averages all the results of the same computation from each process. In this way we “alchemically” transform the original problem into an embarrassingly parallel problem that produces a statistically equivalent result: The asymptotic covariance matrix of the SA estimator can be shown to be the same as that of the estimator based on the full set, i.e., it achieves

the same accuracy. (It should be noted that the speed of convergence of the asymptotics may depend on p , the number of variables/features in the full dataset (Bühlmann et al. 2016).)

Theoretically, the speedup can be derived in time complexity terms. Suppose the complexity of the full algorithm is known to be $O(n^d)$, where n is the number of data points. Let r denote the number of worker threads. Then the SA complexity will be approximately $O[(n/r)^d] = O(n^d/r^d)$, a speedup of about r^d . If $d > 1$, this would be a superlinear speedup, a rarely seen event in the parallel computation world, but that has appeared experimentally in plots of the output using SA (Matloff 2016). (The same analysis shows, interestingly, that one obtains a speedup even in the serial case, for $d > 1$.)

Our experiments so far have shown SA to be useful for several widely used machine learning algorithms. For example, consider the famous Forest Cover dataset in the UCI Machine Learning Data Repository (Lichman 2017), consisting of half a million samples for classification into one of seven classes. Using the random forests algorithm, we can produce a speedup of 4.2 without loss in accuracy. This reduces computation time by over 10 min by just taking advantage of a standard four-core machine with six processes. (The machine used here has *hyperthreading*, which makes it perform in some settings as if it has eight cores.)

In the classification case, one must use a variation of SA. In predicting the class of a new case, each cluster node produces its own prediction. Then “voting” is used: The final predicted class is the one predicted the most often among the r cluster nodes.

The major advantages of SA are its simplicity and generality. One can use it to attain a good speedup on almost any statistical/machine learning algorithm.

Data Input/Output, etc. with `data.table`

As mentioned, `data.table` is an extension of the data frame construct (Dowle 2017). In Big Data contexts, the use of the `data.table` package is indispensable. For most operations – reading

from/writing to disk, data grouping, and so on – it is much faster than the standard R counterparts.

Graphics

Though one might at first think, “The more data, the better,” Big Data can present real problems in terms of graphics. With so many points to plot, there is a real risk of encountering the “black screen problem,” with the points solidly filling major areas of the computer screen, thus rendering the graph meaningless. A number of techniques have been developed to deal with this (Unwin et al. 2007).

In addition, with even moderate values of p , the number of variables/features in our dataset, plotting the data in a visually interpretable way is challenging. Data can readily be visualized in the case $p = 2$, and possibly $p = 3$, but it is difficult for $p > 2$. One method to address this problem is *parallel coordinates* (Inselberg 2009). Here each data point is displayed as a segmented line connecting dots at heights given by the values of the variables in that data point.

Direct use of parallel coordinates with Big Data will typically lead to the “black screen problem.” The `cdparcoord` package (Matloff et al. 2017b; Yang et al. 2017) aims to solve this problem by plotting only the most frequently appearing data tuples.

R

Conclusions

R is a very powerful tool for data science, developed by statisticians, for statisticians. It has truly excellent graphics packages, built-in matrix and linear algebra operations, several types of object-oriented programming models to choose from, and so on. The tremendous repository of contributed packages, CRAN, is a huge advantage by itself.

Care must be taken with speed and memory issues. These are handled by the use of vectorization and taking advantage of several good R facilities for parallel programming, as well as the availability of the `bigmemory` package. Properly used, R is a very strong tool for taming Big Data.

Definitions

RDF compression can be defined as the problem of encoding an RDF dataset using less bits than that required by text-based traditional serialization formats like RDF/XML, NTriples, or Turtle, among others. These savings immediately lead to more efficient storage (i.e., archival) and less transmission costs (i.e., less bits over the wire). Although this problem can be easily solved through universal compression (e.g., gzip or bzip2), optimized *RDF-specific compressors* take advantage of the particular features of RDF datasets (such as semantic redundancies) in order to save more bits or to provide retrieval operations on the compressed information. RDF self-indexes are focused on this latter task.

RDF self-indexes are RDF compressors that provide indexing features in a space close to that of the compressed dataset and can be accessed with no prior (or partial) decompression. These properties enhance scalability (i.e., less resources are required to serve semantic data) and speed up access as more information can be managed in higher levels of the memory hierarchy (typically, main memory or cache). In addition, efficient search algorithms have been proposed to resolve basic queries on top of self-indexed datasets. As a result, RDF self-indexes have been adopted as a core component of semantic search engines and lightweight Linked Data servers.

Finally, *RDF stream compressors* specifically focus on compressing a (continuous) stream of

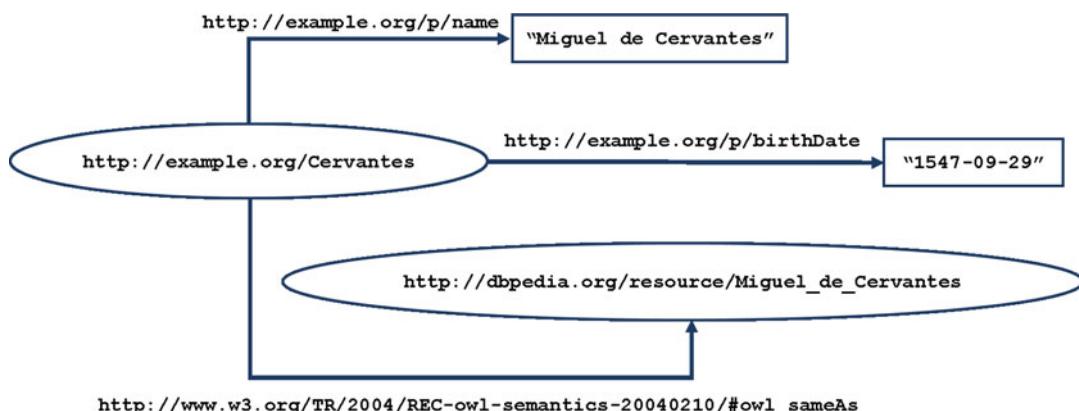

RDF data in order to improve exchange processes, typically in real time. This constitutes a more recent trend that exploits different trade-offs between the space savings achieved by the compressor and the latency introduced in the compression/decompression processes.

This entry introduces basic notions of RDF compression, RDF self-indexing, and RDF stream compression and discusses how existing approaches deal with (and remove) redundant information in semantic datasets.

Overview

RDF (Schreiber and Raimond 2014) stands for *Resource Description Framework*, which allows information about resources (documents, people, physical/logical objects, etc.) to be easily expressed in the form of triples. Each triple comprises the resource being described (referred to as subject), a property of that resource (predicate), and the corresponding value (object). Assuming infinite, mutually disjoint sets U (RDF Uniform Resource Identifiers, *URIs*), B (blank nodes), and L (RDF literals), a triple $(s, p, o) \in (U \cup B) \times U \times (U \cup B \cup L)$ is called an RDF triple (Gutiérrez et al. 2004). A triple (s, p, o) is usually represented as a labeled directed graph: $s \xrightarrow{p} o$.

Figure 1 shows an RDF graph that comprises three triples about the Spanish writer *Miguel de Cervantes*. The node named as [<http://example.org/Cervantes>](http://example.org/Cervantes) declares the corresponding RDF resource, while the labeled edges provide his

RDF Compression, Fig. 1 RDF graph which comprises three triples about *Miguel de Cervantes*

name and *birth date* as literals and a *same as* link pointing to a similar resource <http://dbpedia.org/resource/Miguel_de_Cervantes>, described in DBpedia, a partial conversion of Wikipedia to RDF.

RDF is an extremely simple, but powerful logical model, which can be used to describe and integrate a variety of data from different domains. This flexibility has motivated the adoption of RDF as one of the mainstream semi-structured data model in life sciences, geography, or open-government projects, among other fields of knowledge. Cross-domain datasets, like the aforementioned DBpedia, demonstrate how heterogeneous data can be effectively integrated regardless of its (lack of) structure.

RDF excels at logical level, but important scalability issues arise at physical level. The case of DBpedia is exemplary. The latest edition of this dataset (*DBpedia 2016-10*) consists of roughly 13 billion triples which describe people, places, organizations, films, species, or diseases, among other information available at *Wikipedia*, *Wikipedia Commons*, and *Wikidata*. These descriptions also exploit that the source information is commonly expressed in different languages to consolidate a multilingual RDF-based encyclopedia. The resulting knowledge base is extensively used for multiple purposes and services (e.g., semantic search, entity disambiguation, translation, etc.), and it constitutes a valuable resource for academics and semantic web practitioners. However, although DBpedia can be queried online via different APIs, some applications and services require a complete view of the dataset;

hence, consumers must deal with the high-cost requirements of this huge dataset in terms of space (its current dump needs several hundreds of gigabytes) and the required processing power to operate on this data volume.

These numbers endorse RDF compression as a scalable technique to alleviate the costs of RDF management, which are particularly relevant in a resource-constrained scenario (e.g., light clients or low-performance networks) and Big Semantic Data applications. But, *why are RDF compressors so effective?* Attending to the foundations of data compression, *compression is possible because data is normally represented in a form that is longer than absolutely necessary* (Salomon 2007). This situation is particularly significant in semantic data. An example is depicted in Fig. 2, which shows the previous RDF graph serialized in NTriples (Beckett 2014) and Turtle (Beckett et al. 2014). RDF files are plenty of redundancy, and three different classes are considered (Pan et al. 2014):

Symbolic redundancy is due to symbol repetitions. The main contributors of this significant source of redundancy are the large and highly repetitive URIs used for naming purposes. In practice, an RDF dataset comprises many different URIs, but they are usually defined from a small group of domains and tend to have common long prefixes. Note, for instance, that the prefix <http://example.org/> is shared by three URIs in our example. Some RDF serialization formats, like Turtle, introduce the @prefix constructor to partly address this issue. This allows the original URI to be rewritten as a short reference to the shared prefix (e.g., ns0 or ns1 in Fig. 2)

NTriples

```

ns0:birthDate "1547-09-29" ;
ns1:owl_sameAs <http://dbpedia.org/resource/Miguel_de_Cervantes> .

```

RDF Compression, Fig. 2 Example of RDF serializations (NTriples & Turtle)

and the remaining suffix. Symbol repetitions are also present in infixes/suffixes of URIs, but their impact is much lower. On the other hand, symbolic redundancy from literals depends on the domain being described, and it can be more difficult to predict. Finally, note that no restrictions are made on blank node serialization, but they also tend to share substrings (as in URIs) (Martínez-Prieto et al. 2012b).

Universal compressors, like gzip or bzip2, remove this class of redundancy and generate files which are suitable for storage and exchange. However, this class of compression prevents other purposes, like random access to the compressed data. *String dictionaries* (Martínez-Prieto et al. 2016) arise as an alternative that provides (slightly) less compression than universal techniques but efficient RDF retrieval operations. Dictionary compression identifies all different strings (*vocabulary*) in an RDF dataset and assigns an integer identifier (ID) to each one (typically an ID $i \in [1, n]$ being n the vocabulary size). This simple decision allows for replacing each term occurrence in the RDF dataset by its corresponding ID, thus shifting from managing potential large strings to small-/medium-size integers. In other words, the original RDF graph is re-encoded as a string dictionary, organizing the vocabulary, and an ID-graph. It is worth noting that RDF vocabularies reach non-negligible sizes and must be also compressed (Martínez-Prieto et al. 2012b).

Syntactic redundancy underlies to the graph-shaped structure of RDF datasets and how this structure is serialized. The simplest serialization formats, like NTriples, write one triple per line and serialize explicitly all its components (e.g., the subject URI is written three times, once per triple, in Fig. 2). In contrast, syntaxes like Turtle introduce subject-based encoding to alleviate this issue, i.e., it allows triples to be encoded as adjacency lists of (predicate, object) pairs related to each subject. Similar observations can be done for predicates and objects. Predicates tend to be repeated across different subjects, but they are often restricted to a domain and range of application, whether explicitly described in a vocabulary (ontology) or implicitly in the data. For example,

the *salary* predicate is not typically related to a *book* but a *person*, while the converse applies to the *pages* property. Grouping and splitting the description of books and persons may save repetitions. In turn, some objects are paired with some particular predicates (e.g., 25 °C is tight to a *temperature* predicate), but these pairs could be reused for different subjects.

Particular *graph compressors* should be used to minimize this class of redundancy. These techniques rearrange graphs in terms of their adjacency information and encode it using list or matrix compression approaches. The most well-known techniques come from web or social graph compression scenarios (Boldi and Vigna 2004), but some of them (Brisaboa et al. 2014) have been tuned to address the particular needs of RDF graphs. It is worth noting that graph compressors often operate on integer representations, so an initial dictionary compression stage is first performed to obtain the corresponding ID-graphs.

Semantic redundancy, in contrast to the previous ones, appears at the logical level. It arises when less triples can be used to provide the same knowledge. Thus, the redundancy does not depend on how triples are encoded, but on the knowledge they provide.

This redundancy cannot be removed using traditional compression approaches. In this case, specific RDF compressors must be designed from scratch in order to obtain the minimal subset of “canonical triples” that allows the original knowledge to be effectively reconstructed. Thus, the compression is achieved by reducing the number of unnecessary encoded triples. It is worth noting that symbolic and syntactic redundancies may be still present on the canonical graph; hence, other forms of compression can be applied on top of the semantic-compressed dataset in order to achieve better compression ratios.

R

Key Research Findings

RDF compression has emerged as an active research and development field over the past years, and some *lossless compressors* (i.e., techniques that can exactly recreate the original

dataset from its compressed representation) have been proposed. RDF compressors can be classified into *physical* and *logical*: the former exploits symbolic/syntactic redundancy, while the latter focuses on semantic-based redundancy. Finally, *hybrid* compressors perform at physical and logical levels.

The simplest form of **physical compression** is *universal compression*, i.e., using any general-purpose technique (e.g., gzip or bzip2) to directly compress an RDF file. This choice is simple and efficient in terms of compression ratio and delays (fast to process), and it can be easily integrated in other workflows as it makes use of standard and widespread techniques. In turn, RDF-specific physical compressors can be designed from scratch in order to deal with specific RDF characteristics and achieve better performance than general-purpose techniques.

RDF-specific physical compressors usually perform *dictionary compression*. That is, they translate the original RDF graph into a new representation which includes a string dictionary and an ID-graph encoding:

- The **dictionary** organizes the RDF vocabulary, which comprises all different terms used in the dataset.
- The **ID-graph** replaces the original terms by their corresponding IDs in the dictionary.

Figure 3 shows a dictionary-compressed representation of the graph example. In this case,

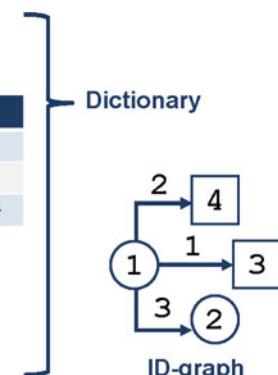

the dictionary comprises three independent mappings by subjects, predicates, and objects, but other configurations are possible. Triples are then encoded as $(1, 1, 2)$ $(1, 2, 3)$ $(1, 3, 1)$, where the original terms can be easily retrieved by using the corresponding mapping; e.g., $(1, 2, 3)$ is translated into:

- $S.get(1) = \langle\text{http://example.org/Cervantes}\rangle$.
- $P.get(2) = \langle\text{http://example.org/p/name}\rangle$.
- $O.get(3) = \text{"Miguel de Cervantes"}$.

Physical compressors propose different approaches to organize and compress RDF dictionaries and to encode the corresponding ID-graph representations.

Dictionary compression has not received much particular attention, in spite that representing the RDF vocabulary usually takes more space than the ID-graph encoding (Martínez-Prieto et al. 2012b). As in our example, RDF vocabularies can be intuitively partitioned by term roles (subjects, predicates, and objects). However, this approach is not totally effective because terms that perform subject and object roles are encoded twice, and these terms can sum up to 60% of the vocabulary terms (Martínez-Prieto et al. 2012b). Thus, a four-vocabulary configuration (Atre et al. 2010) is massively used, where the dictionary holds independent mappings for (i) shared *subjects-objects*, (ii) single *subjects* (not occurring as objects), and (iii) single *objects* (not occurring as subjects) and *predicates*.

ID	Subject Term

2	<code>"1547-09-29"</code>	
3	<code>"Miguel de Cervantes"</code>	

RDF Compression, Fig. 3 Dictionary-compressed representation

Vocabularies are further splitted by URIs, blank nodes, and literals for choosing the best compression technique for each collection of RDF terms. Martínez-Prieto et al. (2016) propose different approaches to compress these RDF vocabularies. URI (and blank node) vocabularies can be effectively compressed using Front-Coding, a differential encoding mechanism that exploits shared long prefixes and reduces URI space requirements up to 20 times. On the other hand, literal vocabularies are, in general, less predictable, hampering their compression. Thus, dictionaries that combine grammar-based compression with Front-Coding or hashing can report huge space savings of up to six to ten times the original space. Besides space reductions, these dictionary compression techniques must be able to efficiently translate IDs into the corresponding RDF terms, ensuring efficient *decoding* performance, most of them working at microsecond level. These techniques often support the inverse *search* functionality to translate an RDF term into its corresponding ID, which is essential for RDF self-indexing. In addition, they can provide *prefix*- and *substring*-based retrieval of RDF terms.

Once removed symbol repetitions, *ID-graph compression* looks for syntactic redundancy on the resulting ID-graph. These techniques model the graph in terms of adjacency lists or matrices, and look for regularities or patterns, which are succinctly encoded. HDT (Fernández et al. 2013) proposes *BitmapTriples*, one of the pioneer approaches for (RDF) ID-graph compression. In essence, it transforms the graph into a forest of three-level trees: each tree is rooted by a subject ID, having its adjacency list of predicates in the second level and, for each of them, the adjacency list of related objects in the third (leaf) level. The whole forest is then compressed using two ID sequences (for predicates and objects) and two bit sequences which encode the number of branches and leaves of each tree. This simple encoding reports interesting compression ratios (10–25% of the original space), while supporting efficient triple decoding. Furthermore, BitmapTriples allows subject-based queries to be resolved by traversing subject trees from the root. HDT con-

solidates a binary serialization format by joining Front-Coding and BitmapTriples to compress dictionaries and ID-graphs, respectively.

OFR (Swacha and Grabowski 2015) proposes another compression scheme for ID-graphs. It first performs dictionary compression (terms are organized into a multi-dictionary using differential encoding), and the resulting ID-graph is sorted by objects and subjects. In this case, *run-length* and *delta* compression (Salomon 2007) are applied to exploit multiple object occurrences, and the non-decreasing order of the consecutive subjects, respectively. OFR compressed files are then recompressed using universal techniques like *gzip* or *7zip*. The resulting OFR effectiveness improves HDT, but its inner data organization discourages any chance of efficient retrieval.

Efficient RDF retrieval is addressed by RDF self-indexes. These approaches do not just compress the ID-graph, but also provide indexing capabilities over it. HDT-FoQ (Martínez-Prieto et al. 2012a) enhances HDT to also support predicate- and object-based queries, adding inverted indexes for predicate and object adjacency lists that, all together, provide excellent performance for resolving SPARQL triple patterns. k^2 -triples (Álvarez-García et al. 2014) provides an alternative organization of the ID-graph, encoding a (binary) adjacency matrix of (subject, object) pairs per predicate. These matrices are very sparse and can be easily compressed using k^2 -trees (Brisaboa et al. 2014). The k^2 -triples approach improves HDT-FoQ compression ratios, and reports competitive numbers for all triple patterns binding the predicate, but results in a poor performance in those queries with unbounded predicates. This is mitigated by adding two additional indexes to store the predicates related to each subject and object, but the pattern that only binds the predicate remains slow. RDFCSA (Brisaboa et al. 2015) is the most recent RDF self-index, which encodes the ID-graph as a compressed suffix array (CSA). RDFCSA also ensures efficient lookup performance, competing with k^2 -triples at the cost of using more space.

Logical compressors look for (redundant) triples that can be inferred from others. These

triples are removed from the original graph, and only the resulting *canonical subgraph* is finally serialized. Different approaches have been followed to obtain these canonical subgraphs. The initial approaches (Iannone et al. 2005; Meier 2008) are based on the notion of *lean subgraph*. The lean subgraph is a subset of the original graph that has the property of being the smallest subgraph that is instance of the original graph. The number of removed triples by a lean subgraph strongly depends on the graph features, but a reasonable lower limit is two removed triples per blank node (Iannone et al. 2005). Nevertheless, some triples of a lean graph can still be derived from others; hence, some semantic redundancy can still be present (Meier 2008).

The rule-based (RB) compressor (Joshi et al. 2013) uses mining techniques to detect objects that are commonly related to a particular predicate (intra-property patterns) and to group frequent predicate-object pairs (inter-property patterns). These patterns are then used as generative rules to remove triples that can be inferred from such patterns. RB is not so effective by itself, and only inter-property patterns enable significant amount of triples to be removed. Venkataraman and Sreenivasa Kumar (2015) state that frequent patterns are not so expressive to capture semantic redundancy and suggest that effectiveness can be improved using more expressive rules. In this case, Horn rules are mined from the dataset, and all triples matching their head part are removed. The resulting canonical subgraph is then compressed using RB. This Horn-rule-based compressor outperforms RB effectiveness, but it introduces latencies in compression and decompression processes.

Hybrid compressors compact the RDF graph by first using a logical approach to remove redundant triples and then performing physical compression at serialization level. Although these techniques could combine the best of logical and physical compression, their application has received relatively little attention until now.

HDT++ (Hernández-Illera et al. 2015) revisits HDT to introduce some methods to detect syntactic and semantic redundancy. HDT++ brings out

the inherent structure of RDF by detecting and grouping the different set of predicates (*predicate families*) used to describe subjects. The original RDF graph is encoded as a set of subgraphs, one per predicate family. The `rdf:type` values are attached to each predicate family, hence removing these triples from the subgraphs. Finally, HDT++ uses local IDs for the terms in each subgraph, thus reducing the number of required bits. As a result, HDT++ reduces the original HDT ID-graph space requirements up to two times for more structured datasets and reports significant improvements even for highly semi-structured datasets.

The *graph pattern-based* (GPB) compressor (Pan et al. 2015) shares some common features with HDT++, also grouping subjects by predicate families, called *entity description patterns* (EDPs). Each EDP is encoded as a pair which includes the corresponding pattern and all instances matching it. This policy consolidates the simplest GPB encoding scheme (LV0), but patterns are then merged to obtain better patterns (LV1), and the merging process can be recursively performed (LV2). GPB results are not compared with other physical compressors, but they excel at logical level, where GPB-LV2 is able to remove more triples than RB.

Finally, *RDF2NormRDF* (Ticona-Herrera et al. 2015) is not a compressor, but an approach to normalize RDF data. It applies different transformation rules to remove duplicated edges and nodes and also deals with particular blank node features. At physical level, RDF2NormRDF focuses on namespace issues and normalizing types and language tags encodings. As expected, RDF2NormRDF does not generally remove more redundancy than other compressors, such as HDT, but it reports better compression ratios for small datasets.

Real-Time Compression

All previous compressors share a common feature: they are designed to perform in batch processing scenarios where time requirements are not so strict. That is, the target system can wait a reasonable time to receive the compressed data, and the compression process is performed *offline*.

However, more and more systems perform *online* data processing (in real time), where delays must be minimized. In these cases, the volume of RDF is traditionally smaller, but triples are continuously generated, and these semantic streams must be efficiently distributed over a network.

Thus, a key challenge for RDF stream processing systems is the ability to consume increasingly large volumes of data with varying and potentially high input rates. This scenario also claims for RDF compression that, in this case, put the focus on minimizing the elapsed time since the original piece of data is available at the producer, until it is ready to be used at the consumer. This process encompasses three tasks: (i) *data compression* (at the producer), (ii) *data transmission* over a network, and (iii) *data decompression* (at the consumer). The real challenge for RDF stream compressors is finding the right space/time trade-off which optimizes the overall workflow performance. RDF-specific compression over streaming data is usually performed at *physical level* and mostly as adaptations of existing RDF compressors.

Streaming HDT (Hasemann et al. 2012) adapts HDT to simplify the associated metadata and restrict the number of terms managed by the dictionary; hence, shorter IDs are used. The approach is then tailored to constrained devices, where the vocabulary of terms is very limited. In turn, RDSZ (Fernández et al. 2014a) uses differential encoding to take advantage of the similarities between consecutive triples sent over the wire. In addition, the resultant scheme is compressed with Zlib to exploit additional redundancies. Overall, RDSZ gains in compression (17% on average) are at the cost of increasing the processing time.

ERI (Fernández et al. 2014b) is an RDF stream compressor that adapts the W3C Efficient XML Interchange (EXI) format (Schneider et al. 2014) for RDF data. Similarly to HDT++ and GPB, ERI tries to detect and encode the predicate families but in a dynamic fashion. In addition, highly repeated object values (besides the values for *rdf:type*) are also encoded in the families. Then, the non-repeated values for each particular predicate in the family are encoded in a channel,

where specific compression can be applied (the concept is then similar to leveraging the locality in column-based databases). As a result, ERI achieves a slightly better compression than general-purpose stream-enabled compressors (such as Zlib) with limited latency overhead. Note that the XML-based compression of EXI can also be adapted to RDF streams by (i) forcing the serialization format of RDF to RDF/XML and, optionally, (ii) generating an application-specific grammar that encodes the repeated values.

The pattern-based approach of ERI has been also followed by two recent techniques, PatBin (Lhez et al. 2017) and FSSD (Karim et al. 2017). PatBin approach performs dictionary-based compression and then splits the graph in ID-patterns (essentially predicate families) and value/variable bindings. The Factorizing Semantic Sensor Data (FSSD) technique uses a deductive database system to encode the repeated predicate families and object values as datalog rules, which are then applied on the input data to achieve important size reductions. However, although FSSD has been tested on sensor data, the factorization is still performed in an offline fashion. In general, finding patterns in RDF Streams efficiently can be seen as an orthogonal approach.

Examples of Application

R

RDF compression has been widely adopted by the Semantic Web community as a standard technique to reduce storage and transmission costs when downloading RDF datasets. Most of the publishers in the Linked Open Data (LOD) cloud make use of universal compression, given its simplicity, usability, and widespread adoption. This is particularly true for projects publishing massive amounts of RDF data, such as DBpedia or Bio2RDF.

Nonetheless, RDF-specific compressors, and in particular RDF self-indexes, are receiving increased attention. Projects like LOD Laundromat (Beek et al. 2014) or Triple Pattern Fragments (TPF) (Verborgh et al. 2016) describe two in-

teresting use cases exploiting compressed RDF. LOD Laundromat is an initiative to crawl and clean (removing syntax errors) RDF data from the LOD cloud. As a result, it exposes more than 650 K cleansed datasets which are delivered in HDT format and can be queried using TPF interfaces. TPF focuses on alleviating the burden of endpoints by serving simple SPARQL triple patterns, paginating the results. This simplification allows servers to scale, while clients can always execute more complex SPARQL queries on top of TPFs by taking care of integrating and filtering the results. Given the simplicity of the required infrastructure at the server, TPF interfaces can make use of RDF self-indexes to serve low-cost operations, being HDT the most used backend in practice. The recently published *LOD-a-lot* dataset (Fernández et al. 2017) combines the benefits from both projects to provide a practical example of efficient management of compressed Big Semantic Data. *LOD-a-lot* integrates all data from LOD Laundromat into a cross-domain mashup of more than 28 billion triples and several terabytes of space (in NTriples). This dataset is then exposed as HDT and the corresponding TPF interface. The queryable self-indexed HDT of such large portion of the LOD cloud takes 524 GB and can serve fast triple pattern resolution with an affordable memory footprint (in practice, 15.7 GB). These numbers are a strong evidence of how RDF compression contributes to make Big Semantic Data management feasible in most Linked Data servers (for online consumption) and clients (for downloading and offline consumption).

RDF compression and self-indexes have also been actively used in other Semantic Web areas such as (i) SPARQL querying and recommender systems (Martínez-Prieto et al. 2012a; Heitmann and Haye 2014), leveraging the retrieval operations supported by self-indexes to support more complex queries; (ii) reasoning (Cure et al. 2015), optimizing the RDF dictionary and triples encoding to serve inference capabilities; (iii) versioned RDF or RDF archives (Fernández et al. 2016), where RDF compression is used to preserve (and query) the history of an RDF dataset; and (iv) constrained and mobile devices (Käbisch et al.

2015) in order to maximize the exploitation of their storage/processing capabilities.

Finally, RDF compression has also been highlighted by RDF stream processing systems: CQELS Cloud (Le-Phuoc et al. 2013) uses a basic dictionary-based approach to process and move IDs (integers) between nodes, and Zstreamy (Fisteus et al. 2014) exploits the Zlib compressor with similar purposes. A last trend regards querying on compressed RDF streams (without prior decompression). A recent approach (Déme et al. 2017) extends RDFSZ to resolve basic SPARQL queries, as well as filters and aggregations.

Future Directions for Research

The state of the art of RDF compression shows many and varied techniques which exploit symbolic, syntactic, and semantic redundancy from different perspectives. They (i) save much storage space, (ii) reduce network latencies, or (iii) improve RDF retrieval performance, among other achievements. Nonetheless, RDF compression still remains an open challenge. We can categorize future directions in three categories, *low-level* optimization, *scalable management*, and *applications*.

First, physical and logical compression should be independently explored to determine more effective approaches which, desirably, should be plugged into powerful hybrid compressors. These achievements should be aligned with recent advances in succinct data structures and self-indexes, which try to squeeze the space requirements while providing additional retrieval operations. Querying compressed RDF is a main direction for research to consolidate scalable and efficient semantic search engines. These additional *low-level* optimizations can boost the adoption of RDF compression and self-indexing, which is already at the edge of conforming a core component of scalable Semantic Web applications.

In general, RDF compression has already proved its ability for storing, exchanging, processing, and querying Big Semantic Data.

However the *scalable management* of compressed RDF datasets has room for optimization. On the one hand, the compression of Big Semantic Data, as well as the creation of RDF self-indexes, suffers from scalability problems, as they can require high amounts of memory and processing power. Although this process is a one-off task in many scenarios, it can introduce unaffordable costs for publishers. Current efforts focus on exploring computation models like MapReduce or Spark to alleviate this burden, yet additional research must be conducted to consolidate a scalable approach for Big Semantic Data compression. On the other hand, most of RDF self-indexes are mainly static or costly to update; hence, dynamic techniques for succinct data structures and self-indexes are an active area of research.

Finally, RDF compression and its *applications* have many unexplored directions. Adoption of RDF compressed techniques in combination with existing triple stores and reasoners, integration within semantic data warehouses, resolution of temporal queries on compressed RDF archives, or integration within natural language processing tasks (e.g., entity discovering and linking) are only some prominent applications which claim for innovative RDF compression techniques to scale in a Big Semantic Data scenario.

RDF Dataset Profiling

Stefan Dietze¹, Elena Demidova¹, and Konstantin Todorov²

¹L3S Research Center, Leibniz Universität Hannover, Hanover, Germany

²LIRMM, University of Montpellier, Montpellier, France

Definitions

In the context of this chapter, *an RDF dataset* is defined in accordance with the dataset definition in the Vocabulary of Interlinked Datasets (VoID), (<http://vocab.deri.ie/void>), namely, “*A Dataset* is a set of RDF triples that are published, maintained or aggregated by a single provider.” According to VoID, a dataset represents a meaningful collection of triples as envisioned by its provider. *An RDF dataset profile* is a formal representation of a set of dataset characteristics (features). It describes the dataset and aids dataset discovery, recommendation, and comparison with regard to the represented features. A *dataset profile feature* is a characteristic describing a certain attribute of the dataset. For instance, “*dataset conciseness*” is a dataset profile feature providing information on the degree of redundancy of the information contained in the dataset. A dataset profile is extensible with respect to the

features it contains. Usually, the relevant feature set is application-oriented and depends on the envisaged application scenarios.

Overview

A number of popular dataset registries have emerged, which tackle the problem of dataset discovery through the curation of lightweight dataset descriptions, often also exposing structured metadata according to the state-of-the-art vocabularies such as DCAT (<http://www.w3.org/TR/vocab-dcat/>) or VoID. Popular examples include DataHub (<http://www.datahub.io>) or DataCite (<https://www.datacite.org/>), while the LinkedUp Catalog (<http://data.linkededucation.org/linkedup/catalog/>) (for education) represents a domain-specific example. However, while such metadata is usually edited and curated manually, it is often sparse, not in sync with the constant evolution of the actual datasets, and prone to errors.

On the one hand, as the Web of Data as a whole is evolving along with the constant evolution of individual datasets, manual assessment and representation of a large variety of dataset features is neither feasible nor sustainable. On the other hand, a wide variety of competing as well as complementary approaches exist, aimed at automatic assessment and description of arbitrary datasets. This body of work is spanning several research communities and includes works in fields such as *dataset characterization*, *data summarization*, *dataset assessment*, or *dataset profiling*. While the problem of dataset profiling is of particular importance in the context of the Web of Data, it has been identified and approached already in other related fields, such as general database and data management research.

Emerging from the aforementioned works, a wealth of tools, methods, vocabularies, and applications for assessing, describing, and profiling datasets has become available throughout the past few years, where Ben Ellefi et al. (2017) provides an initial overview and classification.

The aim of this chapter is to provide researchers, dataset providers, and application de-

velopers with an overview of *dataset profiling* and closely related approaches, including *dataset profile features*, *feature extraction methods and tools*, *vocabularies*, and example *applications* to encourage experimentation and facilitate the broader use of RDF datasets.

Key Findings

In order to provide an overview of RDF dataset profiling, we structure key findings into types of *features*, related *methods and tools*, *vocabularies* for their representation, and actual *applications*.

Features, Methods, and Tools

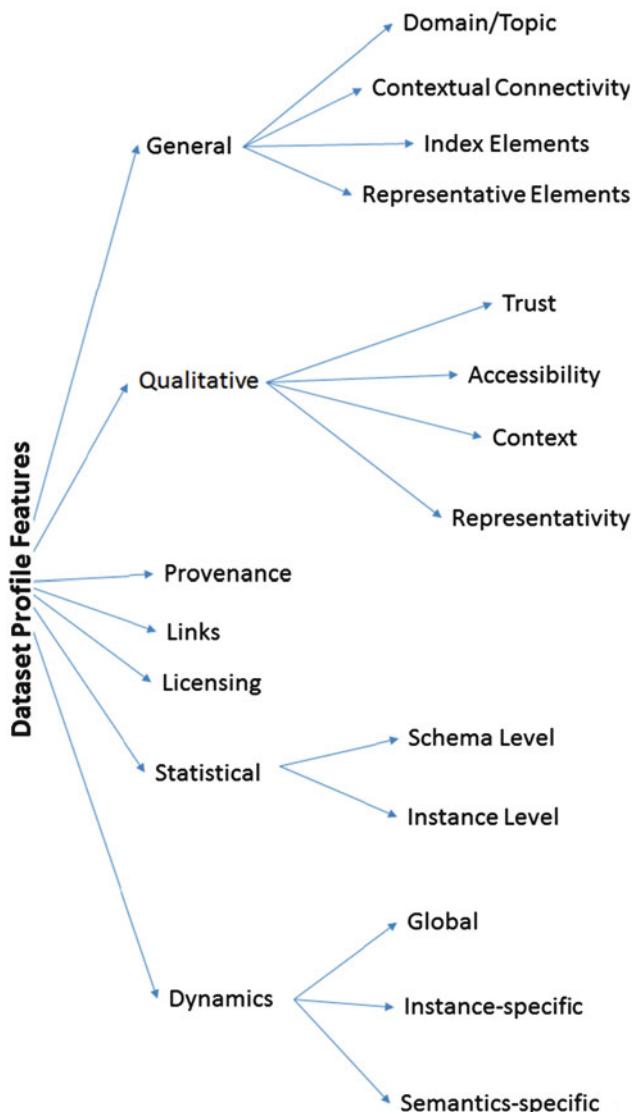

This section provides an inventory of dataset features of relevance for dataset profiling, organized in an extensible feature taxonomy, depicted in Fig. 1. This taxonomy reflects the authors' consensus and provides one of several possible categorization systems. In particular, the features are organized into the following top-level categories: *General*, *Qualitative*, *Provenance*, *Links*, *Licensing*, *Statistical*, and *Dynamics*. This taxonomy guides the categorization of the extraction methods and tools, of which we provide examples for each category. The taxonomy also serves as a backbone for the classification of profiling vocabularies and applications, introduced in the following section. For a complete overview, the reader is referred to the survey (Ben Ellefi et al. 2017).

R

General features. Features in this category carry high-level semantic information, including the *domain* (field of knowledge) or *topic* of the dataset; its *contextual connectivity*, understood as the extensional and/or topical overlap with other datasets; the *index elements* that are pointing to the dataset in a given index or a set of indices; as well as the dataset *representative elements*, i.e., the sets of most descriptive types, properties, or instance samples to characterize the entire dataset.

Extraction Methods and Tools. General features typically require domain knowledge with respect to the content of the dataset. As a best

RDF Dataset Profiling,
Fig. 1 A taxonomy of
dataset profile features

practice, these features should be provided by the data domain experts (e.g., data providers or maintainers) to ensure a high-quality profile. The *topic* and the *contextual connectivity* of the dataset can be described through named entities (NE) extracted from the literal values, as well as categories and clusters of these entities. Furthermore, RDF dataset profiles can include selected *index elements* from the instance-level and schema-level indices or data summaries such as a QTree (Harth et al. 2010). *Representative elements* of an RDF dataset can be the entities with thorough descriptions or predicates obtained

using key discovery approaches. Tools in this category include Linked Data Observatory (Fetahu et al. 2014) and voiDge (Böhm et al. 2011).

Qualitative features. The *Qualitative* features category groups together a number of features known from the long-going study of data quality in computer science in general and the Web of Data in particular (Zaveri et al. 2016; Bizer and Cyganiak 2009). These features are organized into the following subcategories: (1) *Trust*, (2) *Accessibility*, (3) *Representativity*, and (4) *Context/Task Specificity*. *Trust* features relate to the

verifiability of information, its correctness or believability, and the reputation of the publisher and that of the dataset. *Accessibility* regards the facility of access to information and the versatility of access methods, but also the degree of security of information transactions, as well as the access performance.

The features in the *Representativity* group provides information in terms of completeness, understandability, semantic accuracy, conciseness (or redundancy), and consistency (i.e., presence of contradictory information).

Finally, the *Context/Task Specificity* group includes features that measure data quality with respect to a specific task.

Extraction Methods and Tools. For the features in the *Accessibility* category, assessment methods include: (1) exploiting dataset metadata and user annotations to assess *trust*; (2) querying SPARQL endpoints and analysing URIs to measure *availability*; (3) analyzing use of digital signatures and provenance information to assess *security*; (4) assessing latency and scalability in response to the user requests to measure *performance*; and (5) analyzing available serialization formats and languages to assess *versatility*.

Representativity features can be assessed through: (1) exploiting statistical distributions to measure *completeness*; (2) detection of human-readable labeling, metadata availability, as well as communication channels to assess *understandability*; (3) statistical methods and crowdsourcing to measure *semantic accuracy/correctness*; (4) measuring the proportion of unique elements at the schema and instance level to assess *conciseness*; and (5) verification of the schema definitions, correctness of the schema usage, and identification of data inconsistencies (e.g., through semantic constraints) to measure *consistency*.

Context features can be assessed through relevance, sufficiency, and timeliness (e.g., the age of the data and its temporal validity as it is delivered to the user) for a specific task or query.

Example tools to generate qualitative features in several categories include WIQA (Bizer and Cyganiak 2009) and ODPW (Umbrich et al. 2015).

Provenance features. These features are seen as contextual metadata that provide indicators about the origin, timeliness, currency, and update cycles of datasets. These are important characteristics that allow to understand the origins of data, to trace errors, and, ultimately, to establish trust.

Extraction Methods and Tools. *Provenance features* can be extracted from the annotations specified by the data provider via provenance vocabularies using tools like WIQA and ODPW.

Links features. *Links features* are understood as either the number of datasets, with which a dataset is interlinked, or the number of triples in a dataset, in which the subject and the object refer to different datasets. We distinguish between (i) *explicit links* (when datasets have linked instances via owl : sameAs statements) and (ii) *implicit links* (when datasets share topics or contexts, expressed, e.g., by an rdfs : seeAlso statement).

Extraction Methods and Tools. Features related to schema-level and instance-level links can be accessed through the number of interlinked external instances or datasets. These features can be extracted by tools like voiDge (Böhm et al. 2011).

Licensing features. *Licensing features* comprise the type of license under which a dataset is published, indicating whether reproduction, distribution, modification, or redistribution is permitted.

Extraction Methods and Tools. Features in the licensing group are meant to be augmented manually by the data provider and can be collected from the dataset metadata using tools like ODPW.

Statistical features. This type of features may refer to the size of a dataset, its coverage, average number of triples, property co-occurrence, and others. These characteristics can be measured at the *schema level* (class/properties usage count (in general, per subject and per object) or class/properties hierarchy depth) and at the *instance level* (URI usage per subject (/object), triples having a resource (/blanks) as subject (/object), triples with literals, min(/max/avg.) per data type, etc.).

Extraction Methods and Tools. Features from this group can be extracted automatically by applications like LODStats using statement-streaming approaches (Auer et al. 2012). Example statistics include frequencies of vocabulary usage, average length of literals, and number of namespaces used. ProLOD++ (Abedjan et al. 2014) supports different granularities of statistics using clustering approaches prior to the statistics generation.

Dynamics features. This category reflects the dynamic aspects of a dataset and includes features in the global, instance-specific, and semantics-specific categories. In principle, every dataset feature can be dynamic, i.e., changing over time. However, the dynamic aspects of a dataset are considered as separate features describing data, while nonetheless acknowledging their transversal nature (the fact that they span over several of the feature categories described above). These features are organized into three subcategories. *Global* features concern dynamicity aspects related to life span, stability (as an aggregation of the stability of multiple dataset characteristics), and history of update (frequency, degree, and patterns of change). *Instance-specific features* refer to the level of growth of the entities in a dataset, the stability of the identifiers (URIs), and the links between entities. Finally, *semantic-specific* features reflect changes related to structure, domain, and vocabulary.

Extraction Methods and Tools. Global dynamic features can be extracted automatically from the SPARQL endpoints via tracking changes using broadcasting or query techniques as well as by regular crawling of LOD data sources and statistical analysis of the crawls, e.g., in Dyldo (Käfer et al. 2013). Instance-specific dynamic features include observation of resource referencing through notification services, monitoring of links stability, and time-travel tools to access archived representations of the URIs. Note that the extraction of dynamic features, as well as statistical, qualitative, and links features, would in general require

less domain expertise and can be extracted automatically by applications in many cases. To cope with the large scale of data during automatic feature extraction, various sampling techniques can be applied (Fetahu et al. 2014).

Vocabularies

Vocabularies for representing dataset profiles range from general dataset metadata vocabularies to specific vocabularies aimed at representing particular features or feature categories.

The Vocabulary of Interlinked Datasets (VoID) (Alexander et al. 2009) provides a core vocabulary for describing datasets and their links, following a similar rationale as the Data Catalog (DCAT) vocabulary (<http://www.w3.org/TR/vocab-dcat/>), which is partly derived from Dublin Core. Both are widely used to generate basic profiles (Ben Ellefi et al. 2017) and are commonly extended with more feature-specific vocabularies.

With respect to *quality*, the dataset quality (daQ) vocabulary (<http://purl.org/eis/vocab/daq>) (Debattista et al. 2014) and the Data Quality Vocabulary (DQV) (<https://www.w3.org/TR/vocab-dqv/>) provide complementary terms for annotating DCAT dataset descriptions with quality aspects and metrics. Fürber and Hepp (2011) describes the DQM Ontology (<http://semwebquality.org/dqm-vocabulary/v1/dqm>), a general vocabulary for representing data quality features.

Regarding *provenance*, voidp (Omitola et al. 2011) builds on and extends VoID to describe the provenance relationships of data across linked datasets, while the *provenance vocabulary* (<http://trdf.sourceforge.net/provenance/ns.html>) was developed to describe provenance of Linked Data.

From the perspective of archiving and long-term preservation of data, the *Data Dictionary for Preservation Metadata (PREMIS)* (<http://bit.ly/premisOntology>) set of terms can be used to describe the provenance of archived, digital objects (e.g., files, bitstreams, aggregations, and datasets).

Most notably, the *PROV Ontology (PROV-O)* (<http://www.w3.org/TR/prov-o/>) was published

as a W3C Recommendation to be a new quasi-standard for representing provenance and is part of a larger *PROV Family of Documents* (Missier et al. 2013) created to support “the widespread publication and use of provenance information of Web documents, data, and resources.”

Links as important features of Linked Data datasets are represented through a variety of means, covering both schema-level and entity-level links, e.g., instantiating VoID linksets or using *SKOS* (<https://www.w3.org/TR/2009/REC-skos-reference-20090818/>) as a formal vocabulary for defining taxonomic and mapping relations among both concepts and entities. In addition, the Expressive and Declarative Ontology Alignment Language (EDOAL) (<http://alignapi.gforge.inria.fr/edoal.html>) enables the representation of correspondences between entities and concepts in different datasets beyond mere mapping relationships (equivalence, subsumption) using complex formalisms.

General resource metadata vocabularies provide basic features to indicate licensing information, including the *DCMI Metadata Terms* (<http://dublincore.org/documents/dcmi-terms>), featuring dedicated *license* and *rights* properties.

These are complemented through dedicated *licensing* vocabularies, such as ccREL (REL, or rights expression language) vocabulary (https://wiki.creativecommons.org/wiki/CC_REL), which facilitates the representation of Creative Commons licenses in RDF. Similarly, the *Open Digital Rights Language (ODRL)* vocabulary (<http://www.w3.org/community/odrl/two/model/>) enables the fine-grained specification of licensing terms (rights, policies, etc.) in a machine-readable format.

To support the representation of dataset *statistics*, vocabularies such as the RDF Data Cube vocabulary (<http://www.w3.org/TR/vocab-data-cube>), SDMX (<http://sdmx.org>), or SCovo (<http://vocab.deri.ie/scovo>) are used. The VoID guidelines, for instance, recommend the use of SCovo to share statistical dataset features (Alexander et al. 2009). Auer et al. present LODStats (Auer et al. 2012), a framework

for dataset analytics, which introduces a set of 32 statistical features and uses the most recommended combination of VoID and the Data Cube vocabulary.

While there does exist a wealth of methods for assessing characteristics related to the *dynamic* and evolution of datasets, including the *Talis Changeset vocabulary* (<http://vocab.org/changeset/schema.html>), the Delta vocabulary (<http://www.w3.org/2004/delta>), RMO introduced by Graube et al. (2014), or the *Triplify Update vocabulary* (<http://triplify.org/vocabulary/update>), most vocabularies in this area are dedicated to representing the actual evolution of a dataset, rather than higher-level observations about dynamics. A more abstract approach is offered by the *Dataset Dynamics (DaDy) vocabulary* (<http://vocab.deri.ie/dady>), which allows the representation of more abstract dynamics-related observations for a specific dataset, to be used in conjunction with VoID.

Applications

This section illustrates the use of RDF dataset profiles in several cross-domain applications without being exhaustive.

Data linking applications aim to annotate, disambiguate, and interlink entities and events by often using natural language processing (NLP) techniques and external sources including Linked Data. In this context, popular services include DBpedia Spotlight (Daiber et al. 2013) and Babelfy (Moro et al. 2014). Data linking applications typically use features from the *General* category, such as *topics*, *domains*, or *representative elements*.

Applications for data curation, cleansing, and maintenance rely on or generate profile features in order to improve the overall data quality. This includes the application of statistical methods for outliers detection (correcting errors in numerical values) (e.g., in Paulheim and Bizer 2014), link correction, as well as error detection and correction by using existing links. Features from the *Statistical, Provenance and Dynamics*

categories are largely used in this group of applications. Note that new features can also be generated as an outcome of these applications.

Schema inference applications have been developed recently, aiming at filling the gap generated by the lack of explicit vocabularies or by incomplete specifications (e.g., Paulheim and Bizer 2014; Konrath et al. 2012). *Statistical* characteristics of datasets, together with *Provenance* features, play an important role for this type of applications.

Applications for query answering over distributed data comprise the generation of ordered query plans against the mediated schema on a number of data sources. In order to guide distributed query processing, existing applications rely on indices of varying granularity including schema-level indices and data summaries (e.g., Harth et al. 2010). The majority of existing query applications rely on the *General* and *Statistical* characteristics at the schema and data levels. Finally, quality-aware query applications also take into account features from the *Qualitative* category (e.g., *completeness* and *accuracy*).

Reuse of datasets can become apparent when datasets are linked to from other datasets. In this context, *Links* features can provide an indication of dataset reuse (Endris et al. 2017).

Future Challenges

Overall, applications of the whole spectrum of dataset profile feature categories can be found, including general, qualitative, statistical, and dynamic features discussed in this entry. However, individual applications as well as tools commonly use or support only a very limited number of features. Typical stakeholders of the discussed techniques are both data providers, such as archival organizations, libraries, or individual data hosters, and data consumers, for instance, application developers or (domain-specific) data retrieval and search engines. In addition, with respect to Web-scale dataset discovery, the heterogeneous and fragmented landscape of feature definitions and applied vocabularies hinders the automated interpretation of dataset profiles, requiring further effort for

consumers of dataset profiles for interpreting, mapping, and disambiguating existing profiles.

The growing adoption of schema.org markup, particularly of scientific, datasets, driven also by existing community efforts such as the W3C community group on *schema.org for Datasets* (<https://www.w3.org/community/schemaorg4datasets/>) has led to a widespread availability of semi-structured dataset annotations. However, while this constitutes an unprecedented source of dataset-centric information, the diverse and often poorly structured nature of embedded markup (Yu et al. 2017) poses the need for further processing of such dataset profiles, for instance, through disambiguating, resolving, and augmenting dataset descriptions.

While reconciliation of dataset profiles is a general issue of relevance beyond just embedded Web markup, future work has to provide a stronger emphasis on obtaining, resolving, consolidating, and cleaning datasets profiles from a wide variety of signals, including structured RDF dataset annotations, embedded Web page markup, but also less explicit indicators observable on the Web, for instance, in dataset registries, unstructured Web pages, or scientific publications.

Definitions

RDF serialization is the process of writing down RDF graphs into a machine-readable format. RDF formats mainly differ in the concrete syntax to serialize RDF statements (called “triples”) and how to group or nest a set of statements, influencing the amount of storage space and bandwidth required for preserving and exchanging such data. These differences can be rather marginal for small RDF graphs, where the selection of a particular format is mostly driven by user preferences, the set of tools managing the RDF format, and the interoperability with other applications. In contrast, choosing an adequate serialization format can affect the overall performance and present important scalability issues when managing Big Semantic Data collections.

Additional challenges arise in scenarios where triples must be annotated with information about their context, such as provenance, trust, or quality information, to name but a few. The most standard solution in RDF is to consider *named graphs*, i.e., different RDF graphs are managed under a single RDF dataset. Diverse RDF formats have been proposed to cover this scenario and serialize annotated statements (called “quads”), at the cost of paying additional costs to represent triples that can be repeated across graphs.

This situation is particularly challenging when different versions of an RDF graph must be preserved, given that graphs can be near-copies of others. This problem is commonly referred to as *RDF archival*, where specific archival policies have been proposed in recent literature.

This entry provides a historical review of RDF serialization formats to understand their evolution over the years. Basic features are covered for each format, paying special attention to its capabilities for quad serialization. XML-based and text-oriented formats are first introduced to illustrate how RDF was originally used for metadata description. Their limitations led to JSON-based syntaxes, which overcome some processing challenges, but do not scale to the high demanding needs of Big Semantic Data management. This fact motivates the proposal of binary formats,

able to deal with the storing and exchanging needs of large RDF collections. Finally, RDF archival proposals are surveyed and we conclude presenting open research trends.

Overview

RDF (*Resource Description Framework*) (Schreiber and Raimond 2014) proposes a logical model for expressing information about physical (e.g., people, buildings, vehicles, or pictures, among others) and abstract (e.g., films, songs, cities, etc.) resources. The information is represented as ternary relations, called RDF triples (or statements), which are organized into hyperlinked clouds, referred to as RDF graphs. The resulting knowledge is typically oriented for machine consumption. In the following, the main RDF concepts are briefly introduced.

RDF Triple. RDF statements are built on a simple (subject, predicate, object) structure called *RDF triple* (aka statement), which sets a particular value (the “object”) for a given feature (“predicate”) of the resource (“subject”) being described. For instance, an informal representation of a triple which sets the birth date of the singer Bruce Springsteen can be $\langle \text{Bruce Springsteen}, \text{is born on}, 1949-09-23 \rangle$.

The RDF data model (Cyganiak et al. 2014) establishes some restrictions about the universe of possible values for each component of a triple. Thus, a triple $(s, p, o) \in (I \cup B) \times I \times (I \cup B \cup L)$, where I stands for IRIs, B for blank nodes, and L for literals. These mutual disjoint sets of RDF terms are described as follows:

IRIs. International Resource Identifiers (IRIs) are used to identify resources in RDF. For instance, $\langle \text{http://example.org/Springsteen} \rangle$ is used to name the aforementioned resource about Bruce Springsteen. Note that IRIs can also be used to identify predicate and object values of a triple; e.g., $\langle \text{http://example.org/p/birthDate} \rangle$ is a valid IRI to identify the corresponding “birth date” property. IRIs are global identifiers, so they can be reused to provide additional information about a resource or to

convey the same meaning, e.g., a birth date feature in a different context.

Blank Nodes. RDF uses blank nodes (also called anonymous nodes) to declare the existence of a resource without using a particular IRI. Blank nodes can play both subject and object roles, while they never mean that the IRI is unknown for the corresponding resource. In turn, the scope of the blank node is limited to the RDF graph where it is used.

Literals. Final values (numbers, names, dates, etc.) are expressed as RDF literals, always used as objects. Literals are declared by default as strings (a language tag can optionally be associated in this case), but other datatypes can be used. The value “1949-09-23” is an example of an RDF literal.

Figure 1 illustrates the above RDF concepts. It comprises three triples that describe a new resource about Bruce Springsteen, identified by the aforementioned IRI <<http://example.org/Springsteen>>. Two of these triples set his birth name and birth date (using IRIs <<http://example.org/p/name>> and <<http://example.org/p/birthDate>>, respectively), i.e., “Bruce Frederick Joseph Springsteen” and “1949-09-23.” The third triple connects the new resource with an existing description of Bruce Springsteen in DBpedia (<http://dbpedia.org/page/Bruce_Springssteen>), a conversion of Wikipedia to RDF. Note that the predicate reuses the sameAs property, described in the OWL ontology.

RDF is traditionally modeled as a labeled directed graph (as seen in the previous figure) because it provides an easy-to-understand (visual) explanation of the RDF data. This fact motivates the adoption of this concept as part of the RDF model.

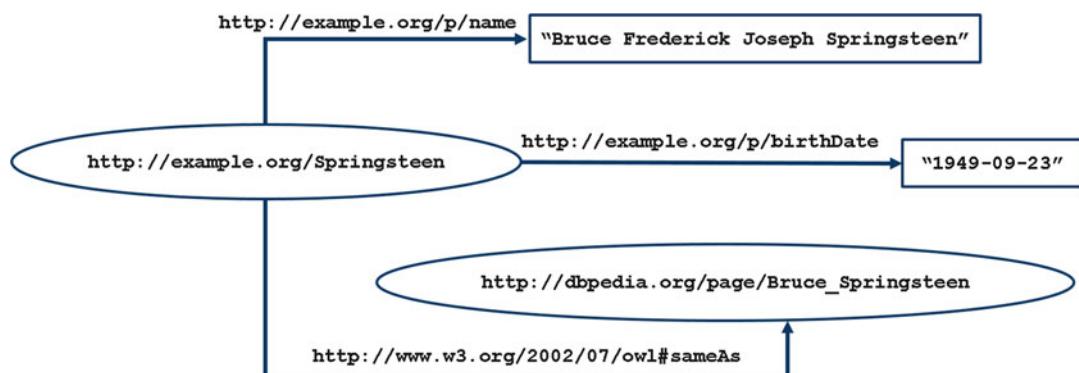

RDF Graph. An RDF graph G is a set of triples declared under the same scope. Thus, a triple belongs to an RDF graph, and a graph contains a well-determined set of triples.

It is worth noting that an RDF graph is only a “mental model,” and its triples must be serialized for preservation or exchanging purposes. Each serialization format has its particular features, but all ensure RDF graphs to be effectively written down.

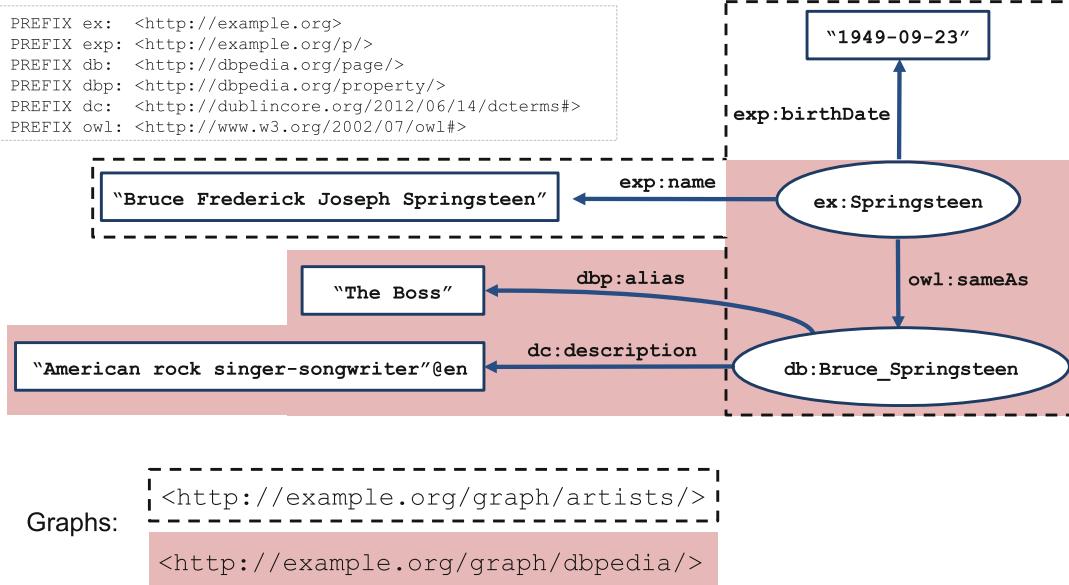

RDF 1.1 extends the original model to support grouping RDF graphs within a single RDF dataset, enabling triples from different contexts to be managed together.

RDF Dataset. An RDF dataset D is a collection of RDF graphs, where one of them is considered the “default graph.” The dataset contains zero or more “named graphs.” Each named graph is a pair consisting of an IRI or a blank node (the graph name) and an RDF graph. Graph names are unique within the RDF dataset, and blank nodes can be shared between graphs.

Figure 2 shows an RDF dataset which comprises two RDF graphs (note that a prefix notation is used to compact their IRIs). The first graph

RDF Serialization and Archival, Fig. 1 RDF graph which comprises three triples about *Bruce Springsteen*

RDF Serialization and Archival, Fig. 2 RDF dataset which comprises two RDF graphs

(dashed) is identified by the IRI <http://example.org/graph/artists> and includes the set of three triples showed in Fig. 1. The new named graph (solid background) declares three more triples about Bruce Springsteen, one of them shared with the original graph: (ex:Springsteen, owl:sameAs, db:Bruce_Springsteen).

The notion of RDF dataset also applies to a logical level. However, serializing triples from a dataset brings an additional requirement, as their context must be preserved.

RDF Quad. An RDF quad is an extended statement that includes the corresponding triple and the name of the graph that declares it (aka context). More formally, an RDF quad q is a quadruple $\langle \text{subject}, \text{predicate}, \text{object}, \text{graph} \rangle$, where graph refers to the name of a graph which exists in the dataset. Thus, a quad $(s, p, o, g) \in (I \cup B) \times I \times (U \cup B \cup L) \times (I \cup B)$.

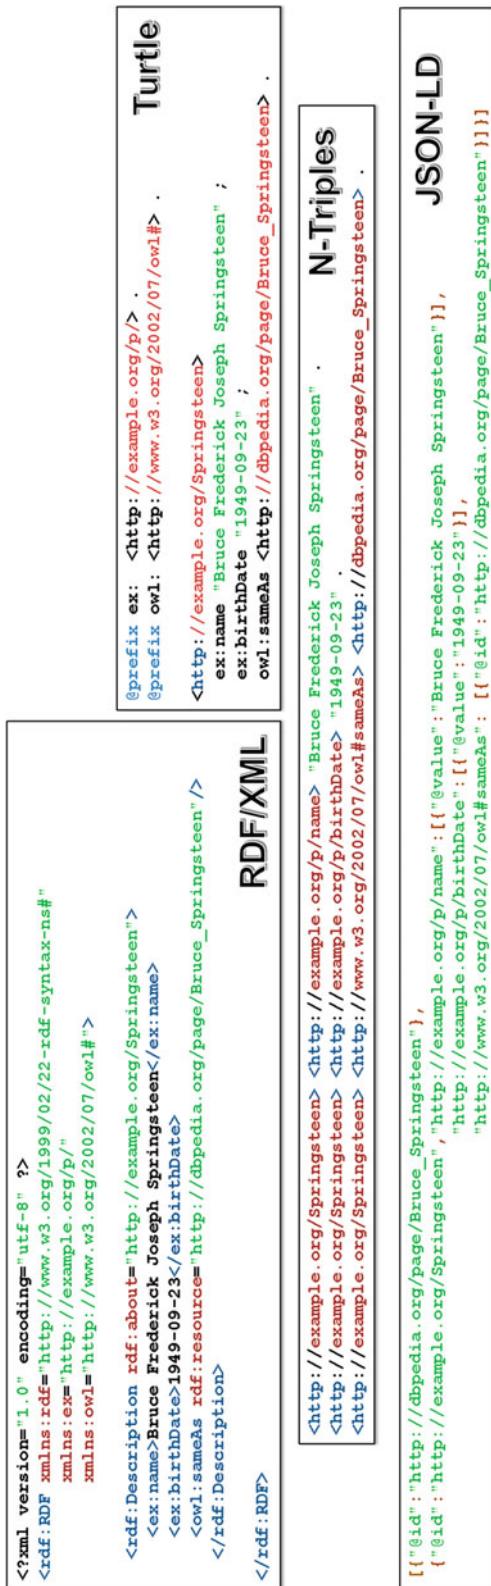

Serialization Formats

The RDF model describes the previous concepts using an abstract syntax, but it does not restrict how they are effectively serialized. Thus, RDF data can be written down in different ways, while

several serialization formats are standards and widely accepted by the Semantic Web community. These formats allow RDF graphs to be effectively serialized, but only some of them are able to cover particular RDF dataset needs.

RDF/XML (Gandon and Schreiber 2014) was released hand in hand with the initial W3C RDF Recommendation. In early dates, RDF/XML was meant to be an ideal first serialization for RDF graphs as it could leverage all XML-based solutions. However, RDF/XML overloads the representation with verbose human-focused information, which can serve the intended exchanging purposes, but only on a small scale. Nonetheless, RDF/XML includes some naive compacting features, such as the possibility to (i) implicitly create blank nodes without giving a concrete identifier, (ii) omit nodes and place values as property attributes in XML, (iii) abbreviate IRI references via base IRIs (namespaces) and relative references, and (iv) create collections to define a set of terms related to a subject.

Figure 3 shows an example of an RDF/XML serialization that encodes triples from Fig. 1. In practice, the result is an XML document, which can be parsed, processed, and queried using well-established technologies (DOM, XPath, XSLT,

RDF Serialization and Archival, Fig. 3 Serializations of triples from Fig. 1

etc.). However, its document orientation is an important weakness to deal with large amounts of RDF triples. Besides, it does not support named graphs.

Trix (Carroll and Stickler 2004) proposes another XML syntax for RDF which organizes triples by graphs, allowing multiple graphs to be serialized into the same document. It is a first approximation to an RDF dataset serialization, but the resulting format shows the same drawbacks that RDF/XML.

XML-based formats have lost relevance, and their usage is limited to small RDF graph serializations (e.g., descriptive metadata about a Web page).

N3 (Notation3) (Berners-Lee and Connolly 2011) is a format designed with human readability in mind. Although it may make sense in the first times of RDF, managing and processing Big Semantic Data are far from any human capability. However, this format breaks with the XML predominance and introduces some interesting constructors which tackle particular RDF features.

sN3 proposes the use of namespaces, as in XML. It is an effective compaction mechanism which allows relative IRIs to be declared to their corresponding namespace. On the other hand, N3 also introduces constructors for triples encoding in the form of adjacency lists: predicate lists allow subjects to be written only once for all triples containing it, while object lists concatenate all object values related with a pair `{subject, predicate}`, which is written once.

This format proposes some other constructors which goes beyond the needs of RDF serialization, making the format relatively complex for such purpose. N3 does not support quads.

N-Triples (Becket 2014) is an extremely simple line-based syntax, easy to parse and generate. In essence, the subject, predicate, and object terms are separated by a white space, and the triple is terminated with a “.” followed by a new line. IRIs are enclosed in “<” and “>” and literals in “ ”, and blank nodes start with “_:”. Figure 3 shows an N-Triples serialization that basically lists the corresponding triples. Note that

N-Triples writes down each full term as many times as it is used in a triple, resulting in a simple but extremely verbose serialization due to long-term repetitions. As a result, N-Triples files need much more space than others, which can result in scalability issues for Big Semantic Data management.

On the other hand, N-Triples can be easily extended to support quad serialization. It only needs the graph name to be appended to the triple. N-Quads (Carothers 2014) formalizes this approach, featuring the same characteristics and limitations as N-Triples.

Turtle (Beckett et al. 2014) is a widely used format that exploits the previous experience of N3 and N-Triples. On the one hand, it delimits the expressive power of N3 to only serialize valid RDF graphs. On the other hand, it addresses N-Triples drawbacks to consolidate a more practical format.

Figure 3 also shows a Turtle excerpt that illustrates some of its more relevant features. For instance, it shows the use of namespaces. Note that each one is declared by the `@prefix` constructor, while IRIs in the terms are rewritten in relative form to their corresponding namespaces. The figure also illustrates the predicate list encoding proposed in N3; e.g., `http://example.org/Springsteen` is written once, but it plays the role of a subject for three different triples. Turtle supports object lists too, and it introduces more constructors and different kinds of syntactic sugar to alleviate RDF verbosity.

Although Turtle is a popular format, it does not support quads. As in the previous case, a new format, called TriG (Bizer and Cyganiak 2014), extends Turtle to allow RDF dataset serialization. It basically encloses triples that belong to each named graph in the dataset.

JSON-LD (Sporny et al. 2014) exploits JSON features to serialize RDF. It comes with the advantage of using a well-established scheme that is easy to parse and widely accepted by Web APIs. The main focus, then, is to be easy for humans to read and write and easy for machines to parse and generate automatically. JSON-LD is designed to be usable directly as JSON, with no knowledge of RDF. Note that JSON-LD supports named graphs

natively, and it is gaining increasingly attention by the community.

Key Research Findings

The above serialization formats have been successfully used for managing small- and medium-sized RDF graphs. However, the steady adoption of RDF, in particular in the context of linked data (Bizer et al. 2009), brings larger graphs including hundreds of millions and even billion triples. For instance, the latest version of DBpedia (2016–10), an RDF conversion of Wikipedia, consists of roughly 13 billion triples, and LOD Laundromat (Beek et al. 2014), a service crawling RDF datasets, reports that around 4000 datasets contain more than 1 million triples.

In addition, named graphs are increasingly incorporated to consolidate complex RDF datasets. However, formats for quads are less mature and also suffer from the lack of scalability. This problem is particularly challenging when the corresponding RDF dataset is a historical archive of a graph, containing its different states over the time.

This section delves into detail of the most innovative binary serialization formats, designed with volume issues in mind in order to solve the aforementioned scalability issues. Some of them also cover quad management, although managing context information is a challenge by itself, which is also reviewed below. Finally, RDF archival foundations are introduced, summarizing the most recent approaches.

Binary Serialization and Compression

Traditional RDF formats were not designed for a scenario of large-scale and machine-understandable Web of data. Their syntaxes have constructors which organizes RDF statements in a human-readable way that adds unnecessary overheads for storing, exchanging, and consuming RDF graphs. Although this scalability issue can be partially solved through universal compression (e.g., gzip or bzip2) over such formats, specific RDF binary serializations and compressors have been also proposed.

These tailored solutions mostly focus on taking advantage of particular features of RDF data in order to reduce the verbosity and produce important space savings at large scale. In the following, the three most prominent binary serializations are briefly reviewed: *HDT*, *RDF Binary*, and *RDF4J*. We then list solutions focused on streaming and provide a summary of RDF compression techniques to provide a big picture of the current state of the art (the interested reader can find a chapter specifically devoted to RDF compression).

The HDT (Fernández et al. 2011, 2013) format proposes a binary syntax for RDF data focused on producing very compact serializations to speed up data exchange, but also efficient data parsing and access. HDT minimizes the repetition of terms (IRIs, blank nodes, and literals) using the so-called HDT Dictionary, which assigns a numerical ID to each different term. Then, the graph structure of the dataset is managed as a graph of (term) IDs, in the HDT Triples component. Both dictionary and triples components are then compacted (e.g., looking for common string prefixes in the terms) and partially indexed. HDT is one of the most widespread RDF binary formats, mainly due to the HDT adoption as a compact data store for LOD Laundromat (Beek et al. 2014), and the data back end of lightweight APIs such as Triple Pattern Fragments (Verborgh et al. 2016).

HDT traditionally focuses on representing single RDF graphs. A recent approach, named HDTQ (Fernández et al. 2018), extends HDT to represent named graphs, keeping compact and retrieval features.

The RDF binary format (RDF Binary 2017) is an alternative solution proposed by the well-known Jena semantic framework. It consists of very simple mappings to encode triples in Apache Thrift (Apache Thrift 2017), which provides a scalable cross-language platform. In this case, rather than compactness, RDF binary mostly focuses on avoiding to parse the textual RDF triples; hence, the overall processing is sped up. RDF binary supports both RDF graphs and RDF datasets (named graphs) encoded as a stream of quads.

The RDF4j (RDF4j 2017) binary format is proposed and used within the Eclipse RDF4J framework. The RDF4j format partially combines both previous strategies. On the one hand, it mostly tackles parsing and processing efficiency, providing a concrete syntax to delimit the extent of each term and triple. On the other hand, it allows for an in-line declaration of a dictionary, where a term is mapped to an ID which can be referred in another triple. Nonetheless, terms are not compressed themselves (e.g., using prefixes such as in HDT); hence, only partial compression is achieved.

Compression is another way of serializing RDF. As explained, combining universal compression and any serialization format is a common practice, but different compressors have been designed from the scratch to deal with particular RDF requirements. RDF compressors can be classified into *physical* and *logical* compressors. Physical compressors (Fernández et al. 2013; Swacha and Grabowski 2015; Álvarez-García et al. 2014; Brisaboa et al. 2015) exploit symbolic/syntactic redundancy, removing term repetitions and compacting repetitive subgraph structures underlying to the dataset. In contrast, logical compressors (Iannone et al. 2005; Meier 2008; Joshi et al. 2013; Venkataraman and Sreenivasa Kumar 2015) focus on semantic-based redundancy, avoiding to represent triples that can be inferred from others in the RDF graph.

In addition, diverse binary formats and compressors have been proposed for RDF streams, i.e., a continuous flow of RDF data. In this case, the challenge consists of exploiting the trade-offs between the space savings achieved by the format and the latency introduced in the creation and parsing processes. Streaming HDT (Hasemann et al. 2012) adapts HDT to simplify the process by restricting the carried metadata and the maximum length of the dictionary; hence, shorter IDs are used. RDSZ (Fernández et al. 2014b) uses differential encoding to compact the similarities between consecutive triples in the stream. ERI (Fernández et al. 2014a) is an RDF stream compressor that adapts the W3C Efficient XML Interchange (EXI) format (Schneider et al.

2014) for RDF data. Note that EXI encoding can also be directly applied over an RDF/XML or JSON serialization. PatBin (Lhez et al. 2017) and FSSD (Karim et al. 2017) perform dictionary-based compression together with pattern-based encoding.

Context Information

As stated, graph names are increasingly used to capture additional information such as trust, provenance, temporal information and other annotations (Carroll et al. 2005; Zimmermann et al. 2012). Although there exist standard RDF syntaxes (such as N-Quads, Trig or JSON-LD) that represent RDF named graphs, serializing annotated RDF data (quads) efficiently remains an open challenge.

In spite of general approaches, such as AnQL (Zimmermann et al. 2012), most solutions focus on managing provenance information, as this is at the core of the linked data distributed philosophy (Bizer et al. 2009). Besides the aforementioned named graphs and the standard RDF reification (Schreiber and Raimond 2014), i.e., using the RDF vocabulary (*rdf:Statement*, *rdf:subject*, *rdf:predicate*, and *rdf:object*) to refer to statements, the main proposals are singleton properties (Nguyen et al. 2014) and N-ary relations (Noy et al. 2006). The former introduces unique predicates that are then annotated with the metadata of the triple it belongs to. The latest, used in Wikidata, represents a relation between a subject and object with a new resource, which is then connected to the subject, on the one hand, and predicate and object, on the other. Further information can be attached to the new resource in order to annotate the statement.

In addition, two recent solutions have been proposed. (Hartig 2017) extends RDF with a notion of embedded triples (encoded between ‘<<’ and ‘>>’), which can be directly used as subject or object of other triples. NdFluents (Giménez-García et al. 2017) creates unique versions of the subject and the object for each annotated triple, which are then linked to a context resource and to the original subject and object resources.

RDF Archival

RDF archival is a particular instance of the problem of managing context information. In this case, the context is set by the moment when a new version of an RDF graph is released. In general, RDF data are not static but evolve naturally, without centralized monitoring nor further advise, following the scale-free nature of the Web. Thus, RDF archiving emerges as a novel challenge aimed at assuring quality and traceability of RDF data over time.

On a high level, the World Wide Web Consortium (W3C) provides basic guidelines on how to perform data versioning on datasets published in the Web (Lóscio et al. 2017). The set of recommendations includes (i) providing a version indicator (e.g., via *owl:versionInfo*); (ii) serving different versions via the Memento framework (de Sompel et al. 2010), which can provide access to prior states of RDF resources using date-time negotiation in HTTP; and (iii) providing the changes made in each version. Nonetheless, these recommendations are generic and do not restrict how RDF data versions are stored or queried across time. Initial works on RDF archiving policies and systems are starting to address these issues, proposing different solutions to efficiently archive and query different versions of RDF data.

Main efforts on RDF archiving fall in one of the following four storage strategies: *independent copies (IC)* and *change-based (CB)* and *timestamp-based (TB)* and *hybrid-based (HB)* approaches.

Independent copies (IC) (Klein et al. 2002; Noy and Musen 2004) is the most naive approach where each version (aka snapshot) is managed as a different, complete graph. On the one hand, IC faces scalability problems as static information is duplicated across the versions. In addition, some operations such as knowing the difference between versions require non-negligible processing efforts. On the other hand, version materialization (retrieve certain version) is as efficient as querying a single snapshot.

Change-based approach (CB) (Volkel et al. 2005; Dong-Hyuk et al. 2012; Zeginis et al. 2011) partially addresses the space issues of IC by storing the differences (deltas) between versions.

In contrast, CB requires additional computational costs for retrieving a particular version given that deltas need to be propagated.

Timestamp-based approach (TB) (Cerdeira-Pena et al. 2016; Gutierrez et al. 2007; Zimmermann et al. 2012) annotates each triple with its temporal validity, i.e., the version. Compression techniques can be used to minimize the space overheads, e.g., using self-indexes, such as in v-RDFCSA (Cerdeira-Pena et al. 2016), or delta compression in B+Trees (Zaniolo 2016).

Hybrid-based approaches (HB) (Stefanidis et al. 2014; Neumann and Weikum 2010; Zaniolo 2016) combine previous policies to inspect other space/performance trade-offs. In particular, the hybrid IC/CB approach (Dong-Hyuk et al. 2012; Meinhardt et al. 2015; Stefanidis et al. 2014) follows a CB solution where full version materialization is additionally provided in some intermediate steps; hence, delta propagation is mitigated. In contrast, other practical approaches (Graube et al. 2014; Neumann and Weikum 2010; Vander Sander et al. 2013; Zaniolo 2016) follow a TB/CB approach in which triples can be time-annotated only when they are added or deleted. Although this reduces the space needs (as it manages less annotations), version materialization requires to rebuild the delta similarly to CB.

R

Future Directions for Research

As a result of standardization efforts by the Semantic Web community, there are many diverse standard “plain” RDF serializations available. Despite potential future trends that may result in adaptations for RDF (such as JSON-LD, adapted from JSON), most research efforts focus on efficient representation of annotated triples, in particular to model provenance information (Giménez-García et al. 2017; Hartig 2017).

RDF binary formats and compression have also emerged as active research and development fields over the past years. The main reason is that (i) current plain RDF formats are dominated by a human-centric view and suffer from scal-

ability problems at large scale and (ii) general compressed solutions still miss some types of redundancy underlying to RDF data. In this regard, there is still room for hybrid compressors leveraging syntactic and semantic redundancies. Then, RDF self-indexing (i.e., compressed and indexed RDF data) is still a main direction for research, in particular in the unexplored field of RDF streaming.

Finally, the community is just starting to face serious scalability issues for RDF archival. In the absence of a scalable archival approach at Web scale, RDF data change and vanish without further notice nor trace of previous versions. Future directions in this regard include further research on scalable archival methods (potentially distributed) as well as efficient mechanisms to resolve structured cross-time queries.

Definitions

Reasoning is the process of deriving new conclusions from knowledge bases using a series of logical steps. Reasoning at scale refers to the ability of applying this process to very large knowledge bases, such as modern knowledge graphs that are available on the Web.

Overview

The Web contains a very large amount of semi-structured datasets that cover encyclopedic knowledge, social or co-authorship networks, experimental results, etc. This data is encoded using RDF (Brickley et al. 2014), and it is interlinked to each other following the principles of linked open data, thus forming a large network of datasets called the Web of Data (WoD) (Bizer et al. 2009).

Automated reasoning can derive a wealth of nontrivial knowledge from these datasets, which can be used, for instance, to augment the WoD with new knowledge or to detect inconsistencies. Unfortunately, the large size of the WoD makes reasoning a challenging task. In fact, the datasets

might be too large to be stored in a single machine, requiring thus some form of distributed computing. Moreover, parallelizing the computation is not trivial due to factors like the input skewness or special corner cases that require sequential processing.

What constitutes the state of the art for reasoning on a large scale? To answer this question, this chapter offers a broad overview of the most recent efforts to execute rule-based reasoning on large inputs. More in particular, it describes the most important optimizations that can be applied to improve the efficiency of reasoning. Some of these optimizations work only with specific rules, while others are more generic. Even though none of them work with all possible inputs, in practice they turned out to be very effective as they enabled reasoning on large knowledge bases, with up to 100 billion triples in the largest experiments.

What Is Scale?

Generally speaking, the term scalability refers to the ability of a system to handle larger instances of a given problem. There can be several reasons that hinder the scalability of a system. First, the problem might have an unfavorable computational complexity which precludes termination within a reasonable time. Second, the algorithms might be poorly implemented. In this case, the system cannot scale well despite the problem is tractable. Third, the hardware might not have enough resources to carry on the computation. Scalability is thus a property that can be judged from three different angles: the theoretical complexity, the implementation, and the hardware requirements.

Before discussing the state of the art and describe how it deals with these challenges, it is important to define more precisely what reasoning is supposed to compute. Let KB be a generic RDF dataset, that is, a set of RDF statements. This dataset can be represented as a labeled directed graph where each triple $\langle s, p, o \rangle$ maps to an edge that connects s to o and is labeled with p . These graphs are typically called *knowledge graphs*. Let

$KG = (V, E)$ be such a knowledge graph where V is the set of entities and E the labeled edges that connect the entities. Given in input a knowledge graph KG , the goal of reasoning is to derive new knowledge that can be inferred from KG . This knowledge takes the form of new triples which can be logically deduced from the KG. For now, it is assumed that V is complete, i.e., KG already contains all the entities of interest. With this assumption in mind, then the triples derived from reasoning can be represented by new edges in KG .

The derivation of new triples is determined by a set of rules, which must be provided as input. Rules are expressions of the form

$$B_1, \dots, B_n \rightarrow H \quad (1)$$

where B_1, \dots, B_n are called *atoms*. An *atom* is an expression $p(\mathbf{x})$ where p is a *predicate* and $\mathbf{x} = x_1, \dots, x_m$ is a tuple of terms that can be either variables or constants. A *fact* is an atom without any variable. In our context, facts are used to represent the KG. They can be unary (e.g., to express the *isA* relation – $Person(Mark)$), binary (e.g., $livesIn(Mark, Amsterdam)$), or ternary (e.g., $T(Mark, livesIn, Amsterdam)$). The set of atoms B_1, \dots, B_n is called the rule's *body*, while H is the rule's *head*.

Notice that rules can be more complex than in (1). For instance, some body atoms might be negated, or the head might contain a conjunction of multiple atoms. All scalable approaches which will be discussed in this chapter assume that rules only contain positive atoms and only one atom occurs in the head of the rule. Moreover, they assume that every variable in the head must also appear in the body (safeness condition). The reason behind these constraints is that they simplify the computation. For instance, negation can introduce non-determinism, while dropping safeness might lead to nontermination.

The computation of the rules can be formalized as follows. Let I be a generic database of facts (i.e., the input KG); σ be a *substitution*, i.e., a partial mapping from variables to other variables or constants; and $r \in P$ be a rule of the

form (1) in the program P . Then, $r(I) = \{H\sigma \mid B_1\sigma, \dots, B_n\sigma \in I\}$ is the set of derivations that can be derived from I using r and $P(I) = \bigcup_{r \in P} r(I)$ is its extension to all rules in the program. The exhaustive application of all rules can be defined recursively by setting $P^0(I) = I$ and $P^{i+1}(I) = P^i(I) \cup P(P^i(I))$. Since the rules are safe and the set of constants is finite, there will be a j s.t. $P^{j+1}(I) = P^j(I)$. In this case, $P^j(I)$ is called the *closure* or *materialization* of I with P .

Materialization with Fixed Rules

Ontological languages are used to serialize semantic relations in RDF knowledge bases in a machine-readable format. For instance, they allow the user to define various semantic relations like subsumption between classes (e.g., *Student* is a subclass of *Person*) or specify that a relation is transitive (e.g., *ancestorOf* or *partOf*).

Ontological statements like the previous two examples can be translated into rules by either considering the standard constructs of the language or by also including the ontology at hand. The following example is useful to understand this difference.

Example 1 Let us assume that the KG contains the following ontological statements: $(:Bob, \text{isA}, :Actor)$ and $(:Actor, \text{soc}, :Man)$ where *soc* is an abbreviation for the standard RDF schema IRI of class subsumption.

A rule of the first type could be

$$\begin{aligned} T(A, \text{isA}, B), T(B, \text{soc}, C) \\ \rightarrow T(A, \text{isA}, C) \end{aligned} \quad (2)$$

while a rule of the second type could be

$$isA(A, :Actor) \rightarrow isA(A, :Man) \quad (3)$$

In the first case, rule (2) simply translates the inference that it is possible to obtain considering the *isA* and *soc* relations. The rule is domain-independent and can be applied to any KG. In

contrast, rule (3) is simpler because it does not require any data join but it has the disadvantage that it can be applied only to the input dataset.

In this chapter, rules of the first type are called *standard rules* since they are derived by standard ontological languages like RDF schema (Brickley et al. 2014) or OWL (Motik et al. 2009). Standard rules are important because they are universal in the sense that they do not depend on a particular input. Therefore, it is possible to introduce tailor-made optimizations to speed up their execution without any loss of generality. However, there are cases when nonstandard rules are preferable since they might be easier to execute. The remaining of this section will describe five optimizations which are crucial to enhance the scalability of reasoning using standard rules. The next section will address scalability with nonstandard rules.

Split instance/schema triples. The first, and perhaps most effective, optimization on current knowledge bases consists of splitting the input statements between the ones that describe instances and the ones that describe the schema. The last type of statements is typically ontological statements that use constructs from the language (e.g., OWL). One key property of current large KGs is that they contain many more instance statements than schema ones, and this is important because there are many standard rules which have two body atoms, one which matches instance statements while the other matches schema ones (Urbani et al. 2012). Rule (2) is such an example: Here, typically there will be many more triples of the form $T(A, \text{isA}, B)$ than of the form $T(B, \text{soc}, C)$.

A strategy to parallelize the computation of such rules is to simply range-partition the instance triples and assign each range to a different processor. If the processors operate in separated memory spaces (e.g., different machines), then schema triples can be replicated on each space.

After the partitioning is done, the rule can be executed in parallel without any intermediate node communication. An example of such computation is graphically depicted in Fig. 1a.

Reducing duplicates. There are cases where different rules might produce the same derivation. For instance, the two standard rules

$$\begin{aligned} T(A, P, B), T(P, \text{domain}, C) \\ \rightarrow T(A, \text{isA}, C) \end{aligned} \quad (4)$$

$$\begin{aligned} T(B, P, A), T(P, \text{range}, C) \\ \rightarrow T(A, \text{isA}, C) \end{aligned} \quad (5)$$

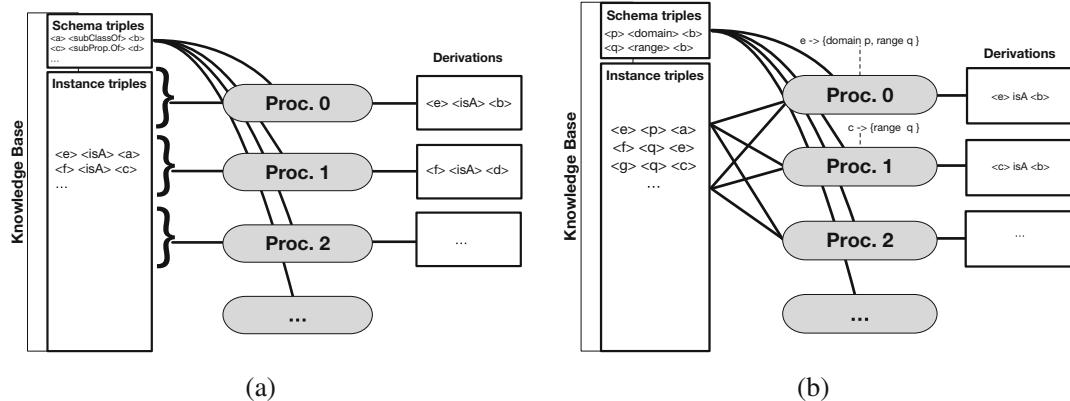

can derive the same information for an entity which is used both as a subject and as an object in different triples. For instance, $\langle Bob, \text{worksIn}, \text{Amsterdam} \rangle$ and $\langle Alice, \text{daughterOf}, Bob \rangle$ can both lead to the derivation $\langle Bob, \text{isA}, \text{Person} \rangle$ if the domain and range of the two predicates are *Person*.

A strategy to remove these types of duplicates is to group instance triples by the list of terms which are used in the head. In the previous case, triples can be grouped either by subject or by object, depending on the rule. Then, rules can be executed in parallel on each group. In this way, it is impossible that two different groups will produce the same derivation because the grouping criterion ensures that derivations must differ by at least one term (i.e., the grouping key).

During the rule computation, duplicates can still be produced within the same group. However, in this case they can be removed in parallel without any synchronization between the various processors. Figure 1b shows an example of such computation for rules (4) and (5).

sameAs table. One category of rules which is widely used in modern knowledge bases encodes reasoning over the equality of concepts, which is a relation that is stated with the predicate *owl:sameAs*. Equality is transitive (if a is the same as b and b is the same as c , then a is the same as c) and symmetric (if a is the same as b , then b is the same as a); thus rules in this category produce a large number of materializations.

To improve the performance, reasoners typically avoid materializing all conclusions but instead build a dedicated table where groups of

Reasoning at Scale, Fig. 1 (a) Parallel execution of a rule that requires a join between schema and instance triples. (b) Execution of a group of rules: in this example,

processor 0 receives all information regarding the entity “e,” which allows it to apply both rules (4) and (5) and remove duplicates locally

equal terms receive a unique representative ID, and all occurrences of these terms in the KB are replaced by the corresponding ID. During the materialization, the reasoner might derive more equality relations. If this happens, then the table needs to be updated, and more occurrences must be replaced with the corresponding ID. Notice that also rules need to be rewritten if they contain constants in the table.

After the materialization is computed, the augmented $P^j(I)$ will contain a compressed version of the full materialization since further derivations can be obtained by simply replacing the occurrences of representative IDs with each of the members of their equality group. However, in practice this operation is often omitted as it can be trivially computed on-the-fly whenever is needed.

Sorting rule execution. For some standard rule sets like the rules from RDF schema, it is possible to define a rule application order to reduce to the minimum the chance that the output of one rule can be used as input for another one. Unfortunately, this optimization guarantees a complete output only on some specific cases, and it is not possible to define an execution order which avoids repeated executions with more complex rulesets like, for instance, the OWL2 RL/RDF ruleset (Motik et al. 2009).

Memoization. Another technique that can be applied to improve the performance is *memoization* (Urbani et al. 2014). Memoization is a special type of caching which consists of storing the output of expensive functions to reduce the cost of repeated executions. For the problem of reasoning, memoization can be used to precompute all answers of some particular atoms. This enables a faster computation of data joins.

An example is useful to clarify this optimization. Let us consider, once again, rule (2). This rule contains two body atoms: One atom matches instance triples while the other matches schema triples. During the materialization, the number of facts that match the second atom will change if other rules derive new triples with soc as predicate. With memoization, before the materialization starts a query-driven materialization procedure like QSQR (Abiteboul et al. 1995) or Magic set (Bancilhon et al. 1985), two well-known query-driven algorithms are invoked to compute all answers for the query $T(B, \text{soc}, C)$. Once this procedure is terminated, we can safely assume that the collection of facts that match this atom is immutable; thus the engine can index this collection more efficiently to facilitate the execution of the rule. In some cases, memoization does not lead to any reduction of the materialization runtime, while in other cases, the advantage is significant.

Materialization with Generic Rules

Nonstandard rules are typically easier to execute since they require less joins and predicates have a smaller arity (i.e., they are unary or binary only). On these rules, however, the previous optimizations might not be applicable. Still, the execution can be improved in two ways: Either by applying more general parallel algorithms or by considering multiple facts at the same time. Both types of improvements are described below.

Parallelizing rule execution. Three different types of parallelism can be applied to the rule execution: *Intra-rule parallelism*, *inter-rule parallelism*, and *instance-based parallelism*.

With intra-rule parallelism, the goal is to distribute the execution of a single rule among different processors. For example, let us consider rule (1). In this case, facts that match B_1 could be partitioned into n different partitions depending on the value of the terms that should be joined with B_2 . Similarly, facts that match B_2 could be partitioned in an equivalent number of partitions in so that “ B_1 ” and “ B_2 ” facts with the same join terms will be in the same partition. In this way, each partition can be processed simultaneously by concurrent processors.

With inter-rule parallelism, the idea is to let concurrent processors execute different rules at the same time. For instance, one processor could execute rule (4) while another one execute rule (5). Notice that neither of these two types of parallelism is perfect: With intra-rule parallelism, the computation could be unbalanced if some partitions are much bigger than others. With inter-rule parallelism instead, the maximum number of concurrent processors is bound by the number of rules.

Intra- and inter-based parallelism are well known in literature and are also used in other scenarios. The third type of parallelism is a more recent variant which was first introduced in the RDFox system (Nenov et al. 2015). The idea is to let a number of concurrent processors to continuously pull not-yet-considered facts from a queue and verify whether they instantiate the body of a rule. If this occurs, then the system

searches for other atoms in the database to compute a full rule instantiation. If this process succeeds, then the processor produces a new derivation and puts it back in the queue and database so that it can be further considered, possibly by other processors.

This type of parallelism is significantly different than the other two because here the processors do not receive a predefined amount of work but are free to “steal” computation from each other whenever they become idle. A limitation of this technique is that it requires a number of data structures that allow a fast concurrent access. While hash tables can provide this functionality, they have the disadvantage that they are not cache-friendly, that is, they do not use efficiently the CPU cache.

Set-based rule execution. Another technique for improving the performance consists of generating meta-facts which represents multiple sets of facts. This technique can be intuitively explained with a simple example. Let us consider the rule:

$$P(X, Y) \rightarrow Q(Y, X) \quad (6)$$

and assume that the input database does not contain any q -facts. In this case, it is clear that each fact that matches the body will generate a new q -fact. Thus, the engine can simply create one single fact $q(y^*, x^*)$ where x^* and y^* are special terms which point to set of terms, namely, all first and second terms that appear in p -facts. For instance, if the database equals to $\{p(a, b), p(c, d)\}$, then $y^* \rightarrow \langle a, c \rangle$ and $x^* \rightarrow \langle b, d \rangle$. Notice that the engine does not need to explicitly materialize the lists $\langle a, c \rangle$ and $\langle b, d \rangle$ but can simply store instructions to compute this list on-the-fly in case it is needed.

This technique was first introduced in the VLog system (Urbani et al. 2016), and empirical results show excellent performance against the state of the art, especially because this technique becomes more effective with larger databases as potentially larger sets of facts can be compressed in a single meta-fact.

- Online machine learning covers methods that update their models after observing a new event and can immediately serve predictions based on the updated model.

Overview

In this chapter, we investigate online learning based recommender algorithms that can efficiently handle nonstationary datasets. We show that online learning for recommendation is rather usual than the exceptional task: For example, if no user history is available, we have to build a user model on the fly, based on the interactions in the live user session.

To the best of our knowledge, this is the first survey with a comprehensive overview of the ideas for recommendation over streaming data and their implementation in various distributed data stream processing systems.

The chapter is based on the notions of online learning, as introduced in the chapter “Overview of Online Machine Learning in Big Data Streams” of this Encyclopedia.

Recommender Systems Over Data Streams

Definitions

- Data stream algorithms process a continuous stream of data with only a limited possibility to store past records.

Introduction

Recommender systems (Ricci et al. 2011) serve to predict user preferences regarding items such as music tracks (Spotify), movies (Netflix), products, books (Amazon), blogs, or microblogs (Twitter), as well as content on friends’ and personal news feeds (Facebook).

Recommenders give a clear, industry-relevant example of the requirements for online machine learning introduced in the Chapter “► Overview of Online Machine Learning in Big Data Streams” of this Handbook. In a typical implementation, users interact with the system by requesting recommendations and then providing feedback by clicking on some of the displayed items. In this way, the users produce a continuous stream of events that can be used for model update and immediate evaluation, for example, by click-through rate. Note that in Žliobaite et al. (2012), it is observed that adaptive learning

models are still rarely deployed in industry. Recommender systems are the main exception: A special class, the session-based recommendation task appears frequently in practice when no past user history is available and user models are built on the fly, using recent interactions in the session.

Recommender systems can be categorized by the type of information they infer about users and items. Collaborative filtering (Linden et al. 2003; Sarwar et al. 2001) builds models of past user-item interactions such as clicks, views, purchases, or ratings, while content-based filtering Lops et al. (2011) recommends items that are similar in content, for example, share phrases in their text description. Context-aware recommenders (Adomavicius and Tuzhilin 2011) use additional information on the user and the interaction, for example, user location and weather conditions. Recent events in a user session (Koenigstein and Koren 2013) serve as a special context.

A milestone in the research of recommendation algorithms, the Netflix Prize competition (Bennett and Lanning 2007), had high impact on research directions. The target of the contest was based on the one- to five-star ratings given by users, with one part of the data used for model training and the other for evaluation. As an impact of the competition, tasks now termed batch rating prediction were dominating research results.

Recommendation models rely on the feedback provided by the user, which can be **explicit**, such as one- to five-star movie ratings on Netflix (Adhikari et al. 2012). However, most recommendation tasks are **implicit**, as the user provides no like or dislike information. Implicit feedback can be available in the form of time elapsed viewing an item or listening to a song, or in many cases, solely as a click or some other form of user interaction. In Pilászy et al. (2015), the authors claim that 99% of recommendation industry tasks are implicit.

As a main difference between recommendation and classification, classifiers usually work independently of the event whose outcome they predict. Recommender systems, on the other

hand, may directly influence observations: They present a ranked top list of items (Deshpande and Karypis 2004), and the user can only provide feedback for the items on the list. Moreover, real systems process data streams where users request one or a few items at a time and get exposed to new information that may change their needs and taste when they return to the service next time. Furthermore, an online trained model may change and return completely different lists for the same user even for interactions very close in time.

By the above considerations, real recommender applications fall in the category of top item recommendation by online learning for implicit user feedback, a task that has received less attention in research so far. In this section, we show the main differences in evaluating such systems compared to both classifiers and batch systems, as well as describe the main data stream recommender algorithms.

Online recommenders seem more restricted than those that can iterate over the data set several times, and one could expect inferior quality from the online methods. By contrast, in Pálovics et al. (2014) and Frigó et al. (2017), surprisingly strong performance of online methods is measured.

As an early time-aware recommender system example, the item-based nearest neighbor (Sarwar et al. 2001) can be extended with time-decay (Ding and Li 2005). Most of the early models, however, are time-consuming to compute and difficult to update from a data stream and hence need periodical batch training. Probably the first result in this area, the idea of processing transactions in chronological order to incrementally train a recommendation model first appeared in Takács et al. (2009, Section 3.5). Streaming gradient descent matrix factorization methods were also proposed in Isaacman et al. (2011) and Ali and Johnson (2011), who use Netflix and MovieLens data and evaluate by root mean square error (RMSE).

The difficulty of evaluating streaming recommenders was first mentioned in Lathia et al. (2009), although the authors evaluated models by offline training and testing split.

Ideas for online evaluation metrics appeared first in Pálovics and Benczúr (2013), Vinagre et al. (2014), and Pálovics et al. (2014). In Vinagre et al. (2014), incremental algorithms are evaluated using recall. In Pálovics et al. (2014), recall is shown to have undesirable properties, and other metrics for evaluating online learning recommenders are proposed.

Finally, we note that batch distributed recommender systems were surveyed in Karydi and Margaritis (2016).

Prequential (Online) Evaluation for Recommenders

To train and evaluate a time-sensitive or online learning recommender, we can use the prequential or online evaluation framework that is described in detail for classifier evaluation in the chapter “► Online Machine Learning Algorithms over Data Streams” of this Handbook. As seen in Fig. 1, online evaluation for a recommender system includes the following steps:

1. We query the recommender for a top- k recommendation for the active user.
2. We evaluate the list in question against the single relevant item that the user interacted with.
3. We allow the recommender to train on the revealed user-item interaction.

Since we can potentially retrain the model after every new event, the recommendation for the same user may be very different even at close points in time, as seen in Fig. 1. The standard

recommender evaluation settings used in research cannot be applied, since there is always only a single relevant item in the ground truth.

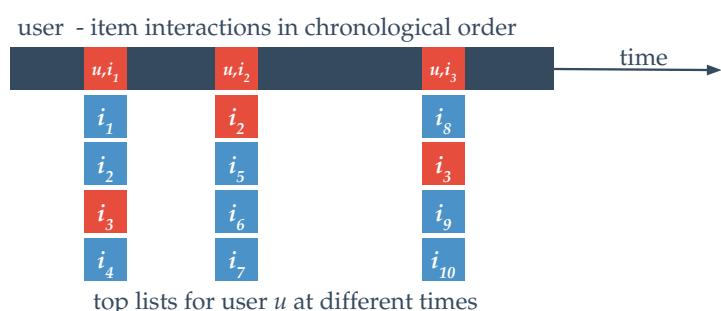

In one of the possible recommender evaluation settings, the **rating prediction** problem, which is popular in research, we consider a user u and an item i . The actual user preference in connection with the item is expressed as a value r_{ui} , for which the system returns a prediction \hat{r}_{ui} . This explicit rating can be a scale such as one to five stars for a Netflix movie, while implicit rating can be the duration of viewing a Web page in seconds. Implicit rating is binary when the only information is whether the user interacted with the item (clicked, viewed, purchased) or not. Depending on whether r_{ui} is binary or scale, the same prequential metrics, such as error rate or mean squared error (MSE), can be applied as for classification or regression. For example, in the Netflix Prize competition, the target was the square root of MSE between the predicted and actual ratings.

Another possible way to evaluate recommenders is **ranking prediction**, where performance metrics depend on the list of displayed items. We note that given rating prediction values \hat{r}_{ui} for all i , in theory, ranking prediction can be solved by sorting the relevance score of all items. For certain models, heuristics to speed up the selection of the highest values of \hat{r}_{ui} by candidate preselection exist (Teflioudi et al. 2015).

To evaluate ranking prediction, we have to take into consideration two issues that do not exist for classifier evaluation. In the case of prequential evaluation, as shown in Fig. 1, the list for user u may change potentially after every

Recommender Systems Over Data Streams, Fig. 1

Prequential evaluation of the online ranking prediction problem

interaction with u . As soon as u provides feedback for certain item i , we can change model parameters and the set of displayed items may change completely. Most of the batch ranking quality measures focus on the set of items consumed by the same user, under the assumption that the user is exposed to the same list of items throughout the evaluation. As this assumption does not hold, we need measures for individual user-item interactions.

Another issue regarding ranking prediction evaluation lies in a potential user-system interaction that affects quality scores. Typically, the set of items is very large, and users are only exposed to a relatively small subset, which is usually provided by the system. The form of user feedback is usually a click on one or more of these items, which can be evaluated by computing the click-through rate. Since users cannot give feedback on items outside the list, the fair comparison of two algorithms that present different sets for the user can only be possible by relying on live user interaction. This fact is known by practitioners, who use **A/B testing** to compare the performance of different systems. In A/B testing, the live set of users is divided into groups that are exposed to the results of the different systems.

Most traditional ranking prediction metrics, to a certain level, rely on the assumption that the same user is exposed to the same list of items, and hence the interactions of the same user can be considered to be the unit for evaluation. For online evaluation, as noted in Pálovics et al. (2014), the unit of evaluation will be a single interaction, which usually contains a single relevant item. Based on this modification, most batch metrics apply in online learning evaluation as well. Note that the metrics below apply not just in A/B testing but also in experiments with frozen data, where user feedback is not necessarily available for the items returned by a given algorithm. For example, if the item consumed by the user in the frozen data is not returned by the algorithm, the observed relevance will be 0, which may not be the case if the same algorithm is applied in an A/B test. Note that attempts to evaluate research results by A/B testing have been made in the information retrieval community (Balog

et al. 2014); however, designing and implementing such experiments is cumbersome.

Next, we list several metrics for the quality of the ordered top- K list of items $L = \{i_1, i_2, \dots, i_K\}$ against the items E consumed by the user. We will also explain how online evaluation metrics differ from their batch counterparts. For the discussion, we mostly follow Pálovics et al. (2014).

Click-through rate is commonly used in the practice of recommender evaluation. It is defined as the ratio of clicks received for L :

$$\text{Clickthrough@K} = \begin{cases} 1 & \text{if } E \cap L \neq \emptyset; \\ 0 & \text{otherwise.} \end{cases} \quad (1)$$

For precision and recall, similar to click-through, the actual order within L is unimportant:

$$\begin{aligned} \text{Precision@K} &= \frac{|E \cap L|}{K}, \\ \text{Recall@K} &= \frac{|E \cap L|}{|E|}. \end{aligned} \quad (2)$$

For batch evaluation, E is the entire set of items with positive feedback from a given user who is exposed to the same L for each interaction. The overall batch system performance can be evaluated by averaging precision and recall over the set of users. For online evaluation, typically $|E| = 1$, where Precision@K is 0 or $1/K$ and Recall@K is 0 or 1 depending on whether the actual item in E is listed in L or not. Precision and recall are hence identical to click-through, up to a constant. As a consequence, the properties of online precision and recall are very different from their batch counterparts. The main reason for the difference lies in the averaging procedure of prequential evaluation: We cannot merge the events of the same user; instead, we average over the set of individual interactions.

Measures that consider the position of the relevant item i in L can give more refined performance indication. The first example is reciprocal rank:

$$RR@K = \begin{cases} 0 & \text{if rank}(i) > K; \\ \frac{1}{\text{rank}(i)} & \text{otherwise.} \end{cases} \quad (3)$$

Discounted cumulative gain (DCG) is defined similarly, as

$$\text{DCG@K} = \sum_{k=1}^K \frac{\text{rel}(i_k)}{\log_2(1+k)} \quad (4)$$

where $\text{rel}(i_k)$ indicates the relevance of the i -th item in the list. For the implicit task, relevance is 1 if the user interacted with the item in the evaluation set, 0 otherwise. For batch evaluation, we can consider all interactions of the same user as one unit. If we define iDCG@K , the ideal maximum possible value of DCG@K for the given user, we can obtain nDCG@K , the normalized version of DCG@K, as

$$\text{nDCG@K} = \frac{\text{DCG@K}}{\text{iDCG@K}}. \quad (5)$$

Note that for online learning, there is only one relevant item, hence $\text{iDCG} = 1$. For emphasis, we usually use the name nDCG for batch and DCG for online evaluation.

Session-Based Recommendation

Previous items in user sessions constitute a very important context (Hidasi and Tikk 2016). In e-commerce, the same user may return next time with a completely different intent and may want to see a product category completely different from the previous session. Algorithms that rely on recent interactions of the same user are called **session-based item-to-item** recommenders. The user session is special context, and it is the only information available for an item-to-item recommender. In fact, several practitioners (Koenigstein and Koren 2013; Pilászy et al. 2015) argue that most of the recommendation tasks they face are without sufficient past user history. For example, users are often reluctant to create logins and prefer to browse anonymously. Moreover, they purchase certain types of goods (e.g., expensive electronics) so rarely that their previous purchases will be insufficient to create a meaningful user profile. Whenever a long history of previous activities or purchases by the user is not available,

recommenders may propose items that are similar to the most recent ones viewed in the actual user session.

Session-based recommendation can be served by very simple algorithms, most of which are inherently online. A comparison of the most important such online algorithms in terms of performance is available in Frigó et al. (2017). Data stream processing algorithms can retain items from the most recently started sessions as long as they fit in their memory. Recommendation is based on the recent items viewed by the user in the actual shopping session. For example, we can record how often users visited item i after visiting another item j . Since fast update to transition frequencies is usually possible, the method is online.

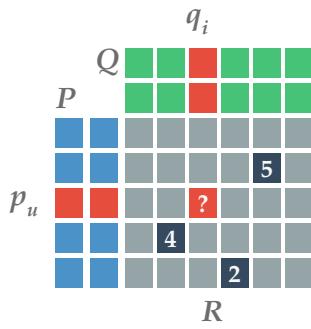

In an even simpler algorithm that is not strictly session-based, we recommend the most popular recent items. This method can be considered batch or online depending on the granularity of the item frequency measurement update. Both algorithms can be personalized if we consider the frequency of past events involving the user. If items are arranged hierarchically (e.g., music tracks by artist and genre), personal popularity and personal session data can involve the frequency of the artists or genres for recommending tracks. More session-based algorithms are described in Koenigstein and Koren (2013).

R

Online Matrix Factorization

Most nontrivial online recommender algorithms are based on matrix factorization (Koren et al. 2009), a popular class of collaborative filtering methods. Given the user-item utility matrix $R = [r_{ui}]$ shown in Fig. 2, we model R by decomposing it into the two dense matrices P and Q . For a given user u , the corresponding row in P is user vector p_u . Similarly, for item i , the corresponding column of Q is item vector q_i . The predicted relevance of item i for user u is then

$$\hat{r}_{ui} = p_u q_i^T. \quad (6)$$

Recommender Systems Over Data Streams, Fig. 2
Utility matrix R and the matrix factorization model built from matrices P and Q

Note that we can extend the above model by scalar terms that describe the biased behavior of the users and the items (Koren et al. 2009).

One possibility to train model parameter matrices P and Q is by gradient descent (Koren et al. 2009; Funk 2006), which can be applied to online learning as well (Pálovics et al. 2014). For a set of interactions E , we optimize Eq. (6) for MSE as target function:

$$MSE = \frac{1}{N} \sum_{i=1}^N (\hat{r}_{ui} - r_{ui})^2, \quad (7)$$

where r_{ui} is the actual and \hat{r}_{ui} is the predicted rating for user u and item i and N is the current size of the data stream.

In one step of gradient descent, we fit P and Q in Eq. (6) to one of the ratings in E . Unlike in batch training, where we can use the ratings several times in any order, in online learning, we have the most recent single item in E . In other words, in online gradient descent, we fit the model to the events one by one as they arrive in the data stream.

For a given (explicit or implicit) rating r_{ui} , the steps of gradient descent are as follows. First, we compute the gradient of objective function F with respect to the model parameters:

$$\frac{\partial F}{\partial p_u} = -2(r_{ui} - \hat{r}_{ui})q_i, \quad \frac{\partial F}{\partial q_i} = -2(r_{ui} - \hat{r}_{ui})p_u. \quad (8)$$

Next, we update the model parameters in opposite direction of the gradient, proportionally to learning rate η , as

$$p_u \leftarrow \eta(r_{ui} - \hat{r}_{ui})q_i,$$

$$q_i \leftarrow \eta(r_{ui} - \hat{r}_{ui})p_u.$$

Overfitting is usually avoided by adding a regularization term in the objective function (Koren et al. 2009).

In the case of implicit feedback, the known part of the utility matrix only contains elements with positive feedback. To fit a model, one requires negative feedback for training as well. Usually, such elements are selected by sampling from those that the user has not interacted with before Rendle and Freudenthaler (2014). We can also introduce confidence values for ratings and consider lower confidence for the artificial negative events (Hu et al. 2008).

Gradient descent can also be used in a mix of batch and online learning, for example, training batch models from scratch periodically and continuing the training with online learning. We can also treat users and items differently, for example, updating user vectors more dynamically than item vectors, as first suggested by Takács et al. (2009).

Another use of online gradient descent is to combine different recommendation models (Pálovics et al. 2014). We can express the final prediction as the linear combination of the models in the ensemble whose parameters are the linear coefficients and the individual model parameters. In Pálovics et al. (2014), two online gradient descent methods are described with regard to whether the derivative of the individual models is available, where all parameters can be trained through the derivative of the final model or otherwise by learning the coefficients and the individual models separately.

Variants of Matrix Factorization

Several variants of matrix factorization that can be trained by gradient descent both for batch

and online learning tasks have been proposed. Bayesian Personalized Ranking (Rendle et al. 2009) has top list quality as target instead of MSE. In asymmetric matrix factorization (Pátek 2007), we model the user by the sum of the item vectors the user rated in the past.

Recently, various factorization models have been developed that incorporate context information (Hidasi and Tikk 2016). Context data can be modeled by introducing data tensor D instead of the rating matrix R . In a simplest case, the data includes a single piece of additional context information (Rendle and Schmidt-Thieme 2010): for example, music tracks can have artist as context.

Alternating least squares (Koren et al. 2009; Pilászy et al. 2010) (ALS) is another optimization method for matrix factorization models, in which for a fixed Q , we compute the optimal P , then for a fixed P , the optimal Q , repeatedly until certain stopping criteria are met. Hidasi et al. Hidasi and Tikk (2012); Hidasi (2014); Hidasi and Tikk (2016) introduced several variants of ALS-based optimization schemes to incorporate context information. By incremental updating, ALS can also be used for online learning (He et al. 2016).

Conclusions

Recommendation differs from classification in that in recommendation, there are two types of objects, users, and items, and a prediction has to be made for their interaction. A practical recommender system displays a ranked list of a few items for which the user can give feedback. In an online learning system, the list shown to the same user at different times may change completely for two reasons. First, as in the prequential classifier training and evaluation setting described in detail for classifier evaluation in the chapter “► Online Machine Learning Algorithms over Data Streams” of this Handbook, the list of recommendations may change because the model changes. Second, the user feedback we use for evaluation depends on the actual state of the model, since the user may have no means to express interest in an item not displayed. Hence for online learning

evaluation, metrics that involve the notion of a volatile list have to be used.

Online learning, as introduced in the chapter “► Overview of Online Machine Learning in Big Data Streams” of this Handbook, is very powerful for recommender systems due to their advantage of having much more emphasis on recent events. For example, if we update models immediately for newly emerged users and items, trends are immediately detected. The power of online learning for recommendation may also be the result of updating user models with emphasis on recent events, which may be part of the current user session. User session is a highly relevant context for recommendation, and most session-based methods are inherently online.

Synonyms

Duplicate detection; Entity resolution

Definitions

Record linkage refers to the task of extracting record information from various input data sources and combining them in such a way that each output record corresponds to a distinct real-world entity.

Overview

Record linkage is part of the broader area of data integration and more specifically data cleaning. It is most commonly used as a means to identify duplicates in a dataset or multiple datasets. The biggest challenge when executing record linkage algorithms is the trade-off between quality and performance. That is, record linkage is often run on high-volume datasets for which even sophisticated algorithms will not be able to provide high-quality results in a suitable timeframe. Thus, techniques such as blocking or incremental computation are applied to improve performance at the cost of decreased result quality. Additional challenges in record linkage include various types of input sources that are not necessarily structured. For example, human-generated data for record linkage has been extensively studied in recent years under the assumption that human-generated data on the similarity of records has better quality than machine-generated data.

Key Research Findings

Record linkage is a decades-old problem that has been studied extensively. It can be split into several key research areas. First, *similarity computation* describes the challenge of identifying whether two records are similar. Second, there exists a variety of *algorithms* that take these similarities as input and output (sets of) records where each record represents a real-world entity. Finally, *performance* challenges have arisen in the context of record linkage due to an increase in data volume and velocity and the inherent quadratic scaling of exhaustive record linkage algorithms.

Similarity Computation

To identify whether two records refer to the same entity, it is crucial to measure their similarity. For example, Table 1 shows different business addresses that can be found in datasets obtained from (semi-)manually curated business listings. Here, different records r_i have different formats, some have erroneous values, and others may have missing data. This exemplifies that comparable similarity computation is not trivial. For example, is r_1 as similar to r_2 (different formatting) as it is to r_3 (wrong phone number)? The most common similarity computation techniques are based on the similarity of the characters in the record strings, Elmagarmid et al. (2007), when comparing two input records. Examples for pair-wise character-based similarity computation techniques are edit distances such as the Levenshtein distance, Levenshtein (1966), or metrics such as the Jaro similarity metric, Jaro (1978). Alternatively, some record linkage systems also use token-based similarity, first proposed by Monge et al. (1996), or phonetic similarity, Russell (1922). The chosen similarity metric often depends on the use case that the record linkage mechanism is applied in.

Given these similarity metrics, it is obvious that resolving the similarity between records r_i and r_j is not always certain. That is, independent of the actual metric, the pair-wise similarity of records r_i and r_j is typically represented as a probability $p \in [0, 1]$ where $p(r_i, r_j) = 1$ signi-

Record Linkage, Table 1 Example business addresses

ID	Name	Address	City	Phone
r_1	Peet's coffee	2124 Vine St Ste1	Berkeley	(510) 841-0564
r_2	Peet's coffee	2124 VINE ST	BERKELEY	5108410564
r_3	Peet's coffee	2124 Vine St	Berkeley	5102257700
r_4	Peet's	2501 Telegraph Ave	Berkeley	(510) 225-7700
r_5	Peet's	2501 Telegraph Ave		(510) 225-7700
r_6	Peet's coffee		Berkeley	

fies that both records are identical. Uncertainty in the similarity computation can thus be expressed explicitly, i.e., $p(r_i, r_j) \approx 0.5$.

Algorithms

Algorithms for record linkage take as input the pair-wise similarity values, evaluate them, and output a partitioning of records $R = \bigcup R_k$. In this partitioning, each record $r_i^k \in R_k$ points to the same real-world entity e_k . This problem has been approached from various angles. Amongst the most significant are techniques such as *probabilistic modeling*, *graph clustering*, and *(semi-)supervised learning* described in detail next. Note that this is not a complete list of record linkage algorithms many of which are explained and evaluated by Hassanzadeh et al. (2009) or discussed in Dong and Srivastava (2015).

Probabilistic Modeling. First formalized by Fellegi and Sunter (1969), the core idea of probabilistic modeling for record linkage is to assign a record pair $\gamma = (r_i, r_j)$ to either a set of matches M or non-matches U based on the computational similarity of γ . Specifically, assigning the pair to M signifies that $r_i = r_j$, while if the pair is in U , then $r_i \neq r_j$ holds. The record pair is assigned to M if the probability of assigning γ to M based on the agreement $m(\gamma)$ is higher than the probability of assigning γ to U based on disagreement $u(\gamma)$, i.e., $P(M|m(\gamma)) > P(U|u(\gamma))$. Using the Bayes rule, this can be rewritten as

$$\gamma \in \begin{cases} M, & \text{if } \frac{P(m(\gamma)|M)}{P(u(\gamma)|U)} > \frac{P(U)}{P(M)}, \\ U & \text{otherwise.} \end{cases} \quad (1)$$

Probabilistic modeling assumes, as the name indicates, that the decision whether γ is a match is non-trivial and has to be expressed as a likelihood. Thus, by design, there will be cases where there exists evidence for γ being in M and U at the same time. To resolve this problem, probabilistic modeling assumes that assigning γ to M even though there exists some evidence that it should be in U incurs an error reflected in a penalty. Finding the assignment of all possible record pairs thus becomes an *error minimization* problem. Furthermore, Fellegi and Sunter (1969) observed that the similarity functions that determine the agreements and disagreements of γ may contain errors. Thus, they loosened their categorization of γ to allow it to be classified as a *possible pair* if there is evidence for both a match and a non-match. Pairs in that group are confirmed by human workers after the automated record linkage has concluded.

Correlation Clustering. Correlation clustering is a popular graph clustering technique for record linkage, Bansal et al. (2004). At its core, it builds upon the idea of probabilistic modeling to determine whether a record pair is a match or non-match, but instead of assigning the pair to distinct classes, correlation clustering assigns them to distinct record clusters where each cluster represents a real-world entity. The assignment is done analogous to the idea of error minimization in probabilistic modeling, i.e., if the penalty of adding a record r_i to a cluster c_k is smaller than the penalty of adding it to any other cluster or keeping it as a singleton cluster, then the record is added to c_k . Note that correlation clustering can also be formulated as an *agreement maximization*

problem which may be easier to implement for some use cases.

Formally, correlation clustering works as follows. Assume that F is the penalty for the a clustering C and $p(r_i, r_j)$ is the probability of r_i and r_j belonging to the same cluster $c_k \in C$. An optimal clustering C^* is the clustering that has the smallest value of F , i.e., F^* , given any possible clustering. Recall that its value is computed as the global penalty. In other words, if records r_i and r_j are in the same cluster c_k but $p(r_i, r_j) < 1$, then this clustering incurs a penalty of $1 - p(r_i, r_j)$. Similarly, if r_i and r_j are not in c_k , the clustering incurs a penalty of $p(r_i, r_j)$. F is thus computed as:

$$F(C) = \sum_{c_k \in C \wedge r_i, r_j \in c_k} 1 - p(r_i, r_j) + \sum_{c_k \in C \wedge r_i \in c_k \wedge r_j \notin c_k} p(r_i, r_j) \quad (2)$$

Note that there may exist multiple clusterings that all have the same value F^* and are thus considered optimal.

Calculating C^* exhaustively is computationally infeasible. Thus, Bansal et al. (2004) propose an approximation algorithm called *cautious* correlation clustering with an approximation parameter δ . It proceeds iteratively as follows on a set of records R :

1. Pick a node $r_i \in R$ at random.
2. Add the neighborhood of r_i , i.e., all records connected to r_i , to cluster c_k .
3. Remove all records in c_k that are not 3δ -good.
4. Add all records in the neighborhood of c_k that are 7δ -good.
5. Remove all records in c_k from R . Jump to 1.

The parameter δ is specific to cautious correlation clustering and is used to give a guarantee of how much the approximated solution diverges from the optimal solution. Specifically, the authors show that with the above algorithm, a $9(\frac{1}{\delta^2} + 1)$ approximation can be found in $O(R^2)$.

(Semi-)Supervised Learning. Learning techniques have shown potential for improvement of record linkage solutions especially for record linkage scenarios where the similarity of records

cannot be captured with simpler similarity comparison techniques such as character-based similarities. Amongst others, there has been work on applying SVMs, Bilenko et al. (2003), and learning how to cluster records that refer to the same real-world entity in a supervised manner, Cohen and Richman (2002). More recently, research in the area of record linkage has seen an increase in work combining crowdsourcing, i.e., human responses, and automated entity resolution techniques. For example, Wang et al. (2012) and as follow-up Wang et al. (2014) discuss strategies to minimize the number of crowd requests while at the same time increasing the quality of the record linkage solution. Specifically, the idea in this line of work is to leverage positive responses of the crowd workers to reduce the search space based on transitivity. That is, if records r_i and r_j represent the same real-world entity, and r_j and r_l refer to different entities, then the crowd does not need to confirm the relationship of r_i and r_l . Other work in this area has also utilized similar techniques as applied for probabilistic modeling to maximize the quality of a crowdsourced record linkage solution, Verroios and Garcia-Molina (2015).

Performance Improvements

With an increase in stored data and processing capabilities, new challenges have arisen for executing traditional record linkage efficiently. For example, large datasets in the 1960s for which some of the original record linkage algorithms were developed, are multiple orders of magnitude smaller than current linkage datasets. Thus, several performance improvement techniques such as *blocking* or *incremental data processing* have been applied in the context of record linkage to make this process computationally feasible. A drawback of these algorithms and mechanisms is that they often trade off quality for performance.

Blocking. The purpose of blocking is to parallelize computationally expensive steps in the record linkage process. Basically, blocking partitions the record set R according to a pre-defined input function f that maps a record $r_i \in R$ to a block B_k , Jaro (1989). The goal of f is to

map all records that point to the same real-world entity to the same B_k . Techniques such as similarity comparison which would have to be run in $O(R^2)$ before can then be run in $O(|B_k|^2)$. The applied mapping function is either based on the record characteristics such as the words, tokens, or k-grams it contains, domain knowledge of the record linkage context, user-specified constraints, Arasu et al. (2009), or techniques such as sorted neighborhood, Hernández and Stolfo (1998). The drawback of defining such functions is that there are no guarantees whether any blocking function will correctly map all records of the same real-world entity to the same block. Approaches to address this problem are, for example, to deploy multiple blocking functions or compute overlapping canopies instead of distinct blocks, McCalum et al. (2000).

Incremental Record Linkage. Datasets that are deduplicated are often static and only occasionally updated. The idea behind incremental record linkage is to leverage that observation and to only (re)compute those parts of the record linkage solution that have been directly or indirectly modified by updates in the input dataset. First discussed by Benjelloun et al. (2009) as agglomerative clustering, the basic idea of incremental record linkage was extended by Gruenheid et al. (2014) to allow any kind of data modification of the input dataset and to provide theoretical guarantees for graph record linkage techniques.

In practice, incremental record linkage does not modify the idea of the original batch linkage algorithm, for example, correlation clustering, but modifies these algorithms to fit an iterative linkage use case. Depending on the applied batch linkage algorithm, this may lead to a decrease in the quality of the linked results if the record linkage computation is global and cannot be localized, i.e., when the whole dataset is required as input to form an optimal solution.

Applications of Record Linkage

Entity resolution is a task important for many different data integration and more recently ma-

chine learning systems. Thus, there exist dedicated systems such as IBM InfoSphere that have been commercializing record linkage for many decades as part of so-called ETL (extract, transform, load) processes. The most common use case for commercial system is that legacy data in companies is stored in various places such as databases, file systems, etc. and needs to be combined efficiently and without losing any of the input data. Deduplication issues arise also if companies merge and the data of the acquired company has to be integrated into the existing internal database. Next to commercial systems, there also exist open source alternatives that can be used for entity resolution such as Konda et al. (2016).

Furthermore, record linkage is part of pipelines used for data cleaning. The goal is to find “dirty” data which is the same record inserted into the system multiple times with slight variations; see Table 1 for an example. It is crucial to have good-quality linkage results for such pipelines as the consolidated entities are often shown in user interfaces. For example, information about restaurants, attractions, etc. can be obtained from a number of input data sources such as the place’s website, community boards discussing the place, or third parties storing information on businesses. Thus, it needs to be consolidated before appearing on platforms such as Facebook or Google Maps.

Future Directions for Research

Although record linkage has been extensively studied, developments in data processing and learning continuously change its scope. For example, with the construction of knowledge bases, record linkage became a focus of those that wanted to interpret user feedback and content. They then developed new techniques for the new context in which record linkage was applied in. Next to specific applications of record linkage, there also exists a general trend to make record linkage part of existing data integration pipelines and to provide tools that enable users to execute record linkage with low overhead and in near

real-time. As a result, one of the challenges and still an open problem of such an integration is interactive record linkage given that most traditional linkage algorithms have been designed for offline processing.

Definitions

- Data stream algorithms process a continuous stream of data with only a limited possibility to store past records.
- Online machine learning covers methods that update their models after observing a new event and can immediately serve predictions based on the updated model.

Overview

In this chapter, we give a brief overview the following special topics in online machine learning: Reinforcement learning; unsupervised data mining methods, including clustering, frequent itemset mining, dimensionality reduction, and topic modeling; finally, we list the most important concept drift adapting learning methods.

This Chapter is an extension of the other chapters in this Handbook, “Overview of Online Machine Learning in Big Data Streams”, “Online Machine Learning Algorithms over Data Streams”, and “Recommender systems over Data Streams”

Reinforcement Learning

Reinforcement learning is an area of machine learning concerned with agents taking actions in an environment with the aim of maximizing some cumulative reward. It is different from supervised learning in that the environment does not provide a target behavior, only rewards depending on the actions taken.

The environment is typically assumed to be a Markov decision process (MDP). Formally, we assume a set of states, S ; a set of actions, A ; and a transition probability function $P(s, a, s')$ denoting the probability of reaching state s' after taking action a in state s and a reward function $R(s, a)$ denoting the immediate reward after taking action a in state s .

While there is a wide range of reinforcement learning algorithms (see, e.g., Sutton and Barto 1998), we focus here on algorithms that fit the streaming model and (possibly) deal with non-stationary environments. The streaming model of

reinforcement learning is constrained not only by a continuous flow of input data but also by a continuous requisite to take actions.

Algorithms for Stationary Environments

Most reinforcement learning algorithms estimate the value of feasible actions and build a policy based on that value (e.g., by choosing the actions with the highest estimates with some additional exploration). An alternative to value prediction methods are policy gradient methods that update a parameterized policy depending on the performance.

Value Prediction

The value of a state is the expected cumulative reward starting from a given state and following a particular policy. In a similar way, the action value is the expected reward starting from a given state with a particular action.

Value prediction methods estimate the value of the state or the value of the actions in particular states. In the former case, to build a policy from the estimated values, an additional transition model is needed as well. Such a model is provided for some domains (e.g., by the rules of a game), but in many cases, the transition model needs to be learned as well. Action values can be used directly for constructing a policy without the need for a model.

Temporal difference (TD) learning learns the state value estimate $V(s)$ by the following update rule after each state transition (S_t, S_{t+1}) :

$$V(S_t) \leftarrow (1 - \alpha)V(S_t) + \alpha(R_t + \gamma V(S_{t+1})),$$

where α is a step-size and γ is the discount factor. TD learning was used in one of the first breakthroughs for reinforcement learning, that is, Tesauro’s backgammon program (Tesauro 1995).

The best-known action-value prediction algorithm is Q-learning (Watkins and Dayan 1992). For each occurrence of a transition (S_t, A_t, S_{t+1}) , the algorithm updates the action-value $Q(S_t, A_t)$ by

$$\begin{aligned} Q(S_t, A_t) &\leftarrow (1 - \alpha)Q(S_t, A_t) \\ &+ \alpha(R_t + \gamma \max_a Q(S_{t+1}, a)). \end{aligned}$$

Q-learning using deep neural network to approximate the action-values has been successfully applied to playing some Atari games at human expert level (Mnih et al. 2015).

Another algorithm that learns action-values is Sarsa (Sutton 1996). For each sequence $S_t, A_t, S_{t+1}, \text{and } A_{t+1}$, the algorithm updates its estimates by

$$\begin{aligned} Q(S_t, A_t) &\leftarrow (1 - \alpha)Q(S_t, A_t) \\ &+ \alpha(R_t + \gamma Q(S_{t+1}, A_{t+1})). \end{aligned}$$

Sarsa was successfully used by Ipek et al. (2008) for optimizing a DRAM memory controller.

The value prediction algorithms above were described with update rules for a tabular representation. In most cases, function approximation is used, and the update rules rely on a gradient step. Online enhancements of gradient descent as well as eligibility traces (Sutton and Barto 1998) can be applied to all variants.

Policy Gradient

While using value functions is more widespread, it is also possible to use a parameterized policy without relying on such functions. Parameterized policies are typically optimized by gradient ascent with respect to the performance of the policy.

A policy gradient algorithm, the REINFORCE algorithm (Williams 1992), was used to optimize policy in a Go playing program that outperforms the best human players (Silver et al. 2016).

Algorithms for Nonstationary Environments

Most reinforcement learning algorithms, including those discussed in the previous section, assume that the environment does not change over time. While incremental algorithms such as Q-learning can adapt well to nonstationary environments, it may be necessary to devise more explicit exploration strategies that can cope with changes, for example, in reward distribution.

A special case of reinforcement learning is the multiarmed bandit problem. In this case, the

agent repeatedly selects an action from K possible choices, obtaining a reward after each choice. This problem retains the notion of reward; however, there are no states and consequently no state transitions. In the non-stochastic variant (Auer et al. 2002), the distribution of the rewards may change over time arbitrarily. Standard algorithms for this problem are Exp3 and its variants (Auer et al. 2002), which rely on an exponential selection algorithm, including some exploration terms as well. Contextual bandits extend the bandit setting with the notion of state (or context); however, state transitions are still missing. This framework was used, for instance, in (Li et al. 2010) to select personalized new stories. We note that the distinguishing feature of recommendation in a bandit setting is that the user can provide feedback only on the recommended items.

Unsupervised Data Mining

The most prominent class of unsupervised learning methods is **clustering** where instances have to be distributed into a finite set of clusters such that instances within the cluster are more similar to each other than to others in different clusters (Pang-Ning 2006). Batch clustering algorithms have been both studied and employed as data analysis tools for decades (Jain et al. 1999; Wunsch 2008). One frequently applied clustering method is **k-means** (Hartigan and Hartigan 1975) where cluster center selection and assignment to nearest centers are iteratively performed until convergence. Another is **DBSCAN** (Ester et al. 1996), a density-based method that groups points that are closely packed together.

Online clustering algorithms are surveyed among other places in Mahdiraji (2009), Kavitha and Punithavalli (2010), Aggarwal (2013), and Silva et al. (2013). The majority of the most relevant methods are data stream versions of k-means or its variants such as k-medians (Zhang et al. 1996; Bradley et al. 1998; Farnstrom et al. Farnstrom; O'callaghan et al. 2002; Guha et al. 2003; Aggarwal et al. 2003; Zhou et al. 2008; Gama et al. 2011; Kranen et al. 2011; Ackermann et al. 2012). Another set of results describes the

data stream implementation of DBSCAN (Cao et al. 2006; Chen and Tu 2007; Kranen et al. 2011). Finally, an online hierarchical clustering algorithm that maintains similarity measures and hierarchically merges closest clusters is described in Rodrigues et al. (2006).

Finding frequent itemsets Agrawal et al. (1993) is another central unsupervised data mining task, both static and streaming. In brief, for a table of transactions and items, the task is to find all subsets of items that occur together in transactions with at least a prescribed frequency. Several variants of the task are described in Aggarwal and Han (2014). Online frequent itemset mining algorithms are surveyed in Cheng et al. (2008b). Algorithms based on counts of all past data in the stream (Chang and Lee 2003; Giannella et al. 2003; Li et al. 2004; Yu et al. 2004; Lee and Lee 2005) are also called landmark window-based approaches. In some of these algorithms, time adaptivity is achieved by placing more importance on recent items (Chang and Lee 2003; Giannella et al. 2003; Lee and Lee 2005). Sliding window-based approaches (Chang and Lee 2003; Chi et al. 2006; Chang and Lee 2006; Song et al. 2007; Cheng et al. 2008a; Li et al. 2009; Yen et al. 2011; Calders et al. 2014) are particularly suitable for processing data with concept drift. For a comparative overview, see, for example, how MOA’s algorithm was selected (Quadrana et al. 2015). Note that a special subtask, finding frequent items in data streams, is already challenging and requires approximate data structures (Charikar et al. 2004).

Principal component analysis (PCA) is a powerful tool for dimensionality reduction (Jolliffe 1986) based on matrix factorization. Online variants are based on ideas to incrementally update the matrix decomposition (Bunch and Nielsen 1978; Hall et al. 2000; Brand 2002). The first PCA algorithms suitable for online learning are based on neural networks (Oja 1982; Sanger 1989; Oja 1992). Similar to linear classification and regression models, PCA can also apply the kernel trick to involve nonlinear modeling (Schölkopf et al. 1998). Iterative **kernel PCA** is described in Kim et al. (2005) and Günter

et al. (2007) and online kernel PCA in Honeine (2012). We note that for nearest neighbor search in the low-dimensional space provided by PCA, the heuristics for selecting large inner products is applicable (Teflioudi et al. 2015).

Probabilistic topic modeling fits complex hierarchical Bayesian models to large document collections. A topic model reveals latent semantic structure that can be used for many applications. While PCA-like models can also be used for latent semantic analysis (Deerwester et al. 1990), recently the so-called **Latent Dirichlet Allocation (LDA)** (Blei et al. 2003) has gained popularity. Most topic model parameters can only be inferred based on Markov Chain Monte Carlo sampling, a method difficult to implement for online learning. LDA inference is possible based on either online Gibbs sampling (Song et al. 2005; Canini et al. 2009) or online stochastic optimization with a natural gradient step (Hoffman et al. 2010). Several online LDA variants are described in Smola and Narayananurthy (2010), Ho et al. (2013), Li et al. (2014), Yuan et al. (2015), Yu et al. (2015), Jagerman et al. (2017).

Concept Drift and Adaptive Learning

In dynamically changing and nonstationary environments, we often observe concept drift as the result of data distribution change over time. The phenomenon and mitigation of concept (or dataset) drift for online learning are surveyed in several articles (Widmer and Kubat 1996; Tsymbal 2004; Quionero-Candela et al. 2009; Žliobaite et al. 2012; Gama et al. 2014). The area of transfer learning where the (batch) training and the test sets are different (Pan and Yang 2010) is closely related to concept drift (Storkey 2009) but more difficult in the sense that adaptation by learning part of the new data is not possible.

Adaptive learning refers to the technique of updating predictive models online to react to concept drifts. One of the earliest active learning systems is STAGGER (Schlimmer and Granger 1986). In Žliobaitė (2009), the main steps of online adaptive learning are summarized as (1) making assumptions about future distribution, (2)

identifying change patterns, (3) designing mechanisms to make the learner adaptive, and (4) parameterizing the model at every time step.

A comprehensive categorization of concept drift adaptation techniques is found in Gama et al. (2014). Online learning algorithms can naturally adapt to evolving distributions. However, adaptation happens only as the old concepts are diluted due to the new incoming data, which is more suitable for gradual changes (Littlestone 1988; Domingos and Hulten 2000). For sudden changes, algorithms that maintain a sliding window of the last seen instances perform better (Widmer and Kubat 1996; Gama et al. 2004; Kuncheva and Žliobaitė 2009). Another option is to include explicit forgetting mechanisms (Koychev 2000; Klinkenberg 2004; Elwell and Polikar 2009). The most important distinction is whether changes are explicitly or implicitly detected: **Trigger-based** methods aim at detecting when concept drift occurs to build a new model from scratch (Gama et al. 2004). **Evolving learners**, by contrast, do not aim to detect changes but rather maintain the most accurate models at each time step. Evolving learners are method-specific, most of them are based on ensemble methods (Wang et al. 2003; Kolter and Maloof 2003).

A few papers (Minku et al. 2010; Moreno-Torres et al. 2012) give overviews of different types of environmental changes and concept drifts based on speed, recurrence, and severity. Drift can happen gradually or suddenly, in isolation, in tendencies or seasonally, and predictably or unpredictably, and its effect on classifier performance may or may not be severe. In Schlimmer and Granger (1986), Gama et al. (2004), several artificial data sets with different drift concepts, sudden or abrupt, and gradual changes are described.

A large variety of single classifier and ensemble models capable of handling concept drift are described in Tsymbal (2004). Perhaps the majority of the results consider tree-based methods Alberg et al. (2012). For example, concept drift adaptive online decision trees based on a statistical change detector that works on sliding windows are described in Bifet and Gavald (2009),

Bifet (2010). More examples include Bayesian models (Gama et al. 2003; Bach and Maloof 2010), neural networks (Gama and Rodrigues 2007; Leite et al. 2013), and SVM (Syed et al. 1999; Klinkenberg and Joachims 2000). Concept drift adaptation methods exist for clustering (Rodrigues et al. 2006; Silva et al. 2013). Sliding window-based data stream frequent itemset mining is also adaptive (Quadrana et al. 2015). Some of the results do not follow the data stream computational model but rather use computational resources with little restriction. One class of such methods are incremental algorithms with partial memory (Maloof and Michalski 2004). We also note that there is a MOA-based software system for concept drift detection (Bifet et al. 2013).

Rendezvous Architectures

Ted Dunning and Ellen Friedman
MapR Technologies and Apache Software
Foundation, Santa Clara, CA, USA

Definitions

Rendezvous architectures are a class of streaming microservice architecture designed to manage multiple implementations of a streaming function so that new implementations can be deployed easily and accurately, input data can be archived precisely, and past operations can be audited while maintaining strict service-level guarantees. Although suitable for more general application, rendezvous architectures are particularly useful for the special case of managing machine learning models. The discussion here follows the trend of associating rendezvous architecture with machine learning and is largely limited to that context.

Historical Background

The management of logistics in machine learning systems has always been notoriously difficult, particularly when there are multiple data sources and, as is almost always the case, multiple models being iteratively developed, evaluated, and deployed at the same time. Requirements include stability and reliability in production along with agility in response to changes. The challenges are even greater when this needs to be done at large scale, in a production setting, and in such a way as to meet critical service-level agreements that increasingly include guaranteed low latency (Böse et al. 2017; Dunning and Friedman 2017). People who are new to machine learning may think that machine learning models can be managed in the same way as normal software, by using continuous integration techniques to deploy a single high-quality model, but the reality for machine learning systems is far different. Successful projects involve a large number of models

both in development and in production simultaneously. Simply determining which model is more accurate is difficult. Moreover, the proliferation of machine learning frameworks means that production models may not share common base technologies. Maintaining strict availability and latency service levels while simultaneously dealing with these other difficulties can be particularly difficult.

Another source of challenges lies in the fact that the process of machine learning model development and evaluation is iterative and needs to operate in a sufficiently flexible and agile way that allows for experimentation and timely response to the need for new or retuned models without compromising operational characteristics like worst-case latency or failure tolerance. Even when models are running well in production, there is still a need for continuous deployment in part because external conditions change. For example, customer behavior may change, fraudsters may develop new tricks, or business goals and requirements may be realigned, thus degrading the performance of a once-effective model.

Additional challenges in machine learning logistics arise from the need for consistency of conditions relative to the production environment during experimentation and evaluation. Even apparently trivial environmental differences between development and production can result in unwanted surprises upon deployment.

It is also important to allow large amounts of experimentation and trials in production settings, but at the same time, it is critical to bound the risk of failed experiments.

Solving these logistical problems with bounded risk is the primary motivation for rendezvous architectures.

Foundations

Rendezvous architectures are best understood in the context of managing machine learning logistics in large-scale systems even though they can be applied to any streaming transformation. In order to meet the challenges of handling

input and output data and managing models, the rendezvous design takes advantage of several key techniques. These include stream-based architecture, a microservice approach, and the use of containers for isolation. The major goals of rendezvous architectures are to be able to:

- Preserve raw data that exactly reflects operational reality.
- Make it easier to manage multiple model versions.
- Provide for smooth and predictable model deployment into production.
- Meet stringent latency and availability guarantees with no planned violations and no accidental violations except under major failure scenarios.
- Work in an iterative and agile fashion.

Overview of Rendezvous Architecture

The distinctive architectural features of rendezvous architectures are the decomposition of a query-response microservice into a set of streaming microservices, the *rendezvous server* itself, and the way that all live models take inputs from and put their results to common streams.

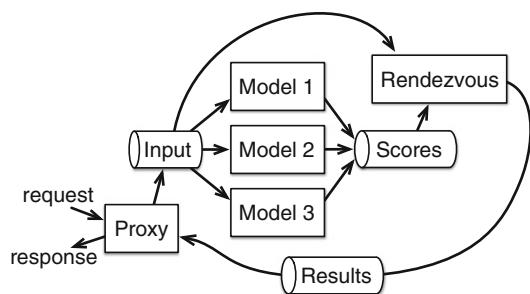

The main rationale for using streaming as the backbone of the rendezvous architecture is that new models can start reading requests from the input stream and writing results into the output stream with no configuration or service discovery burden. This means that the overall management of running models is very simple and dynamic. New model implementations merely need to be told where to get their input and where to put results, and they can start operation. If a model is slow as it warms up or has other problems that prevent it from keeping up with production loads, there is no problem with partial results.

The rendezvous server itself is what makes this work. Results from models for each incoming request are buffered by the rendezvous server until one of the results is received that meets the requirements of a schedule that defines the

trade-off between model preference and latency guarantees. That is, we might have a favored model, but we will only wait for a certain amount of time for that model to give us a result before using a less-favored model. The schedule can even specify a default result to be used in case no model produces a result in the required time.

The overall design of a rendezvous architecture is depicted in Fig. 1. In this figure, a request is accepted by any of a number of proxies and inserted into the `input` stream. All live models run in containers, evaluate as many requests as they can, and put all responses into the `scores` stream. The rendezvous server sees all incoming requests and starts a timer for each such request. As results are received from the live models, they are correlated against pending requests. The rendezvous server has a schedule of preferred model priorities versus latencies, and as soon as a result meets the requirements of the schedule, that result is put into the `results` stream and returned by the original proxy. All other results are ignored by the rendezvous server, although they are preserved in the `scores` stream for a configurable amount of time.

The final step of deploying a new model into production after it has been started and is evaluating requests is for the rendezvous server to stop ignoring the new model's results. This design makes it easy to roll out new models or to roll back to a previous model if performance of the

Rendezvous Architectures, Fig. 1 The general structure of a rendezvous architecture. Incoming requests are handled by one or more proxies that inject requests into a stream so that multiple models can evaluate each request. The rendezvous server sees the original request and selects a result to return to the proxy from the scores stream according to a policy designed to ensure service levels

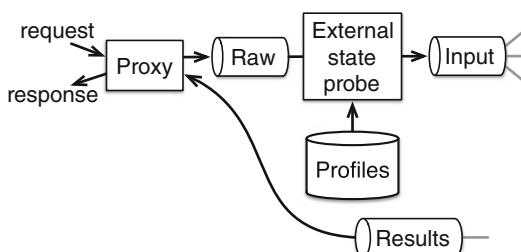

new model is not as expected. Moreover, if the new model crashes or slows down unacceptably, the rendezvous schedule will allow other models to take up the slack and avoid violation of service-level guarantees.

Note that this design also allows raw data to be augmented by additional variables or features before use as input data. This is illustrated in Fig. 2 where the raw request stream is transformed by the addition of common features or insertion of external state information before the models evaluate the requests. By adding common features or injecting external state at this point, all models are guaranteed to have exactly the same inputs.

In order to manage the conflicting environmental requirements for different models, it is a best practice to run each model in a container. This decreases the likelihood that the model behavior will change as it is put into production due to changes in the execution environment. Typically, an orchestration system such as Kubernetes (Burns et al. 2017) is used to manage such containers, but the very simple coordination and discovery for models in a rendezvous architecture make almost any orchestration system acceptable.

Versioning of the Rendezvous Components

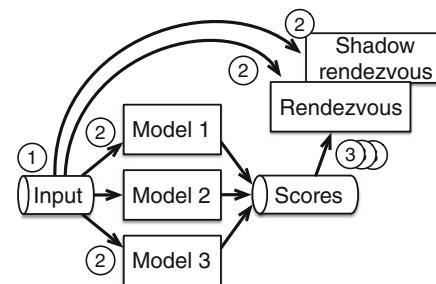

All of the components of the rendezvous architecture can be upgraded during operation with

Rendezvous Architectures, Fig. 2 The incoming requests can be augmented with the result of probing external state (such as user profiles). The same module could be used to compute commonly used input features. This approach avoids race conditions between different models' probes of the external state and makes it easier to maintain exact consistency of all model inputs

no downtime or latency disturbances. This can be done by injecting transition tokens into the input of the system. As these tokens pass through the system, old versions of each component stop processing of messages, and new components take over. For elements such as the feature extraction or external state access which are pure transformations, this is straightforward since all messages are processed entirely by one version or the other. Figure 3 illustrates the more complex case of upgrading the rendezvous server itself. Extra complexity arises because the old rendezvous server has to keep track of any pending requests that arrived before the transition even if the results arrive after the transition, while the new rendezvous server must be sure to keep track of only requests that arrive after the transition token. The process starts with the token at position 1 in the figure at the input to the system. At this point, a shadow rendezvous server will have been started and will be listening to the same inputs as the production server. The token propagates to all models and to the inputs of the current and shadow rendezvous servers at the points marked 2. The models each pass the transition token unchanged so that multiple copies appear in the scores stream.

The production rendezvous server buffers results for all requests that arrive *before* the transition token is seen on the input stream. The

Rendezvous Architectures, Fig. 3 Upgrading the rendezvous server using a transition token that passes through the system to locations marked 1, 2, and 3 at times t_1 , t_2 , and t_3 , respectively. Control over processing transitions in stages from the production rendezvous server to the shadow server that will become the new production server after the transition token has passed all the way through

shadow server takes over the production role by initiating coverage on all requests that are received after the transition token. The overall result is that only one rendezvous server ever produces a result for each request even if a rendezvous server is restarted during the upgrade. The old production rendezvous server can be retired once it reports results for all pending requests. In fact, it may be preferable to keep the old server around for a time in case it becomes necessary to fail back.

Since maximum response latencies for systems where a rendezvous server makes sense are typically less than a second, the hand-off process will appear to be nearly instantaneous once the transition token is introduced to the system.

This upgrade process is related to the Chandy-Lamport (Chandy and Lamport 1985) checkpointing algorithm and to the process that Apache Flink (Friedman and Tzoumas 2016) uses to upgrade program versions but is somewhat simpler.

Key Properties of Rendezvous Architectures

The rendezvous architecture uses streaming microservices (Dunning and Friedman 2016) internally to build a microservice that exposes a query-response interface externally. A rendezvous architecture is characterized primarily by a few properties:

Synchronous requests are evaluated internally in a streaming microservice style. This is highly unusual in large-scale machine learning systems. Much more common is to use a load balancer that distributes individual requests to individual models that evaluate requests synchronously. The use of streams to distributed requests is unusual, and it makes many operations in the rendezvous architecture much easier, largely because persistent streams allow simpler handling of failure modes.

Input requests are sent to all live models identically. In machine learning systems that do not use rendezvous techniques, secondary requests

may be made by the load balancer to fallback models, mostly as hedges against latency violations. Similarly, requests are sometimes broken into pieces and sent to shared decision engines. Results are collected until complete or until a deadline looms and the results are “complete enough.” Doing this with streaming and nearly universally for all queries as in the rendezvous server is very unusual but it deployment of models and the framework itself. It also makes it relatively easy to guarantee response latencies even in the presence of process failures or during the deployment and warmup of new models or the retirement of old ones.

All input requests are evaluated by multiple models. In non-rendezvous systems, evaluation of individual requests by multiple models at the same time, sometimes known as speculative evaluation, is the exception rather than the rule. Historically, high degrees of speculative execution were avoided due to worries about computational capacity, but this is much less of a consideration now, so the aggressive speculative execution of the rendezvous architecture is more viable.

All model results are put into a common stream of results. This is a unique characteristic of rendezvous architectures which allows the implementation of the rendezvous server to be substantially simplified.

A rendezvous server selects which result for each request to return Allowing the rendezvous server to select which result to return according to a trade-off schedule allows the concerns of accuracy and reliability to be separated. Accuracy, the primary goal of the model developer, is embodied in the models themselves. Reliability, particularly with respect to the satisfaction of service-level guarantees, is the focus of site reliability engineers and operations staff and is the key purpose of the rendezvous server. Separating these concerns makes it easier to satisfy both.

Key Applications

The primary application of rendezvous architectures is to allow continuous integration of machine learning models while maintaining promised service levels.

The types of machine learning for which the rendezvous pattern of architecture is most appropriate are those that involve decisioning, that is to say, applications that should return a “correct” answer as estimated by a model without much correlation between different decisions. These systems generally are synchronous in design in that they involve a query-response pattern of interaction with bounded request and response sizes. Examples include predictive analytics, image or speech recognition using deep learning techniques such as medical image analysis or speech-to-text, fraud detection in financial transactions, and IoT sensor data processing for manufacturing or for churn prediction in telecommunications and for web-based decision systems.

This chapter described new advancements in data partitioning for modern applications that are ad-

hoc in nature and do not have any upfront query workload.

Overview

Data partitioning is a well-known technique for improving the performance of database applications. By splitting data into partitions and only accessing those that are needed to answer a query, databases can avoid reading data that is not relevant to the query being executed, often significantly improving performance. Additionally, when partitions are spread across multiple machines, databases can effectively parallelize query processing across them.

This chapter summarizes traditional data partitioning techniques, motivates the need for a more *robust* data partitioning over modern ad hoc query workloads, introduces the concept of hyper-partitioning for creating a robust partitioning tree and hyper-join to process join queries over such a partitioning tree, and finally discusses repartitioning techniques for adapting the partitioning tree in a robust manner.

Traditional Partitioning Approaches

The traditional approach to data partitioning is to split a table on some key, using hash or range partitioning. This helps queries that have selection predicates involving the key go faster, by only accessing the relevant portions of data. Likewise, for queries with joins, queries will benefit when the database is partitioned on attributes involved in the join, due to local co-partitioned join processing in each partition. Because of these performance gains, many techniques have been proposed in the literature.

Workload-Based Partitioning

The typical approach is to find a good data partitioning for a given query workload. These approaches assume that the query workload is either provided upfront or collected over time, and try to choose the best partitioning for that workload. Examples include fine-grained parti-

tioning (Curino et al. 2010), hybrid of fine- and coarse-grained partitioning (Quamar et al. 2013), skew-aware partitioning (Pavlo et al. 2012), deep integration of partitioning with the query optimizer (Nehme and Bruno 2011), interdependence of different physical design decisions (Zilio et al. 2004), integrating vertical and horizontal partitioning decisions (Agrawal et al. 2004), and partitioning a B⁺-Tree on primary keys (Graefe 2003). Workload-based partitioning need to be reconfigured every time the workload changes.

Multidimensional Partitioning

Several partitioning techniques have been proposed for multidimensional data, e.g., k-d trees, R-trees, and quadtrees. These are typically used for spatial data with two dimensions. Other approaches include binary search trees such as splay trees (Sleator and Tarjan 1985) and MAGIC to *decluster* data on multiple attributes (Ghandeharizadeh and DeWitt 1994). Recent approaches layer multidimensional index structures over distributed data in large clusters. This includes SpatialHadoop (Eldawy and Mokbel 2015), MD-HBase (Nishimura et al. 2011), and epiC (Wang et al. 2010) or adapting the multidimensional index to the workload in TrajStore (Cudré-Mauroux et al. 2010). Commercially, Oracle and MySQL support *sub-partitioning* to create nested partitions on multiple attributes. IBM DB2 supports multidimensional clustering tables to cluster data along multiple dimensions and build block-based indices on them.

Big Data Partitioning

Big data storage systems, such as HDFS, partition datasets based on size. Developers can later create attribute-based partitioning using a variety of data processing tools, e.g., Apache Hive and SCOPE (Zhou et al. 2012). However, such a partitioning is no different than traditional database partitioning since (i) partitioning is a static one time activity and (ii) the partitioning keys must be known a priori and provided by users. Recently, Sun et al. (2014) proposed to create data blocks in HDFS based on the features extracted from each input tuple. Again, the fea-

tures are selected based on a workload, and the goal is to cluster tuples with similar features in the same data block. AQWA looks at adaptive data partitioning for spatial data (two dimensions). Their techniques do not scale to higher dimensions (Aly et al. 2015). Apart from single table partitioning, Hadoop++ (Dittrich et al. 2010) and CoHadoop (Eltabakh et al. 2011) propose to co-partition datasets in HDFS to speed up join queries. These systems still assume a workload.

Database Cracking

Database cracking (Idreos et al. 2007) is a technique to adapt the layout of data and indexes as queries arrive. Partial sideways cracking extends this idea to generate adaptive indexes on multiple columns (Idreos et al. 2009). Cracking is designed for in-memory column stores, and it adapts the data to *every* query in the system. It does not naturally apply to a distributed setting for two main reasons. First, the cost of repartitioning in a distributed setting is higher than in a main memory system. So, it is very expensive to repartition data on every access as cracking does. Second, cracking splits the data on every new predicate it encounters, which can result in a large number of blocks. However, in a distributed setting, the number of data blocks that can be created is limited because blocks must be a certain size to amortize latencies of disk and network access. As a result, adding a split for a new predicate involves merging existing partitions and re-splitting them to keep the number of blocks constant.

Robustness

Modern data analytics has newer data partitioning needs. Data science, for instance, often involves looking for anomalies and trends in data. There is no representative workload for this kind of ad hoc, exploratory analysis, and the set of tables and predicates of interest will often shift over time. For example, an analyst may look for patterns in a database of multidimensional web click events (with user history, demographic informa-

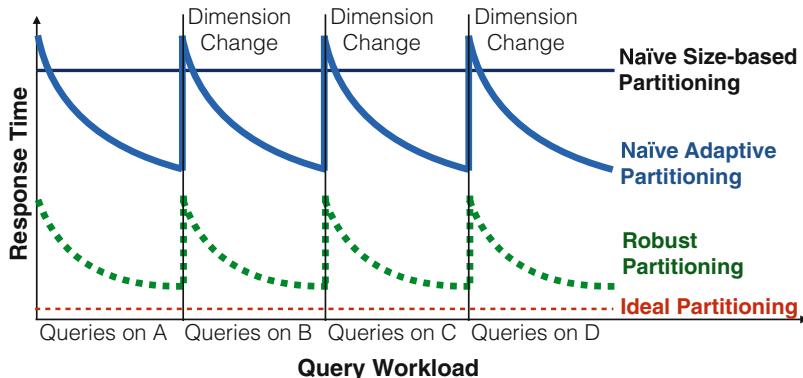

tion, and platform information as dimensions). The analyst may want to view this data according to any of its dimensions – e.g., they may want to query according to the user’s past browsing patterns, by their age or income or by whether they are using a mobile phone or a laptop. As the specific set of attributes of interest is not necessarily known upfront, workload-based partitioning techniques cannot be applied. Furthermore, as the workload is ad hoc in nature, database cracking cannot be applied as well. Figure 1a illustrates the data partitioning dilemma that analysts face with modern workloads.

Analysts are either stuck with naïve size-based partitioning that offers no data skipping capability and hence very poor performance (full scan). Or, alternatively, they could pick one of the more recent adaptive partitioning techniques, e.g., cracking (Idreos et al. 2007) that would make the first few queries even slower than full scan, but will gradually improve if successive queries are on the same dimension, i.e., having a selection predicate on the same attribute. In case the query dimension changes, the performance again goes back worse than full scan before gradually improving with successive queries on the new dimension (referred to as naïve adaptive partitioning). This is really painful for an analyst exploring multiple dimensions: analysts want a data partitioning scheme that is **robust to the ad hoc nature of the modern workloads and provides good performance from the first query itself, adaptively improving from there on**.

R

Hyper-partitioning

Distributed storage systems, such as HDFS, subdivide a dataset into chunks, called blocks, based on size (usually 128 MB). Workload-based partitioning techniques for such systems, including content-based chunking (Bhatotia et al. 2011) and feature-based blocking (Sun et al. 2014), create blocks such that irrelevant blocks could be quickly skipped for the specific query workload. Hyper-partitioning goes a step further by creating blocks based on a partitioning tree that allows to skip data over almost *all* ad hoc queries,

Robust Data Partitioning, Fig. 1 Need for robust data partitioning

without having any information about the query workload. Such a partitioning also serves as a good starting point for an adaptive query executor to improve upon.

Since hyper-partitioning partitions the data along several dimensions, it could end up de-clustering the data blocks across machines and performing random I/Os for each block. However, this is still fine; large block sizes in distributed file systems (Ghemawat et al. 2003) combined with fast network speeds lead to remote reads being almost as fast as local reads (Ananthanarayanan et al. 2011; Binnig et al. 2016). Essentially, hyper-partitioning sacrifices some data locality in order to quickly locate the relevant portions of the data on each machine in a distributed setting.

The rest of this section first introduces the notions of robust partitioning tree and attribute allocations in that tree and then describes how to construct and query such a tree.

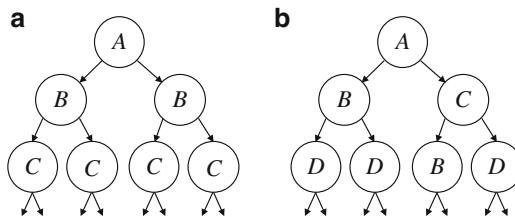

Robust Partitioning Tree

The hyper-partitioning partitioning tree, or simply the *robust tree*, is represented as a balanced binary tree, i.e., the dataset is successively partitioned into two until it reaches the maximum partition size. For HDFS, hyper-partitioning takes the block size as the maximum partition size. The choice of binary tree is deliberate as it is more general (a four-way partitioning can be achieved by two successive two-way partitioning) as well as fine-granular when adapting the tree

to workload changes later. Each node in the tree is represented as A_p , where A is the attribute being partitioned on and p is the cut point. All tuples with $A \leq p$ go to the left subtree and rest go to the right subtree. A leaf node in the tree is a **bucket**, having a unique identifier and a file name in the underlying file system. This file contains the tuples that satisfy the predicates of all nodes traversing upwards from the bucket to the root of the tree. Note that an attribute can appear in multiple nodes in the tree. Having multiple occurrences of an attribute in the same branch of the tree increases the number of ways the data is partitioned on that attribute.

Traditional binary partitioning trees, such as k-d tree (Bentley 1975), partition the space by considering the attributes in a round robin fashion, until the smallest partition size is reached. Hence, the tree can only accommodate as many attributes as the depth of the tree. Figure 2 shows a k-d tree where the three levels of the tree divide the dataset on attributes A , B , and C , respectively. In general, for a dataset size D , minimum partition size P , and n way partitioning over each attribute, the partitioning tree contains $\lfloor \log_n \frac{D}{P} \rfloor$ attributes. With $n = 2$, $D = 1$ TB, and $P = 64$ MB, only 14 attributes can be accommodated in the partitioning tree. However, many real-world schemas have way more attributes.

In contrast to k-d tree, the robust tree performs *heterogeneous branching* in order to accommodate more attributes by partitioning

Robust Data Partitioning, Fig. 2 Multidimensional partitioning tree. (a) k-d tree. (b) Robust tree

different branches of the partitioning tree on different attributes. In other words, robust tree sacrifices the best performance on a few attributes to achieve robustness, i.e., improved performance over more attributes. This is reasonable as without a workload, there is no evident reason to prefer one attribute over another. Figure 2b shows a robust partitioning tree. After partitioning on attribute A , the left side of the tree partitions on B , while the right side partitions on C . Thus, the tree is now able to accommodate *four* attributes, instead of *three*. However, attributes B and D are each partitioned on 75% of the data, while attribute C is partitioned on 50%. Ad hoc queries would now gain partially over all four attributes, which makes the partitioning more effective.

The number of attributes in the robust partitioning tree, with c as the minimum fraction of the data partitioned by each attribute and r as the number of replicas, is given as $\frac{1}{c} \cdot \lceil \log_n \frac{D}{P} \rceil$. With $n = 2$, $D = 1\text{TB}$, $P = 64\text{MB}$, and $c = 50\%$, the number of attributes that can be partitioned is 28. Note that the number of attributes that can be partitioned increases with the dataset size. This shows that with larger dataset sizes, hyper-partitioning is even more useful for quickly finding the relevant portions of the data.

Robust tree can further leverage the data replication in distributed storage systems, e.g., 3 \times replication in HDFS. Such replication mechanisms first partition the dataset into blocks and then replicate each block multiple times. Instead, first, the entire dataset is replicated, and then each replica is partitioned using a different partitioning tree. While the system is still fault tolerant

(because it has the same degree of replication), recovery becomes slower because it needs to read several or all replica blocks in case of a block failure. Essentially, fast recovery time is sacrificed for improved ad hoc query performance. Such a scheme can either increase the number of attributes in the partitioning tree, or increase the data fraction covered per attribute. Both of these lead to improved query performance due to greater partition pruning.

Attribute Allocation

The goal of robust tree is to allocate attributes to nodes in the tree such that all attributes have similar advantage in terms of data skipping or parallel processing. Therefore, the allocation of an attribute is defined as the weighted sum of its fanout on each of the nodes it appears in the partitioning tree T , i.e., the allocation of attribute i is given as:

$$\text{Alloc}_i(T) = \sum_{n \in \text{nodes}(T,i)} \text{DataFraction}_n \cdot \text{Fanout}_n$$

The *allocation* defined above gives the granularity of data partitioning over an attribute. Higher allocation means more data skipping is possible. For example, in Fig. 2b, attribute B appears on two nodes, one covering 50% of the data while the other covering 25% of the data. Thus, B has an allocation of $(0.5 * 2 + 0.25 * 2) = 1.5$. With no query workload, the goal is to balance the benefit of partitioning across all attributes in the dataset. This means that same selectivity predicates on any two attributes X and Y should have similar speedups, compared to scanning the entire dataset. To achieve this, the total allocation is distributed equally among all attributes. Each attribute gets an allocation of $b^{1/|\mathbb{A}|}$, where $|\mathbb{A}|$ is the number of attributes and b is the number of buckets. For instance, if there are eight buckets, and three attributes, the allocation (average fanout) per attribute is $8^{1/3} = 2$. In case of prior workload information, users can provide relative weights of the attributes, and the attribute allocation will be distributed proportional to these weights. The intuition is then to compute the maximum per-attribute allocation and then place

attributes into the tree so as to approximate this ideal allocation.

Hyper-partitioning Algorithm

Algorithm 1 shows the pseudocode to generate the robust partitioning tree. It first calculates the depth of the tree to be created (Line 3), then initializes the queue with the root node of the tree (Line 4), and starts a breadth-first traversal to assign an attribute to every node. The attribute to be assigned at a given node is given by the function `LeastAlloc`, which returns the attribute which has the highest allocation remaining. If two or more attributes have the same highest allocation remaining, the algorithm randomly chooses among the ones that have occurred the least number of times in the path from the node to the root. `Med` returns the median of the attribute assigned to this node by finding the median in the sampled data which comes to this branch. The algorithm starts with an allocation of 2 for the root node, since it partitions the entire dataset into two. Each time it goes to the left or the right subtree, it reduces the data it operates on by half. Once an attribute is assigned to a node,

Algorithm 1: CreateRobustTree

```

Input : Int  $D$ , Int maxPartitionSize, Float[] alloc,
        Tuple[] initSample

1 Tree tree;
2 numBuckets  $\leftarrow \lfloor D/\maxPartitionSize \rfloor$ ;
3 treeDepth  $\leftarrow \log_2(\text{numBuckets})$ ;
4 Queue queue  $\leftarrow \{(\text{tree.root}, \text{treeDepth},$ 
   initSample)\};
5 while queue.size > 0 do
6   node,depth,sample  $\leftarrow$  queue.first();
7   if depth = 0 then
8     node  $\leftarrow$  NewBucket();
9     Continue;
10    node.attr  $\leftarrow$  LeastAlloc(alloc);
11    node.val  $\leftarrow$  Med(sample,node.attr);
12    IS, rS  $\leftarrow$  SplitSample(node.attr,
13      node.val);
14    node.left  $\leftarrow$  CreateNode();
15    node.right  $\leftarrow$  CreateNode();
16    alloc[node.attr]  $\leftarrow 2/2^{\maxDepth - \text{depth}}$ ;
17    depth  $\leftarrow$  1;
18    queue.add((node.left, depth, IS));
19    queue.add((node.right, depth, rS));

```

it subtracts from the overall allocation of the attribute (Line 13). The algorithm creates a leaf-level bucket in case it reaches the maximum depth (Line 18).

Query Processing

A hyper-partitioning query processor considers the filter predicates in incoming queries and filters out partitions that do not match any of the query predicates. For example, if there is a node A_5 in the tree and one of the predicates in the query is $A \leq 4$, then any of the partitions in right subtree of the node don't need to be scanned.

Using Spark, for instance, a job can be constructed where relevant partitions are split into tasks, a set of partitions such that the total size is not more than 4 GB. Each task reads the blocks from HDFS in bulk and iterates over the tuples in main memory. A tuple is returned if it matches the predicates in the query. Tasks are executed independently by the Spark job manager across all machines, and the result is exposed to users as a Spark RDD. Users can use these RDDs to do more analysis using the standard Spark APIs, e.g., run an aggregation.

This section described hyper-partitioning and processing selection queries over a hyper-partitioned input. The following section describes techniques for processing join queries over two or more hyper-partitioned inputs.

Hyper-joins

Hyper-partitioning may end up partially partitioning tables on several different attributes, such that when two tables A and B are joined, a partition in A may join with several partitions in B , each located on HDFS. One option is to simply perform a shuffle join, i.e., repartition both A and B so that each partition of A joins with just one partition of B . However, this can be suboptimal if each partition of A only joins with a few partitions on B ; instead, building a hash table over some partitions of A (or B) and probing it with partitions from B (or A) can result in significantly less network and disk I/O.

Example 1 Suppose table A has three partitions and table B has three partitions. Suppose A_1 joins with B_1 and B_2 ; A_2 joins with B_1 , B_2 , and B_3 ; and A_3 joins with B_2 and B_3 , and each machine \mathcal{M}_i has memory to hold 2 partitions to build hash tables on A . Consider building a hash table over A_1 and A_3 on \mathcal{M}_1 ; we will need to read B_1 , B_2 , and B_3 . We then build another hash table over A_2 on \mathcal{M}_2 and again read B_1 , B_2 , and B_3 . In total, we read six blocks. As an alternative, building a hash table over A_1 and A_2 on \mathcal{M}_1 and another one over A_3 on \mathcal{M}_2 requires reading just B_1 , $2 * B_2$, $2 * B_3 = 5$ blocks.

Thus, building hash tables over different subsets of partitions will result in different costs. Unfortunately, finding the optimal collection of partitions to read is NP-Hard. However, heuristically, solving the problem can still provide significant performance gains over shuffling. To obtain these gains, partitions must be constructed such that, for a join between tables A and B , each partition of A only joins with a subset of the partitions of B . Hyper-join provides this property and is designed to move fewer blocks throughout the cluster than a complete shuffle join when tables are not co-partitioned.

The rest of this section formulates hyper-join as an optimization problem, presents an optimal solution based on mixed integer programming, introduces an approximate algorithm which can run in a much shorter time, discusses hyper-joins for multiple join predicates, and finally shows a two-phase partitioning technique to add join attributes into the robust partitioning tree.

Problem Definition

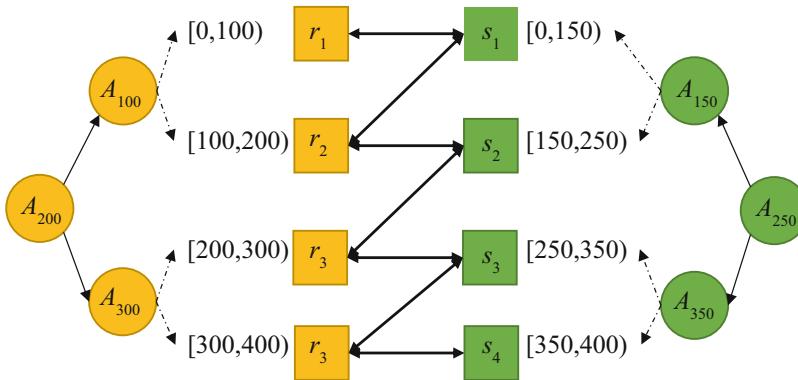

Consider relations R and S , which can join on attribute t . Let $R = \{r_1, r_2, \dots, r_n\}$ and $S = \{s_1, s_2, \dots, s_m\}$ be the collection of data blocks obtained from hyper-partitioning. Let $V = \{v_1, v_2, \dots, v_n\}$ be a collection of m -dimensional vectors, where each vector corresponds to a data block in relation R . The j -th bit of v_i , denoted by v_{ij} , indicates whether block r_i from relation R overlaps with block s_j from relation S on attribute t (these are the

blocks that must be joined with each other). Let $\text{Range}_t(x)$ be a function which gives the range (min and max values) of attribute t in data block x and $\mathbb{1}(s)$ be a function which gives 1 when statement s is true. Given two relations R and S , and for each block r_i from R and s_j from S , let $v_{ij} = \mathbb{1}(\text{Range}_t(r_i) \cap \text{Range}_t(s_j) \neq \emptyset)$. A straightforward algorithm to compute V has a time complexity of $O(nm)$. The Range_t values for each block are stored with each block in the partitioning tree. Let $P = \{p_1, p_2, \dots, p_k\}$ be a partitioning over R , where P is a set of disjoint subsets of the blocks of R and its union is all blocks in R . Each p_i is constrained to be able to fit into memory of the node performing the join. $\tilde{v}(p_i)$ is used to denote the union vector of all vectors in p_i , i.e., $\tilde{v}(p_i) = \bigvee_{r_j \in p_i} v_j$, where v_j is the vector for block r_j . Let $\delta(v_i) = \sum_{k=1}^m v_{ik}$ indicate the number of bits set in v_i . Given a partition p_i , $C(p_i)$ defines the cost of joining p_i with all partitions in S as the number of bits set in $\tilde{v}(p_i)$, i.e., $C(p_i) = \delta(\tilde{v}(p_i))$. This corresponds to the number of blocks to be read to join p_i . Next, the cost function $C(P)$ over a partitioning is defined as the sum of $C(p_i)$ overall p_i in P :

$$C(P) = \sum_{p_i \in P} C(p_i)$$

Thus, the problem of computing hyper join is finding the optimal partitioning P of relation R .

Consider the example in Fig. 3, with table $R = \{r_1, r_2, r_3, r_4\}$ and table $S = \{s_1, s_2, s_3, s_4\}$ and assume $|P| = 2$, i.e., that there is sufficient memory to store $|R|/|P| = 4/2 = 2$ blocks of R in memory at a time. The interval on each partition indicates the minimum and maximum value on the join attribute from all the records. The arrows in the figure indicate the two corresponding partitions overlapping on the join attribute. From the figure, r_1 needs to join with s_1 , r_2 needs to join with s_1 , s_2 , etc. Therefore, $V = \{v_1 = 1000, v_2 = 1100, v_3 = 0110, v_4 = 0011\}$. A hash table could be built over multiple yellow partitions to share some disk access of green partitions. For example, a hash table could be built over the first two yellow blocks (r_1 and r_2) and another one over the last two yellow blocks

Robust Data Partitioning, Fig. 3 Illustrating hyper-join

(r_3 and r_4), so that only 5 green blocks need to be read from disk, assuming only one green block is in memory at a time. In this way, the partition $P = \{p_1 = \{r_1, r_2\}, p_2 = \{r_3, r_4\}\}$, which is optimal. The overall cost $C(P) = 5$, since $\tilde{v}(p_1) = 2$ and $\tilde{v}(p_2) = 3$.

Intuitively, the objective function $C(P)$ is the total number of blocks read from relation S , with some blocks being read multiple times. From the perspective of a real system, the size of p_i is constrained, both due to memory limits and to ensure a minimum degree of parallelism (the number of partitions should be larger than a threshold). If memory is sufficient to hold B blocks from relation R , then we need $c = \lceil n/B \rceil$ partitions. We now define the *minimal partitioning* problem.

Problem 1 Given a set of data blocks from relation R , find a partitioning P over R such that $C(P)$ is minimized, i.e.,

$$\begin{aligned} \arg \min_P \quad & C(P) \\ \text{subject to} \quad & |P| = c, \\ & |p_i| \leq B, \forall p_i \in P. \end{aligned}$$

Optimal Algorithm

This section describes a mixed integer programming formulation which can generate the minimal partitioning. Given the maximum number of data blocks B that can be used to build a hash table due to available worker memory, the total number of hash tables to be built are $c = \lceil n/B \rceil$.

For each data block r_i from relation R and each partition p_k , the assignment of r_i to partition p_k is indicated with a binary decision variable $x_{i,k} \in \{0, 1\}$. Likewise, for each data block s_j from relation S , a binary decision variable $y_{j,k} \in \{0, 1\}$ indicates if the j -th bit of $\tilde{v}(p_k)$ is 1.

The first constraint in Problem 1 requires that the size of each partition p_k is under the memory budget B :

$$\forall k, \quad \sum_{i=1}^n x_{i,k} \leq B$$

The second constraint requires that each data block r_i from relation R is assigned to exactly one partition:

$$\forall i, \quad \sum_{k=1}^c x_{i,k} = 1$$

Given a partitioning P , for each partition p_k , every overlapping data block from relation S must also be in partition p_k . Let J_k be the set of data blocks from relation R which overlaps with data block s_k from relation S .

$$\forall i, \forall k, \forall j \in J_k, \quad y_{i,k} \geq x_{i,j}$$

We seek the minimal input size of relation S :

$$\min \sum_{j=1}^m \sum_{k=1}^c y_{j,k}$$

Solving integer linear programming (ILP) of this form is generally exponential in the number of decision variables; hence the running time of this algorithm may be prohibitive. The proof for NP-hardness of the problem can be found in Lu et al. (2017).

Approximate Solution

Taking B data blocks from relation R with smallest $\delta(\tilde{v}(\mathcal{P}))$ is NP-hard, and there is no algorithm for $n^{1-\epsilon}$ -approximation for any constant $\epsilon > 0$. However, an approximate bottom-up algorithm, as shown in Fig. 4, can provide practical runtimes.

The algorithm starts from an empty set of partitions P and an empty partition \mathcal{P} . It iteratively adds a data block r_i into \mathcal{P} with smallest $\delta(r_i \vee \tilde{v}(\mathcal{P}))$ until there are B blocks in partition \mathcal{P} or no data block left in relation R . It then adds \mathcal{P} into P until P contains all blocks from relation R . A straightforward implementation of this algorithm has a time complexity of $O(n^2)$ (where n is the number of blocks of R), since the minimum cost block (requiring a scan of the non-placed blocks) needs to be computed n times.

Joins Over Multiple Relations

Hyper-join technique can be extended to multiple inputs. Consider TPC-H query 3. If the join order is $(\text{lineitem} \bowtie \text{orders}) \bowtie \text{customer}$ and the intermediate result of the first two tables is denoted by tempLO , then the relation customer needs to join with tempLO on custkey . If custkey is the join attribute in the customer partitioning tree, only tempLO needs to be shuffled based on custkey , and then hyper-join can be used instead of an expensive shuffle join, in which both tempLO and customer need to be shuffled.

Robust Data

Partitioning, Fig. 4 A bottom-up approximate solution

With more relations to join, shuffle join over two intermediate outputs of hyper joins could be more efficient. Consider TPC-H query 8. If the join order is $((\text{lineitem} \bowtie \text{part}) \bowtie \text{orders}) \bowtie \text{customer}$, then the intermediate result with relation lineitem needs to be shuffled twice. Instead, changing the join order to $(\text{lineitem} \bowtie \text{part}) \bowtie (\text{orders} \bowtie \text{customer})$ can use hyper-join twice and a shuffle join over the intermediate results.

Two-Phase Hyper-partitioning

Hyper-join leverages hyper-partitioning; however, the robust partitioning tree described so far partitions data based solely on the selection predicates. Thus, it's unlikely to have the join attribute in very many nodes in the tree, and it's highly possible that every partition will overlap with a large number of partitions. Two-phase partitioning tackles this challenge by injecting the join attributes into the partitioning tree, as depicted in Fig. 5. The first phase splits on join attributes (shown in orange), while the second phase splits on selection attributes (shown in blue). During the first phase, median values of the join attributes are used to recursively split the dataset into two. During the second phase, the join partitions are further partitioned on selection attributes using the standard hyper-partitioning.

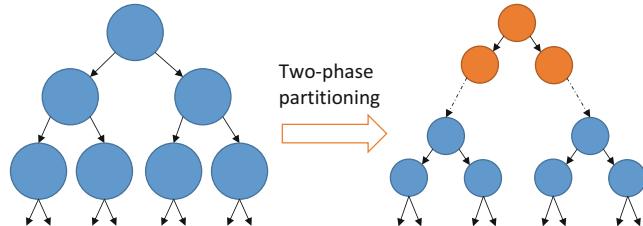

Consider the left partitioning tree in Fig. 3 as an example. There are two levels in the tree which are reserved for the join attribute, which, assuming data is uniformly distributed in the range $[0, 400]$, leads to four disjoint partitions with range $[0, 100)$, $[100, 200)$, $[200, 300)$, and $[300, 400)$. The same procedure is also applied to the right partitioning tree, which creates four disjoint partitions with range $[0, 150)$, $[150, 250)$, $[250, 350)$, and $[350, 400)$.

```

 $R \leftarrow \{r_1, r_2, \dots, r_n\}, P \leftarrow \emptyset, \mathcal{P} \leftarrow \emptyset$ 
while  $R$  is not empty:
    merge  $\mathcal{P}$  with data block  $r_i$  with smallest  $\delta(r_i \vee \tilde{v}(\mathcal{P}))$ 
    if  $|\mathcal{P}| = B$  or  $r_i$  is the last one in  $R$ :
        add  $\mathcal{P}$  to  $P$  and  $\mathcal{P} \leftarrow \emptyset$ 
        remove data block  $r_i$  from  $R$ 
return  $P$ 

```

Robust Data Partitioning, Fig. 5
Illustrating two-phase partitioning

Robust Repartitioning

Hyper-partitioning and hyper-join allow an analyst to quickly get started with her ad hoc queries. However, the analyst also wants the partitioning to adapt as her analysis progresses, e.g., drilling down web click data into successively smaller age groups, to provide even better query performance. *Robust repartitioning* provides the mechanisms to achieve this. When a query is submitted, a repartitioning optimizer explores alternative partitioning trees to find the best one and decides whether repartitioning is worthwhile. The optimized plan only accesses data which is to be read by input queries, i.e., data that is not read by queries during repartitioning is not accessed. This has two benefits: (i) data that is not touched by any query is never repartitioned and (ii) query processing and repartitioning share scans reducing the cost of repartitioning.

The rest of this section describes the cost model used, introduces three basic transformations used to transform a given partitioning tree, describes a divide-and-conquer approach to consider all possible alternatives generated from the transformation rules for inserting a single predicate, discusses how to handle multi-predicate queries, and lastly shows a smooth repartitioning technique to adapt to changing join predicates. It is worth noting that the entire optimization process is transparent to users, i.e., users do not have to worry about making repartitioning decisions and their queries remain unchanged with the new access methods.

Cost Model

Consider a window (W) of queries that happened in the past X hours. X is a parameter in

adaptive query executor, and it determines how quickly the system reacts to workload changes. For each query q in the query sequence, the cost of processing q using partitioning tree T is given as:

$$\text{Cost}(T, q) = \sum_{b \in \text{lookup}(T, q)} n_b$$

where $\text{lookup}(T, q)$ returns the set of relevant buckets for query q in T and n_b is the number of tuples in bucket b . The cost of the query window is the sum of the cost of individual queries. For a query being executed, the optimizer might want to transform the partitioning tree to a new partitioning tree T' resulting in a set of buckets $B \subset \text{lookup}(T, q)$ being repartitioned. The benefit of this transformation is

$$\text{Benefit}(T') = \sum_{q \in W} \text{Cost}(T, q) - \sum_{q \in W} \text{Cost}(T', q)$$

and the added cost of repartitioning is given as

$$\text{RepartitioningCost}(T, q) = c \sum_{b \in B} n_b$$

where c is the write multiplier, i.e., how expensive writes are compared to a read. Repartitioning is expensive; however, it only happens when the resulting decrease in the cost of the query window (benefit) is greater than the repartitioning cost. This check prevents constant re-partitioning due to a random query sequence and bounds the worst case impact. To illustrate, consider a single node in the tree and a query sequence of the form $\sigma_A < 2, \sigma_B < 2, \sigma_A < 2, \sigma_B < 2, \dots$. In this case, the data is not constantly repartitioned. After doing it once, say on A , the total cost

goes down, and hence the repartitioning on B would not happen as Benefit < Repartitioning-Cost.

Tree Transformations

A set of transformation rules allow exploring the space of possible plans when repartitioning the data. Consider a query predicate of the form $A \leq p$, denoted as A_p . Only partitioning transformations that are local, i.e., that do not involve rewriting the entire tree, are considered. These local transformations are cheaper and amortize the repartitioning effort over several queries. The three basic transformations are discussed below.

(1) Swap. Replaces an existing node in the partitioning with the incoming query predicate A_p . As only the accessed data is repartitioned, we consider swapping only those nodes whose left *and* right children are fully accessed by the incoming query. Applying swap on an existing node involves reading both sub-branches, and restructuring all partitions beneath the left subtree to contain data satisfying A_p and the right subtree to contain data that does not satisfy A_p . Swaps can happen between different attributes (Fig. 6a), in which case both branches are completely rewritten in the new tree. Swaps can also happen between two predicates of the same attribute (Fig. 6b), in which case the data moves from one branch to the other. For example, in the Fig. 6b, if node $A_{p'}$ is A_{10} and predicate A_p is $A \leq 5$, then data moves from the left branch to the right branch, i.e., the left branch is completely rewritten while the right branch just has new data appended.

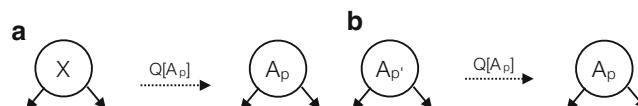

Swaps serve the dual purpose of unpartitioning an existing (less accessed) attribute while refining on another (more accessed) attribute. As both the swap attributes as well as their predicates are driven by the incoming queries, they reduce the access times for the

incoming query predicates. Finally, note that it is cheaper to apply swaps at lower levels in the partitioning tree because less data is rewritten. Applying them at higher levels results in a much higher cost.

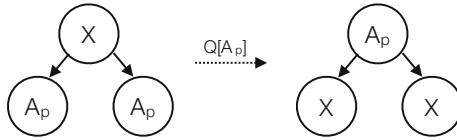

(2) Push-up. Pushes a predicate as high up the tree as possible. This can be done when both the left and the right child of a node contain the incoming predicate, as a result of a previous swap, as shown in Fig. 7. This is a logical partitioning tree transformation, i.e., it only rearranges the internal nodes without any modification to the leaf nodes.

A push-up transformation is checked every time a swap transformation is performed. The idea is to move important predicates (ones that have recently or frequently appeared in the query sequence) progressively up the partitioning tree, from the leaves right up to the root. This makes important predicates less likely to be swapped immediately, because swapping a node higher in the partitioning tree is much more expensive. Another advantage of push-up is that it causes a churn of the attributes assigned to higher nodes in the upfront partitioning. When such a dormant node is pushed down, subsequent predicates can swap them in an incremental fashion, affecting fewer branches, thus making the tree transformations more robust.

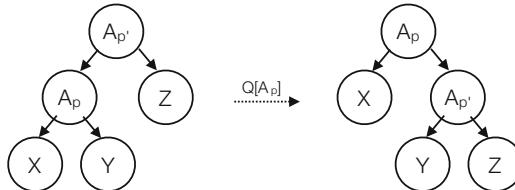

(3) Rotate. Transformation rearranges two predicates on the same attribute such that more important (recently accessed or frequently appearing in the query sequence) predicate appears higher up in the partitioning tree. Figure 8 shows a rotate transformation involving predicates p and p' on attribute A . The goal here is to churn the partitioning tree such that predicates on less important attributes are more likely to be replaced first. Similar to the push-up transformation, rotate is a logical transformation, i.e., it only rearranges the internal nodes of the parti-

Robust Data Partitioning, Fig. 6 Node swap in the partitioning tree **(a)** Different attribute. **(b)** Same attribute

Robust Data Partitioning, Fig. 7 Node pushdown in partitioning tree

Robust Data Partitioning, Fig. 8 Node rotation in partitioning tree

tioning tree and it is always performed wherever possible.

Above three partitioning tree transformations can be combined to capture a fairly general set of repartitioning scenarios. Figure 9 shows an example, where first nodes D_4 are swapped with incoming predicate A_2 at the lower level, then A_2 is pushed up one level above, and finally it is rotated with nodes A_5 and C_3 . In the process, only half the leaves are repartitioned. Thus, in larger trees, repartitioning mostly happens on small fractions of the data modifying a few subtrees locally.

Divide-and-Conquer Repartitioning

Given a query with predicate A_p and a partitioning tree T , there are many different combinations of transformations that need to be considered. However, observe that the data access costs over a subtree T_n , rooted at node n , could be broken down into the access costs over its subtrees, i.e.,

$$\text{Cost}(T_n, q_i) = \text{Cost}(T_{n_{left}}, q_i) + \text{Cost}(T_{n_{right}}, q_i)$$

where $T_{n_{left}}$ and $T_{n_{right}}$ are subtrees rooted respectively at the left and the right child of n . Thus, finding the best partitioning tree can be broken down into recursively finding the best left and right subtrees at each level and considering parent node transformations only on top of the best child subtrees. For each transformation, the

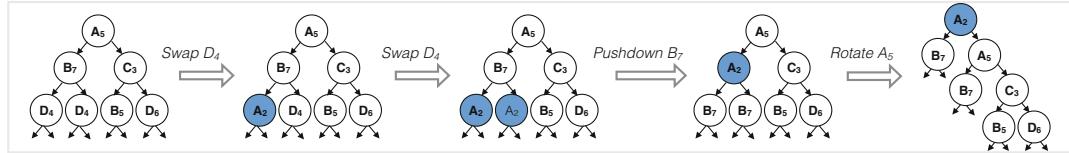

benefit and cost of that transformation is considered, and the one which has the best benefit-to-cost ratio is picked. Table 1 shows the cost and benefit estimates for the different transformations. For the swap transformation, denoted as $P_{\text{swap}}(n, n')$, the query costs are recalculated. However, push-up and rotate transformations, denoted as $P_{\text{swap}}(n, n')$ and $P_{\text{pushup}}(n, n_{\text{left}}, n_{\text{right}})$, respectively, inherit the costs from children subtrees. Applying none of the transformations at a given node is denoted as $P_{\text{none}}(n)$. This approach helps to significantly reduce the candidate set of modified partitioning trees.

Above divide-and-conquer algorithm has a complexity of $O(QN \log N)$, where N is the number of nodes in the tree and Q is the number of queries in the query window. More details on the algorithm can be found in Shanbhag et al. (2017).

Repartitioning with Multiple Predicates

A predicate of the form $A \leq p$ gets inserted in the tree as A_p , and on insertion, only the leaf nodes on the left side of the node are accessed. $A > p$ is also inserted as A_p with the right side of the node being accessed. For $A \geq p$ and $A < p$, let p' be $p - \delta$ where δ is the smallest change for p 's data type. We insert $A_{p'}$ into the tree. $A = p$ is treated as combination of $A \leq p$ and $A > p'$.

Now consider a query with two predicates A_p and A_{p2} . The brute force approach is to consider choosing a set of accessed nonterminal nodes to be replaced by A_p , and then for every such choice, choose a set of remaining nodes to be replaced by A_{p2} . Thus, the number of choices grows exponentially with the number of predicates. A greedy approach is to try to insert each predicate in the query into the partitioning tree. The best among the best plans obtained for different predicates is picked, and the corresponding predicate is removed from the predicate set. Likewise, the remaining predicates are inserted into the best plan obtained so far. The algorithm stops when either all predicates have been inserted or when the tree stops changing. Doing this adds a multiplicative complexity of $O(|P|^2)$ where P is the set of query predicates.

Robust Data Partitioning, Fig. 9 Introducing predicate A_2 into the partitioning tree

Robust Data Partitioning, Table 1 The cost and benefit estimates for different partitioning tree transformations

Transformation	Notation	Cost (C)	Benefit (B)
Swap	$P_{\text{swap}}(n, n')$	$\sum_{b \in T_n} c \cdot n_b$	$\sum_{i=0}^k [\text{Cost}(T_n, q_i) - \text{Cost}(T_{n'}, q_i)]$
Pushup	$P_{\text{pushup}}(n, n_{\text{left}}, n_{\text{right}})$	$C(P(n_{\text{left}})) + C(P(n_{\text{right}}))$	$B(P(n_{\text{left}})) + B(P(n_{\text{right}}))$
Rotate	$P_{\text{rotate}}(p, p')$	$C(P(n_{\text{left} \mid \text{right}})), \text{ for } p' \text{ on } n_{\text{left} \mid \text{right}}$	$B(P(n_{\text{left} \mid \text{right}})), \text{ for } p' \text{ on } n_{\text{left} \mid \text{right}}$
None	$P_{\text{none}}(n)$	$C(P(n_{\text{left}})) + C(P(n_{\text{right}}))$	$B(P(n_{\text{left}})) + B(P(n_{\text{right}}))$

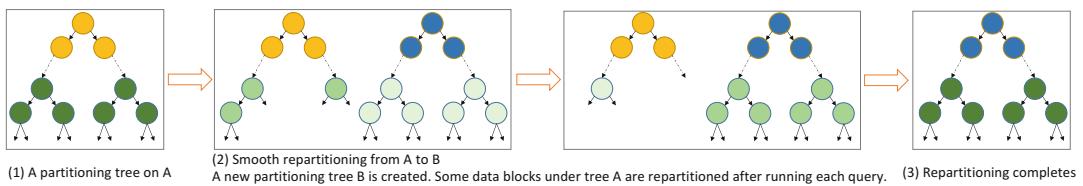

Smooth Repartitioning

A key limitation of the repartitioning techniques presented so far is that they do not adapt in response to join queries. Instead, each table adapts independently, and tables end up being partitioned on different attributes and ranges, such that hyper-join would not provide a performance advantage over shuffle joins. After the initial two-phase partitioning, with new incoming queries containing a new join attribute, the partitioning tree should also shift to the new join attribute. However, repartitioning all of the data immediately would introduce a potentially very long delay and, when the workload is periodic, could lead to oscillatory behavior where it switches from one partitioning to another. Furthermore, a table with multiple foreign keys may join with multiple tables. For example, in TPC-H, queries join lineitem and orders on order_key, and lineitem and supplier join on supplier_key. Smooth repartitioning addresses these challenges by maintaining multiple partitioning trees, building each when a new popular join attribute is seen, and migrating blocks between them. The key goal is to adapt partitioning trees in a way that facilitates joins while still maintaining the performance advantages of partitioning for selection queries.

Smooth partitioning creates a new partitioning (initially empty) tree, when it observes a

query with a new join attribute. The new tree's join attribute comes from the new query, and its predicates are used to build the lower levels of the tree. Smooth repartitioning also repartitions $1/|W|$ of the dataset from the old tree to the new tree, where $|W|$ is the length of the query window. This is accomplished by randomly choosing $1/|W|$ of the blocks in the old tree and inserting them into the new tree (because files are only appended in HDFS, it is possible to do this without affecting the correctness of any concurrent queries). To avoid doing repartitioning work when rare queries arrive, smooth repartitioning can be configured to wait to create a new partitioning tree until the query window contains some minimum frequency f_{\min} of queries for a new join attribute; in this case once the tree is created, $f_{\min}/|W|$ of the blocks will be moved.

As more queries arrive with the new join attribute, smooth repartitioning repartitions more data into the new partitioning tree using the following algorithm. It first calculates the percentage of two types of queries in the query window and the data in each of the partitioning trees. If the incoming query's join attribute is the same as the newly created partitioning tree and the fraction of data in the new partitioning tree is less than the fraction of its type in the query window, data from the old partitioning tree is moved to the new one, again by randomly selecting blocks and moving them.

Robust Data Partitioning, Fig. 10 Illustrating smooth repartitioning

Consider the example in Fig. 10. The algorithm starts from a partitioning tree optimized for join attribute A . When a query with new join attribute B comes, a new partitioning tree for B is created with two-phase partitioning and repartitions $1/|W|$ of the dataset from the old partitioning tree. The color of nodes from the lower levels of the partitioning trees indicates the size of data. The darker the color is, the larger the size of data is. After the new tree is created, both the partitioning trees are maintained with different join attributes. As more queries with join attribute B appear in the query window, more data from the old partitioning tree is repartitioned to the new one. The above procedure is iterated until the query window only includes queries with join attribute B . After the dataset finishes repartitioning, the old partitioning tree for join attribute A is removed, and only the partitioning tree for join attribute B is maintained, which is depicted by the last sub-figure in Fig. 10. (Of course, in many applications, there will not be a complete shift from one join to another, in which case multiple trees will be preserved.)

Conclusion

This chapter described new advancements in data partitioning for modern applications that are ad hoc in nature and do not have any upfront query workload. The key ideas presented include the notion of robustness, the concept of hyper-partitioning for creating a robust partitioning tree without upfront query workload, a hyper-join technique to efficiently process join queries over hyper-partitioned data, and a set of robust repartitioning techniques to steadily adapt the partitioning tree to changes in the workload.

Robust data partitioning revisits the design of a database in the face of modern ad hoc query workloads, recalibrating the database systems to the expectations of modern users – good performance from the first query itself and adaptively improving from there on.

Definitions

Scala is a statically typed General-purpose Programming Language (GPL) which blends object-oriented and functional programming features. Scala source code compiles to bytecode that runs on the Java Virtual Machine (JVM) and is fully interoperable with code written in Java.

Overview

Scala was designed by Martin Odersky at the École polytechnique fédérale de Lausanne (EPFL) in 2001 and first released in 2003 (Odersky 2006). The original design goal was to combine features from object-oriented and functional programming in a programming language that can be used in practice. The following paragraphs summarize the main features of Scala in comparison to Java.

Objects and Classes

Scala distinguishes between classes – which can be instantiated multiple times using the new

keyword (as in Java) – and objects, which can be understood as a singleton instance of an implicitly derived class definition. An object and a class that share the same name are called companions. Methods and fields that would be declared static in Java must be defined within the companion object of the corresponding class in Scala. For example, the bar method in the following code snippet corresponds to a static method declaration in Java.

```
class Foo {  
    ...  
}  
object Foo {  
    def bar(): Unit = ...  
}
```

Scala also supports Java-like abstract classes using the abstract keyword.

Inheritance and Traits

Instead of interfaces, Scala relies on the concept of traits. Similar to a Java interface, a Scala trait defines methods and fields that can be attached to an object or a class by means of inheritance. In contrast to Java interfaces, however, traits (a) can be partially implemented (which is also possible in Java since version 8) and (b) allow for multiple inheritance – an object or a class can inherit from multiple traits at the same time. The following code snippet defines a class Cat which inherits from Animal, Eyes, and Mouth. Cat instances therefore can call the blink and eat methods defined in their parent traits.

```

abstract class Animal
trait Eyes {
  def blink(): Unit = ...
}
trait Mouth {
  def eat(f: Food): Unit = ...
}
class Cat extends Animal
  with Eyes
  with Mouth

```

Type System

Scala's type system offers more principled support for generics with declaration-site variance, whereas Java allows only for use-site variance. For example, since `Cat` inherits from `Animal`, a covariant type parameter `A` in the generic type `List` (indicated with `+`) allows for assigning instances of type `List[Cat]` to a variable of type `List[Animal]`.

```

class List[+A] { ... }
var xs: List[Animal] = null
xs = List.empty[Cat]

```

In addition, Scala also supports type members and path-dependent types. For example, the following trait defines a trait for comparators for an abstract element type `T`

```

trait Cmp {
  type T
  def cmp(a: T, b: T): Int
}

```

and the `sort` method below accepts a comparator `c` and a sequence of comparable elements of type `c.T` and returns them as a sorted sequence.

```

def sort
  (c: Cmp)
  (s: Seq[c.T]): Seq[c.T]

```

The type `c.T` in the method declaration is *path-dependent* as it depends on the parameter value `c`.

Implicits

Scala implicits encompass a range of language features that enable a number of idiomatic encodings.

Implicit method parameters can be omitted from method applications. The Scala compiler

automatically provides arguments for implicit parameters from the set of implicit values available at the call site. For example, the `sort` method from the previous section can be also declared as follows.

```

def sort[T]
  (s: Seq[T])
  (implicit c: Ord[T]): Seq[T]

```

The above declaration permits incomplete method calls such as

```
sort(Seq(3, 4, 1, 5))
```

if an implicit value of type `Ord[T]` is available in the surrounding lexical scope. A shorthand notation which expands to the above method definition can be used to encode F-bounded polymorphism (Canning et al. 1989) in Scala.

```

def sort[T: Ord]
  (s: Seq[T]): Seq[T]

```

While an unconstrained type parameter `T` corresponds to universal quantification, the `Ord` type constraint corresponds to existential quantification: for all types `T`, the existence of an instance of type `Ord[T]` implies that given a value of type `Seq[T]` we can produce a sorted value of type `Seq[T]`.

TODO

Implicit classes provide a language facility for automatic type conversion. An idiomatic use of this feature is the so-called “pimp my library” pattern. It allows to attach methods and fields to types provided by external libraries in an ad hoc manner. To illustrate the pattern, assume that the `Cat` type from the previous section is provided by an external library that we cannot modify, but we want to add walking facility to `Cat` instances. Implicit classes allow us to achieve that as follows.

```

implicit class CatOps(c: Cat) {
  def walk(): Unit = ...
}
val tom = new Cat
tom.walk()

```

Because the `CatOps` class is declared as `implicit`, the Scala compiler will

automatically wrap the `Cat` instance in the `tom.walk()` call into a `CatOps` constructor call.

```
new CatOps(tom).walk()
```

Implicit conversions are another feature that can be used to encode the “pimp my library” pattern. To that end, instead of declaring the `CatOps` class as `implicit`, we define an `implicit` method called `cat2ops` which converts a `Cat` instance into a `CatOps` instance.

```
implicit def cat2ops(c: Cat) =  
  new CatOps(c)
```

The expanded version of `tom.walk()` now uses the `cat2ops` method instead.

```
cat2ops(tom).walk()
```

Metaprogramming

Metaprogramming is the ability of a programming language to reflect on its own terms and types, manipulate those, and generate new terms and types. Since version 2.10, Scala ships with experimental support for compile-time and run-time metaprogramming in the form of Scala macros (Burmako 2013) and Scala reflection (Coppel et al. 2008). These metaprogramming facilities are extensively used to reduce boilerplate code when designing Domain Specific Languages (DSLs) embedded in Scala, especially in combination with F-bounded polymorphism.

Actor Model and Akka

Akka is a widely used third-party Scala library that implements the actor model for concurrent computation. In the actor model, computation is modeled by actors which exchange messages in an asynchronous manner. Akka hides specifics regarding actor placement behind a uniform API. This allows programmers to run Akka code within same process, within multiple processes on same machine and on different machines without any modifications.

Key Research Findings

From a programming language perspective, the essence of Scala’s type system has been recently formalized in terms of the Dependent Object Types (DOT) calculus and proven sound using a mechanized proof by Rompf and Amin (2016). An influential line of research in Scala-based Embedded Domain Specific Languages (eDSLs) is based on the Lightweight Modular Staging (LMS) framework by Rompf and Odersky (2010). In the domain of Big Data analytics, LMS has been used in the Delite framework (Sujeeth et al. 2014) and a DSL called Jet (Ackermann et al. 2012).

From a data management perspective, Scala has been successfully used as implementation language for a number of research systems for Big Data analytics, most notably Spark (Zaharia et al. 2010) and Stratosphere/Flink (Alexandrov et al. 2014).

Examples of Application

Due to its concise and flexible syntax and its built-in interactive shell, Scala is a popular choice for a host language for eDSLs. In the domain of Big Data analytics, Scala has been popularized by Apache Spark and its Resilient Distributed Dataset (RDD) and Dataset/DataFrame DSLs (Armbrust et al. 2015; Zaharia et al. 2010), by Apache Mahout and its Samsara DSLs (Schelter et al. 2016), and by the Scala DSLs offered by systems such as Summingbird (Boykin et al. 2014) and Apache Flink (Carbone et al. 2015).

Embedded DSLs can be either shallow or deep (Gibbons and Wu 2014). In shallow embedding, eDSL terms evaluate themselves directly at runtime. Contrary, deeply embedded DSLs evaluate themselves in a two steps, first reflecting on their structure in an Intermediate Representation (IR) and then interpreting (and possibly optimizing) this IR. The DSLs mentioned above can be classified as deep, and their embedding mechanism as type-based. The following paragraphs illustrate how the Scala features outlined above are

commonly applied in these DSLs based on their implementation methodology.

Type-based DSLs are structured around a collection of domain-specific types, realized as Scala classes with possible companion objects. The core types in Spark are `RDD` (in the `RDD` DSL) and `Dataset` (in the `Dataset/DataFrame` DSL) which represent a distributed collection managed by the Spark runtime. The core types in Apache Mahout are `Matrix` which represents an in-core matrix and `DrmLike` which represents a Distributed Row Matrix (DRM). The core type in Summingbird is `Producer`, which represents a streaming or batch data producer. Finally, the core types for the various DSLs exposed by Apache Flink are `DataSet`, `DataStream`, or `Table`.

Implicit classes and conversions are often used in the design of type-based DSLs in order to provide ad hoc methods for a specific kind of instances of the associated core DSL types. For example, `RDD`s in Spark offer a set of operators that are only available on an `RDD`s of key-value pairs. The implicit method `rddToPairRDDFunctions` converts value of type `RDD[(K, V)]` into a value of an `RDDOps`-like type `PairRDDFunctions[K, V]`. This allows to leverage the existing Scala infrastructure in order to statically ensure that expressions such as

```
val rdd: RDD[Int, Int] = ...
rdd.countByKey()
```

are valid, while expressions such as

```
val rdd: RDD[Int] = ...
rdd.countByKey()
```

fail with a Scala type error due to a missing implicit conversion.

Embedded DSLs for data-intensive analytics hosted in Scala also rely on Scala's metaprogramming facilities, usually in conjunction with F-bounded polymorphism. For example, in order to reduce the pressure on the JVM garbage collector, the `Dataset` DSL in Spark and the DSLs offered by Flink rely on engine-specific memory management on serialized data. This

means that for a distributed collection of type `Dataset[A]` (in Spark) or `DataSet[A]` (in Flink), the runtime needs to know how to serialize and deserialize instances of the generic element type `A`. To ensure that, every DSL method that changes the element type of the enclosing distributed collection is constrained by an associated type that provides the encoding and decoding functionality for the new element type. For example, the `map` method in Spark is constrained by an `Encoder[B]` instance

```
def map[B: Encoder] (
  f: A => B
): Dataset[B]
```

and the corresponding method in Flink by a `TypeInformation[B]` instance.

```
def map[B: TypeInformation] (
  f: A => B
): Dataset[B]
```

The frameworks also provide generic implementations that can implicitly synthesize `Encoder[A]` and `TypeInformation[A]` instances based on reflected type information about the type argument `A`. Spark's implementation is based on Scala's runtime reflection library, while Flink's implementation is based on Scala macros.

Future Directions for Research

In the area of core language development, current and future research in Scala is mostly related to the next-generation Scala compiler called Dotty developed at the EPFL (Odersky et al. 2016, 2018; Odersky 2006). The Dotty design aims for a combination of faster compilation times and more principled and sound language design based on the DOT calculus.

In the area of DSL development, future research aims to provide a more stable foundation and better tooling for rapid development of optimizing DSLs embedded in Scala. An important milestone in this direction is the Squid metaprogramming framework by Parreaux et al.

(2018). Squid combines the flexibility of dynamic quasiquotes (in the style offered by Lisp) with the typing and scoping guarantees of static quasiquotes (in the style offered by MetaML).

Scalable Architectures for Big Data Analysis

Peng Sun and Yonggang Wen

School of Computer Science and Engineering,
Nanyang Technological University, Singapore,
Singapore

Overview

The era of big data is upon us. However, traditional data management and analysis systems, which are mainly based on relational database management system (RDBMS), may not be able to handle the ever-growing data volume. Therefore, it is important to design scalable system architectures to efficiently process big data and exploit their value. This chapter discusses various horizontal and vertical scaling big data platforms, focusing on their architectural principle for big data analysis applications, such as machine learning and graph processing. This chapter could aid users to select right system architectures or platforms for their big data applications.

Introduction

This is an era of big data, evidenced by the sheer volume of data from a variety of sources and its growing rate of generation. According to a report from the International Data Corporation (IDC), the global data volume will grow by a factor of 300, from 130 exabytes (1 exabyte = 10^6 terabytes) to 40,000 exabytes, from 2005 to 2020 (Gantz and Reinsel 2007). These data come from everywhere (Hu et al. 2014), such as user-generated contents (e.g., images and videos) posted to social media sites, transaction records, and embedded sensors used to gather information for IoT (Internet of Things) applications.

The concept of big data has been defined as early as 2001. META group (now Gartner) analyst Doug Laney presented a “3Vs” model (Laney 2001) to define challenges and opportunities of data growth, i.e., increasing volume,

velocity, and variety. Although this description was not originally used to define big data, many industries continue to use this “3Vs” model to describe big data 10 years later (Chen et al. 2014). In 2012, Gartner updated the definition of big data as follows: “*Big data is high volume, high velocity, and/or high variety information assets that require new forms of processing to enable enhanced decision making, insight discovery and process optimization*” (Beyer and Laney 2012).

Traditional data management and analysis systems are mainly based on the relational database management system (RDBMS), which could not efficiently handle big data. Specifically, RDBMSs could only support structured data, while big data typically includes masses of semi-structured and unstructured data. Also, the ever-growing data volume could easily extend beyond the ability of average RDBMSs to capture, store, manage, and analyze big data.

To address these challenges and exploit the value of big data, the research community and industry have proposed various scalable big data analysis platforms. Scalability is the ability of a data analysis system to process increasing amounts of data in an appropriate manner. Typically, a big data analytic system should be able to support very large datasets and could be capable of scaling to address the ever-growing size of complex datasets generated in the future (Hu et al. 2014).

This article discusses various big data analysis platforms and focuses on the scalability and the architectural design. Specifically, we categorize existing big data analysis platforms into two types of scaling: horizontal and vertical scaling. For each type of scaling, we illustrate the architectural principle of several representative general-purpose and dedicated big data platforms. Moreover, this article also discusses the advantages and drawbacks of horizontal and vertical scaling to aid users to select the appropriate platforms for specific big data applications or algorithms.

The rest of this article is organized as follows. Section “[Scalability in Big Data Analysis](#)” presents the fundamental concept of scalability for big data analytics. Section [Horizontal Scaling](#)

Platforms introduces various horizontal scaling big data analysis platforms, including general-purpose systems like Hadoop and Spark and dedicated systems for machine learning and graph processing. Section “Vertical Scaling Platforms” describes vertical scaling big data analysis platforms using graphics processing units (GPUs) and field-programmable gate arrays (FPGAs). A brief conclusion with recommendations for future studies is presented in section “Summary”.

Scalability in Big Data Analysis

To capture, manage, and analyze exploding datasets, scaling has become a key technique for big data analysis. A scalable big data analysis platform could adapt to rapid changes in the growth of data. Different platforms incorporate different scaling techniques to support big data analysis.

Horizontal and Vertical Scaling

Popular big data platforms usually use the following two types of scaling to handle big data:

- **Horizontal Scaling:** Horizontal scaling, which is also known as “scaling out,” involves distributing the computation workload across a cluster with multiple commodity servers. With this approach, a big data analysis platform could easily improve its processing capability by adding independent machines. Typically, each machine runs its own operating system and could communicate with other machines via network to exchange intermediate data and controlling information for big data analysis.
- **Vertical Scaling:** Vertical scaling, which is also known as “scaling up,” involves adding more resources, such as processors and memory, to a single server for improving its data processing capability. With this approach, a big data analysis job runs in a single machine with a single operating system. Note that vertical scaling is often done through multi-threading computation and in-process message passing.

Comparison of Horizontal and Vertical Scaling

Table 1 compares the advantages and drawbacks of horizontal and vertical scaling. Most of the existing single-node data analysis tools could take advantage of faster hardware to improve the processing capability. However, it is hard to continuously scale up vertically after a certain limit (Hu et al. 2014). As a comparison, horizontal scaling could continuously increase system performance by installing new machines. Note that network could easily be the performance bottleneck for big data analysis when scaling out. Horizontal scaling big data analysis platforms must take care of this issue to reduce the communication overhead.

The initial investment costs of horizontal scaling big data platforms are relatively less than vertical scaling platforms. Specially, users could build a small commodity cluster to deal with the current big data analysis workload and install more machines to handle exploding datasets generated in the future. As a comparison, when a data analysis system is designed for vertical scaling only, users are locked into certain minimum initial investment costs driven by the hardware, which could handle current and future workload.

Regarding maintenance costs, vertical scaling big data platforms have an advantage than horizontal scaling platforms. Specifically, when users select vertical scaling platforms, they only need to cool a single server. As a compression, when using horizontal scaling platforms with multiple servers and network components, the cooling system may consume a huge amount of energy, which could significantly increase the maintenance costs (Dayarathna et al. 2016).

S

Horizontal Scaling Platforms

Many horizontal scaling platforms have been proposed for big data analysis. Message Passing Interface (MPI), MapReduce, and Spark are thee widely used general-purpose big data platforms. There are also a lot of dedicated platforms that are proposed for machine learning or graph processing.

Scalable Architectures for Big Data Analysis, Table 1 Advantages and drawbacks of horizontal and vertical scaling for big data analysis

Scaling	Advantages	Drawbacks
Horizontal scaling	• Increase processing capability by adding machines	• Network could easily be the performance bottleneck
	• Could avoid the single point of failure problem	• May have high power consumption to cool a cluster
	• Could handle big data with commodity machines	• Time-consuming to configure multiple machines
Vertical scaling	• Existing data analysis tools and softwares could easily take advantage of faster hardware in a single machine	• High financial investment to improve the processing capability of a single-node data analysis system
	• Easy to manage the hardware within a single machine	• Hard to scale up vertically after a certain limit
	• Lower power consumption with just one machine	• May have the single point of failure problem

General-Purpose Big Data Analysis Platforms

MPI

MPI (Gropp et al. 1999) is a standard communication protocol for programming parallel computers using the peer-to-peer architecture. Typically, MPI is used to set up the communication channel between different computation nodes. Thus, each node could exchange data and control information with each other to execute big data analysis applications. MPI is available for many programming languages and has several well-tested and efficient implementations, such as Open MPI (Gabriel et al. 2004), MPICH (Karonis et al. 2003) and MVAPICH (Panda et al. 2013).

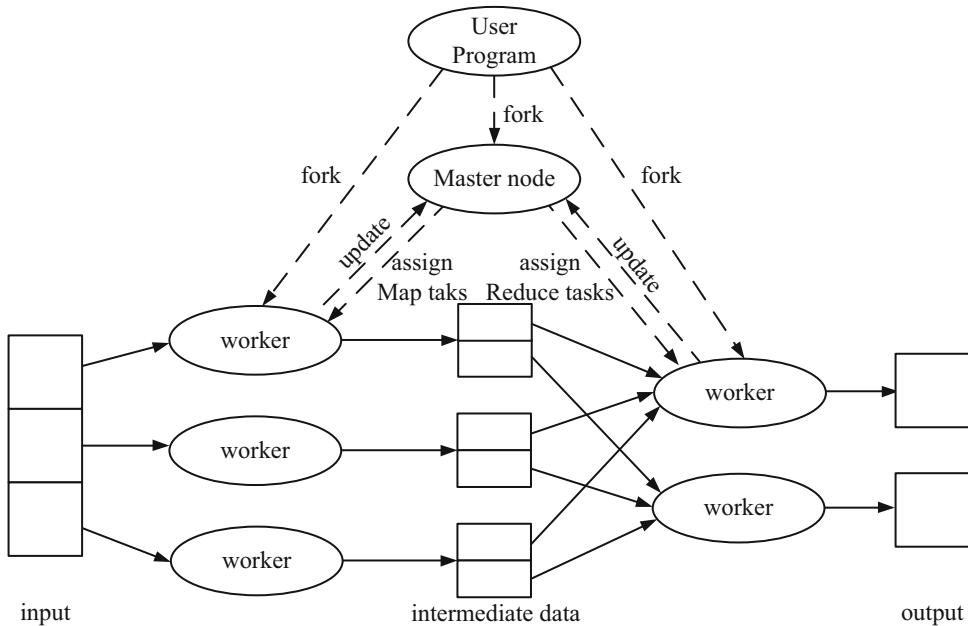

MPI supports both point-to-point and collective communication. More specifically, point-to-point communication is the method to send and receive messages between two individual nodes. Collective communication is a method of communication which involves the participation of all selected nodes. For example, “Broadcast,” one of the standard collective communication techniques, sends the same data to all selected nodes. MPI also provides a set of methods to control the progress of each node. For example, the “Barrier” method puts a barrier and allows all computation nodes to synchronize (reaching up to a certain point) before proceeding further. With these APIs, users could implement their own big data analysis applications and run them in an

MPI-enabled cluster with the specified amount of resources.

Although MPI offers high flexibility for users to develop big data analysis applications, it has some major drawbacks. First, MPI has no mechanism to handle faults. Thus, when running MPI-based big data analysis applications with unreliable hardware (e.g., commodity machines), a single-node failure could cause the whole application to crash. Thus, it is users’ responsibility to design and implement fault-tolerance mechanism when processing big data with MPI. Second, MPI requires more programming changes to design and implement a distributed data analysis application. Hadoop MapReduce and Spark have been designed to addresses these challenges and become popular for big data analysis.

Hadoop MapReduce

Apache Hadoop (White 2012) is an open source project for storing, managing, and processing large-scale datasets using clusters of commodity machines. Hadoop is designed to scale out to hundreds or even thousands of computation nodes. Hadoop contains various components, including Hadoop Distributed File System (HDFS) for reliable big data storage, Hadoop Yarn for efficient cluster resource management, and Hadoop MapReduce for big data analysis.

Scalable Architectures for Big Data Analysis, Fig. 1 Mapreduce architecture

MapReduce, which was firstly proposed by Google (Dean and Ghemawat 2008), is the programming model used in Hadoop. As shown in Fig. 1, there are two types of nodes in a MapReduce cluster: master node and worker. Specifically, the master node (i.e., JobTracker) is in charge of scheduling the submitted MapReduce jobs: partitioning each job into two types of tasks (i.e., Map tasks and Reduce tasks) and assigning them to available workers for execution. Current Hadoop MapReduce uses slots, which is usually configured by the number of CPU cores, to partition the computation resources of a worker. For example, if one server is configured to have two Map slots and two Reduce slots, it could run two Map tasks and two Reduce tasks in parallel.

To perform big data analysis, users just need to write two functions: Map function and Reduce function. When a job is submitted, the underlying MapReduce execution engine will automatically parallelize, distribute, and execute the job on a cluster and process data with two phases, Map phase and Reduce phase, as shown in Fig. 1. Specifically, during the Map phase, workers read input, generate a number of intermediate data, and send them to corresponding workers. During

the Reduce phase, workers process each group of intermediate data in parallel and generate the final results.

One of the major drawbacks of MapReduce is its inefficiency for executing iterative algorithms. Specifically, when executing iterative algorithms with MapReduce, workers would read the same input data from disks at the beginning of each iteration. After each iteration, the results should be written into disks, which may be loaded into memory again in the following iteration. As a result, disk access could be a major performance bottleneck, which significantly degrades the data processing performance. To address this problem, HaLoop (Bu et al. 2010) and Twister (Ekanayake et al. 2010) extend Hadoop MapReduce and improve the performance of executing iterative algorithms by caching input, output, and intermediate data.

S

Spark

Spark (Zaharia et al. 2012) was developed in 2012 in response to limitations in MapReduce. It offers a programming model similar to MapReduce but extends it with a data-sharing abstraction called resilient distributed datasets (RDDs).

RDDs are fault-tolerant, parallel data structures across multiple machines, which let users persist input, output, and intermediate results in memory (if the data does not fit in memory, RDD would also spill it to disk), control their partitioning to optimize data placement, and manipulate them using a rich set of operators. With the help of RDD, Spark could eliminate the disk I/O overhead of Hadoop MapReduce for running iterative big data analysis applications.

The Spark developers have also proposed the Berkeley Data Analytics Stack (BDAS) as an open source software stack to make sense of big data. In BDAS, Alluxio (formerly Tachyon) is a reliable, memory speed, distributed storage system. It could help to reduce data access overhead for big data analysis platforms. BDAS contains a cluster resource management systems called Mesos (Hindman et al. 2011), which could efficiently share cluster resources with multiple distributed computing systems. Spark is the processing engine of BDAS. BDAS also contains many Spark wrappers to optimize the performance Spark for certain applications. For example, Spark Streaming (Zaharia et al. 2013) is used for large-scale stream processing. GraphX (Gonzalez et al. 2014) is proposed for high-performance distributed graph processing. MLlib (Meng et al. 2016) focuses on distributed machine learning.

Dedicated Big Data Analysis Platforms

Many big data analysis platforms have been proposed for dedicated purposes, such as machine learning and graph processing. Compared to aforementioned general-purpose platforms like Hadoop MapReduce and Spark, these dedicated platforms usually could offer much higher performance for certain applications or algorithms.

Machine Learning

Machine learning (ML) builds models from training data and use them to make predictions on new data. It is used in a wide range of applications, including image recognition, object detection, natural language processing, and recommender systems. Typically, an ML model consists of a

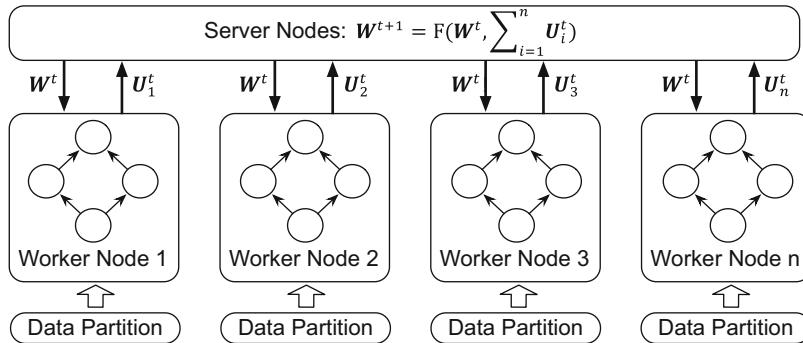

large number of *parameters*, represented as dense or sparse vectors and matrices. To minimize the prediction error, an ML application usually uses an iterative-convergent algorithm to iteratively compute *updates* from training datasets and to aggregate *updates* with the current version of *parameters*.

In industrial ML applications, the size of training data sets could be hundreds to thousands of terabytes. For example, the Yahoo News Feed dataset stands at roughly 110 billion lines of user-news interaction data; ImageNet contains approximately 14 million labeled images; ClueWeb12 has 733 million web pages. Due to the limitation in storage and computation resource, modern single-node ML systems, such as Caffe (Jia et al. 2014) and Theano (Bergstra et al. 2011), cannot cope with such large training datasets.

To handle big training datasets, various distributed ML systems have been proposed based on the parameter server (PS) architecture (Li et al. 2014), such as Petuum (Xing et al. 2015), MXNet (Chen et al. 2015b), Project Adam (Chilimbi et al. 2014), SINGA (Wang et al. 2015), Factorbird (Schelter et al. 2014), and TensorFlow (Abadi et al. 2016). As shown in Fig. 2, the PS architecture can scale to large cluster deployments by having *worker* nodes performing data-parallel computation and having *server* nodes maintaining globally shared *parameters*. When training ML models, *worker* nodes continuously pull latest *parameters* from *server* nodes, perform computation on partitions of the training dataset, and push generated *updates* to *server* nodes, which aggregate them and return a new version of *parameters*. This is done iteratively to bring *parameters* closer to the optimal value.

Graph Processing

Graphs are immensely useful for data mining applications, such as social influence analysis, recommendations, clustering, and anomaly detection. As graph sizes increase exponentially, industrial graph processing applications need to process massive graphs at the scale of millions of vertices and hundreds of billions (or even a trillion) edges (Ching et al. 2015). These massive graphs might not fit in the memory of a single

**Scalable Architectures for Big Data Analysis, Fig. 2**

The PS architecture. In PS, *worker* nodes are in charge of computing *updates*, and *server* nodes manage globally

machine and cannot be processed by existing single-node in-memory graph computation systems, such as Ligra (Shun and Blelloch 2013) and Ligra+ (Shun et al. 2015).

To address single node's memory limit problem, many distributed in-memory graph computation systems have been proposed for fast graph analytics at scale. They usually follow the “think-like-a-vertex” philosophy and abstract graph computation as vertex-centric programs. Specifically, Pregel (Malewicz et al. 2010), Giraph (Ching et al. 2015), Pregel+ (Yan et al. 2014), GPS (Salihoglu and Widom 2013), MOCGraph (Zhou et al. 2014), and HuSky (Yang et al. 2016) adopt the Pregel model: they assign the input graph's vertices to multiple machines and provide interaction between vertices by message passing along out-edges. PowerGraph (Gonzalez et al. 2012), PowerLyra (Chen et al. 2015a), GraphX (Gonzalez et al. 2014), and LiGraph (Zhao et al. 2016) use the Gather-Apply-Scatter (GAS) model: they split a vertex into multiple replicas and could parallelize the computation for a single vertex in different machines. GraphPad (Anderson et al. 2016) and CombBLAS (Buluç et al. 2011) express common graph analyses in generalized sparse matrix-vector multiplication (SpMV) operations and leverage high-performance computing (HPC) techniques to speed up large-scale SpMV. These distributed in-memory approaches, including Pregel-based, GAS-based, and SpMV-based systems, proceed in iterations, where an iteration

shared *parameters*. PS uses a pull/push communication model to exchange data between *worker* nodes and *server* nodes

is called a superstep. In each superstep, several user-based function (UDFs) are called by active vertices to update their values. A lot of benchmarking results (Hu et al. 2014; Iosup et al. 2016) have shown that these dedicated distributed in-memory systems could offer much better performance than general-purpose cluster computing systems like Hadoop MapReduce and Spark.

To further reduce memory footprint of distributed graph processing, researchers have proposed several out-of-core systems to enable large-scale graph processing beyond the memory limit, such as GraphD (Yan et al. 2017), Pregelix (Bu et al. 2014), and Chaos (Roy et al. 2015) which could handle big graph analytics in a small commodity cluster. Typically, these systems manage all or part of vertices in memory and stream edges from disks to reduce memory footprint.

S

Vertical Scaling Platforms

This section introduces vertical scaling platforms utilizing heterogeneous devices: GPU and FPGA.

GPU

GPUs started out as graphics accelerators. In recent years, due to their massively parallel architecture, researchers started to use graphics adapters for non-graphics applications. In this context, many programming frameworks start to give rise to GPGPU (general-purpose computing

on graphics processing units). For example, in 2006, NVIDIA released the first version of CUDA (Compute Unified Device Architecture), a parallel computing platform and programming model for general-purpose algorithms on GPUs.

Take NVIDIA's Pascal architecture as an example, GPUs are connected to RAM via PCIe. A GPU contains multiple streaming multiprocessors (SM). Each SM consists of several single-precision arithmetic logic units (ALUs) ("CUDA Cores"). Therefore, compared to multi-core CPU, GPU usually contains a large number of processing cores. For example, TITAN X, featuring the NVIDIA Pascal architecture, contains 3584 CUDA cores. In addition, GPU also has its own high-throughput DDR5 memory, which is much faster than typical DDR3 memory. Thus, GPUs could offer much higher performance than typical CPUs when executing certain big data analysis algorithms.

Nowadays, GPU is playing an important role in big data analysis, especially when executing machine learning and graph processing algorithms. In a single server, GPU could help Caffe (Jia et al. 2014) and Theano (Bergstra et al. 2011) to speed up the training process of deep learning models by a factor of up to 100. Gunrock (Wang et al. 2016), Medusa (Zhong and He 2014), and CuSha (Khorasani et al. 2014) enable fast and simple graph processing on GPUs.

FPGA

FPGAs contain arrays of programmable logic blocks and a hierarchy of reconfigurable interconnects, which allow the blocks to be "wired together." The FPGA configuration is specified using a hardware description language, such as VHDL or Verilog. Due to customized hardware, FPGAs can be highly optimized for certain big data analysis applications. One of the drawbacks of FPGAs is the high development cost, since FPGAs require developers to have a low-level knowledge of the hardware.

FPGAs are used in various big data analysis applications. For example, FPGAs now are widely used to accelerate deep convolutional neural networks (Zhang et al. 2015; Qiu et al. 2016; Ovtcharov et al. 2015). Graphgen (Nurvitadhi

et al. 2014) and Fpgp (Dai et al. 2016) start to perform vertex-centric graph computation over FPGAs.

Summary

This article surveys various big data analysis platforms and discusses their architectural design and scaling technique. Existing big data platforms could be categorized into two types of scaling: horizontal and vertical scaling. This article illustrates several representative big data analysis platforms for each scaling type and discusses the advantages and drawbacks of these two scaling techniques. This article could aid users to select right platforms for certain applications.

- ## Overview
- Processing big data to drive useful information has been in spotlight in recent years. Numerous approaches have been proposed to explore different ways to analyse the big data. However, data privacy has been an issue during the process because data could have been from various sources and they may contain sensitive personal information of individual. Hadoop MapReduce has been considered as one of the most promising approaches for big data processing. This chapter provides an overview of MapReduce environment, privacy challenges faced during the processing of data in MapReduce cluster, existing approaches adopted by various researchers to mitigate these issues. We also provide future guidelines for anonymized data processing to ensure individual privacy in MapReduce.

Introduction

Big data analytics is an emerging technology for finding new insights from large amounts of data. Processing and analyzing these large amounts of data require an extra set of tools and services. Traditional approaches for processing such data unfortunately are no longer effective because of its inherent limitations like computation power, storage capacity, analyzing, visualizing, searching, and sharing (Adnan et al. 2014). For example, Google searching is accessed 38,000 times in 1 s, more than 2.2 billion users send 144 billion emails in 1 day, Facebook manages its users' 40 billion photos, and Walmart stores approximately 2.5 petabytes of data and manages more than million customer transactions per hour (Patel et al. 2012). In the past years, the requirement for processing and storing data used in traditional approaches was quite different than they are today. For example, the traditional approaches did not provide scalability to complete the processing requirement within a given time (Peralta et al. 2015). Scalability is essential when the dataset is too large to be processed on a single machine or the processing becomes unacceptably slow. A careful plan was needed ahead of time to avoid unnecessary hassles, for example, processing the data in a multiple nodes. Similarly, some tasks are simply too time consuming as often computation required to process the data is too complex and resource hungry to run on a single computer. Running machine learning algorithms on large datasets is one of such tasks.

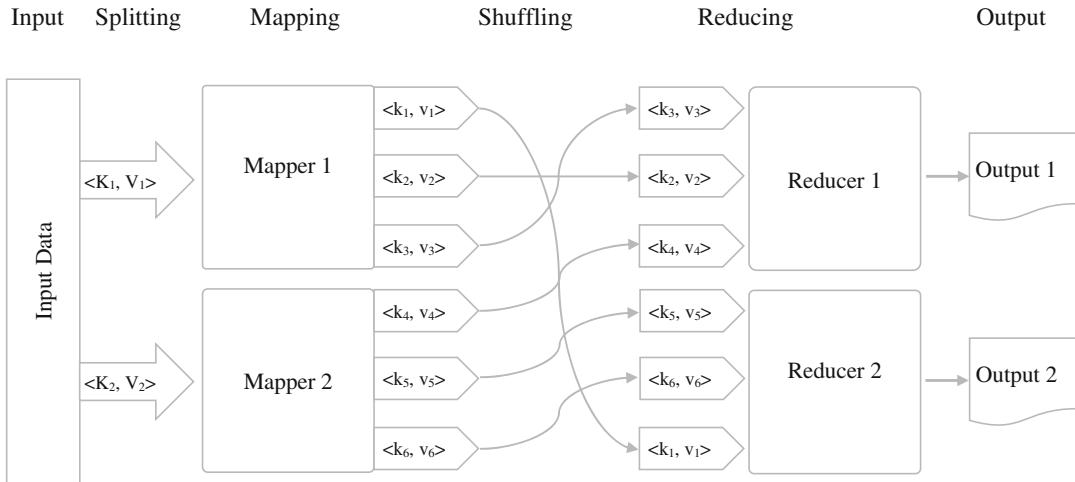

Fortunately, the commodity hardware has become cheaper, and putting several computers together to provide a high processing power has become easier in many cases. Even more, many third-party companies, such as Cloud, offer an hourly rental of hardware/software resources which has made the horizontal scaling very attractive lately. Many frameworks have been designed to use on the commodity hardware/software for specific computing which include MapReduce and Apache Spark among other choices (Dean and Ghemawat 2008; Zaharia et al. 2010).

Data owners are continuing in search of multi-node cluster platform which provides a powerful parallel and distributed architecture to process the big data fast and more efficiently (Aggarwal and Philip 2008). However, the privacy of data processed in such platform has given a data mining community a new concern. There are various techniques to achieve the privacy which includes perturbation, cryptographic-based techniques such as homomorphic encryption and secure multiparty computation, and data anonymization-based techniques such as k-anonymity and differential privacy. However, these techniques exist in isolation from each other in which often are tailored to address a specific problem of a specific domain. This chapter will highlight current big data platform architecture through MapReduce programming model, privacy issues found while processing big data in such architecture, and how existing approaches can (or can't) mitigate the privacy concern. Finally, this chapter will conclude with the future research directions which can provide more advanced approaches to address current privacy concerns.

What Is MapReduce?

The MapReduce-based solutions are considered to be better suited for big data analytics by some as it provides both flexibility and scalability. The MapReduce framework consists of two main functions, mapper and reducer. The mapper function is responsible for splitting an input job (typically large) into a number of smaller manageable jobs. The reducer function collects the divided smaller jobs and processes it further then writes the result to an output file. Figure 1 shows a diagram for the MapReduce programming model.

The mapper function is responsible for splitting an input file into smaller jobs where each job is defined by a key (i.e., an id to a job) and value (i.e., actual job) pairs. The map phase consists of multiple mappers – the same map function is carried out on each mapper. Mappers are executed independently, meaning that there are no interactions among them. There is no

Scalable Big Data Privacy with MapReduce, Fig. 1 The MapReduce programming model

relationship between the input and output types. Figure 1 shows the input to the mapper phase which is abstract as $\langle k_i, V_j \rangle$ and the output of the map phase which is abstract as $\langle k_x, v_y \rangle$. The mapper functions produce partial results, and these partial results are shuffled and sorted by respective key once the mapper function execution is completed. An intermediate data is stored in a local disk which contain the results of shuffled and sorted key value pairs.

Reducer functions collect the intermediate data and perform aggregation on it. Once the mapper tasks are complete, each reducer function accepts a list of values for a same key. The inputs for the reducer function are from the intermediate data. For the list of values, the programmer can define their own process. Finally, the final outputs of the reduce function are emitted at last. The output is still in tuple format (i.e., key and their values) where the key remains the same as input key, while the value is usually the aggregation of all the values in the input. Output tuples are written to their respective files in the file system.

Mapper and reducer functions execute their respective parts separately on different nodes which are often distributed and run in parallel. Hadoop (White 2012) implements MapReduce with Hadoop Distributed File System (HDFS) for an open-source project. This

project automatically handles task distribution, fault tolerance, and other aspects of distributed computing. This makes it much easier for programmers to write parallel processing. It also enables Google to develop a large number of commodity computers to achieve high performance computing at a fraction of the cost compared to a system that is built from a fewer but more expensive high-end servers. MapReduce scales performance by scheduling parallel tasks on several nodes that store the task inputs. Each node executes the tasks with loose communication with other nodes. HDFS is an open-source DFS inspired by Google File System (GFS) and designed to run Hadoop's batch jobs in massive parallelism. HDFS does not implement leases and users can choose which data replica is to be written. HDFS does data-balancing during writes and not periodically like GFS.

Privacy Concern

Unfortunately, distributed data and replicated nature in the MapReduce processing opens up an opportunity for a new huge variety of threats and attacks. While these threats share similarities for attacks in cloud computing models, the effects of attacks for the MapReduce framework are

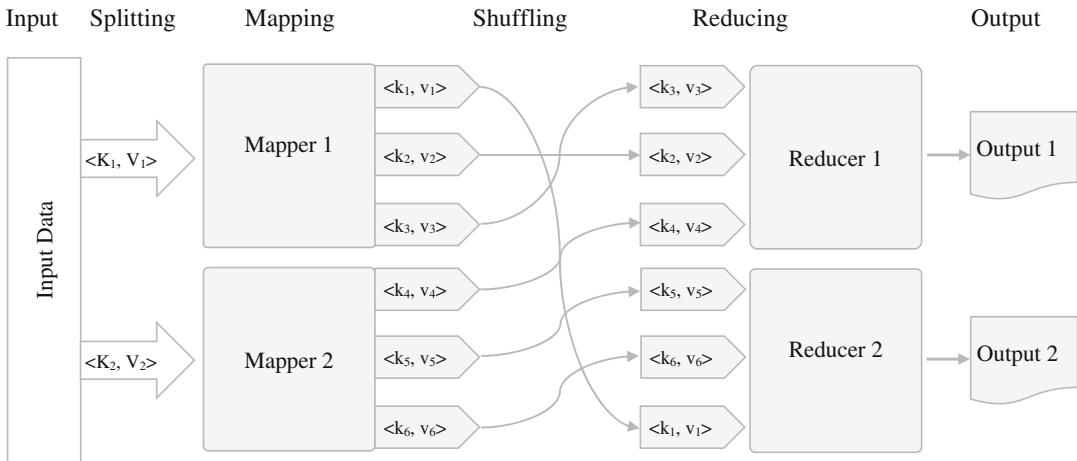

quite different (Derbeko et al. 2016). MapReduce deployed in public clouds is more open to threats and attacks compare when it is deployed in private clouds. The private cloud deployment is more secure because it is deployed in a trusted boundary of a company. This can reduce the danger of attacks and can also prevent company's resources from the threats. Executing the MapReduce jobs in public clouds introduces new challenges in the form of data privacy. In MapReduce, there are multiple mappers and reducers involved in processing data. If one of the many mappers or reducers is compromised by an adversary, it may provide incorrect outputs. A powerful adversary can compromise mapper and reducer function to access information from input, intermediate process, or final output. In these situations, it becomes increasingly difficult to protect individual's privacy in mapper or reducer function. In addition, in MapReduce operations, mappers transform input original key and value pairs to calculate an intermediate key and value pairs, while reducers aggregate an intermediate values set, compute, and write to the output. The output however can bring serious privacy concerns. Firstly, the output can directly leak sensitive information because it contains the global view of the final computation. Secondly, the output can also indirectly leak information via composite attacks where the adversary can link it with public information published via different sources such as Facebook or Twitter. Due to these reasons cloud users hesitate to upload their private information in public clouds. A Cloud computing client may delete sensitive information of individuals present in dataset to ensure their privacy and process the dataset in the public clouds because of its size and convince of computing in the said cloud platform. A Cloud user can delete their sensitive information if the user thinks their data is at risk. However, this is still not enough to protect the user data privacy because third-party administrator controls the public cloud. Third party administrator can easily monitor and eavesdrop client information, and the MapReduce code. Ensuring privacy protection in a compromised cloud service provider is a big concern and can breach the primary

aim of privacy which is to allow clients to use MapReduce services without compromising their data privacy.

Critiques on Emerging Approaches

The conventional anonymization approaches were applied on the output of MapReduce to provide privacy protection. Although it ensures the privacy of data but if the adversary has any access to MapReduce, processing it may leak private information before anonymization is applied to the data. The MapReduce processes data in plain text which is vulnerable from unauthorized monitoring and modification if data operations are executed in untrusted boundaries. In recent years, researchers have adopted anonymization approaches not only on the output but in different stages of MapReduce platform to ensure privacy. In Fig. 2, the areas highlighted in gray are used for anonymization. More number of research is done in the reducer function like Airavat (Roy et al. 2010), Sedic (Zhang et al. 2011), and others. However, the some studies also focus on mapper function to ensure privacy before exaction in plain text and explained as follows.

The current MapReduce framework cannot fully fulfill the requirement for privacy and security features for various applications and infrastructures. One of the cryptographic approaches for privacy-preserving computations is the homomorphic encryption. The technique, considered to be the holy grail of cryptography (Micciancio 2010), allows to perform computation on the cipher text itself without requiring any decryption. The usefulness of such a scheme is evident in the era of cloud computing, particularly in scenarios where organizations are worried about the privacy of their data contents. In traditional cryptographic schemes, the actual data, called plaintext, is encrypted to a distorted representation, called the ciphertext, which is not suitable for direct computations. In such schemes, we must decrypt the ciphertext to the actual data so that we can perform meaningful computations. This, however, is not the case with homomorphic

Scalable Big Data Privacy with MapReduce, Fig. 2 Anonymised MapReduce programming model

encryption schemes where, even after converting to the ciphertext, we can perform certain evaluations without seeing the plaintext. In this way, the plaintext can be kept secret from a third party who can perform calculations on the ciphertext and still provide the correct results. Another most common approach for protecting the security and privacy of data would be to use secure multiparty protocols for computation. This approach has long been studied as in Goldreich et al. (1987). In this technique, a protocol is established between the parties involved such that they all participate in calculating a desired result but without knowing the inputs of other parties (Goldreich 1998). The major cryptographic techniques used in MPC are homomorphic encryption (Cramer et al. 2001) and garbled circuits (Yao 1982). Kamal et al. (Dankar and El Emam 2012) introduce a cryptographic cloud storage service that enables search operation on encrypted data in the cloud, while also ensuring that no information is leaked in the process, and also allows users to verify the integrity of the data at any time. The proposed solution utilizes the combination of attribute-based encryption, searchable encryption, and proof of storage. Mayberry et al. proposed a private information retrieval for MapReduce (PIRMAP). PIRMAP uses mapper phase for parallel computation while homomorphic aggregation is performed in reducer function

(Mayberry et al. 2013). PRISM, a MapReduce technique introduced by Blass et al. (2012), can be efficiently computed in MapReduce. However, these approaches do provide privacy during the execution process but also significantly increase time to encrypt and decrypt the data during computation and do not support many operations on encrypted data.

HybrEx (Ko et al. 2011) and Sedic (Zhang et al. 2011) use MapReduce framework in hybrid cloud to provide privacy for computation data. The HybrEx model presents four execution models for providing privacy to data in a hybrid cloud, that is, map hybrid, horizontal partitioning, vertical partitioning, and hybrid. Each execution model is designed for different setting of map, reducing function execution in multiparty cloud environment. However, the paper does not provide any implementation for any of the proposed model. Sedic implemented the map hybrid model on top of Hadoop, in which reducer operation is only executing in the private cloud without utilizing the public cloud resources. However, the sensitivity of given dataset should be defined in the system before the execution, which eliminates the chances of using chained or iterative MapReduce process. Roy et al. (2010) present Airavat, a security and privacy preservation platform for MapReduce. Airavat ensures individual's data privacy using differential privacy by

adding calculated noise to each query in MapReduce. There are two approaches proposed by the authors. First, it provides mandatory access control (MAC) to ensure only authorized users have access to authorized tasks and resources. The MAC is activated when privacy leakage exceeds a defined limit. Tran and Sato (2012), however, if adversary, manage to sneak reducer code by changing user rights as a trusted user; the proposed solution fails to provide privacy guarantee. Zhang et al. (2012) proposed a privacy-preserving layer over MapReduce, which satisfies privacy demands itemized by data publishers built on diverse MapReduce privacy models. Mohan et al. then present GUPT (Mohan et al. 2012) which is another improved version of Airavat. GUPT defines the differentially private parameters in such a way that it automatically chooses and distributes the privacy parameter. However, Airavat add p reconfigured noise for query which limits its application. Clifton and Tassa (2013) observed that Airavat, unable to pick a suitable privacy budget and sensitivity value for selective quarry, leaves the privacy choice up to the user. In addition, Xiao and Xiao (2014) assign the executing task to new worker node and compare both results to eliminate the malicious node. The existing schemes have certain limitations such as inefficiency to handle incremental data, time taken to update records is more, experiences poor scalability, absence of parallelization, poor execution time, higher rate for loss of information, and inequity between data utility and anonymization.

Future Direction

Processing big data for multi-node cluster involved many vulnerabilities, for example, administrative control of data processing environment, distribution of data on an untrusted node in a public cloud for processing, etc. Victor et al. (2016). To address this limitation, state-of-the-art privacy protection methodologies, such as k-anonymity and differential privacy, have received great attention from the scientific community in recent years, and there are few implementations

offered in the area (Bello-Orgaz et al. 2016). However, these approaches were adopted in the earlier versions of big data processing platform like earlier version of Hadoop. Since the architecture and design for these approaches have been improved radically, the data anonymization algorithm used for previous deployments also needs to be updated to work efficiently (Jain et al. 2016).

K-anonymity ensures the privacy of data where perturbation and cryptographic approaches failed with well-known datasets such as AOL, adult dataset, and Netflix (Bayardo and Agrawal 2005). K-anonymity is the first data anonymization technique with formal mathematical support as a proof. Latanya Sweeney in 2002 (Sweeney 2002) introduced k-anonymity by stating that without ensuring k individuals in aggregation single aggregate statistic should not be published. The formal definition of k-anonymity formalized as each release of the data must be such that every combination of values of quasi-identifiers can be indistinguishably matched to at least k respondents. Quasi-identifiers (QID) are attributes in dataset which may be linked from publicly available dataset by join linkage. The main goal to achieve k-anonymity is to replace QID values with more general values, e.g., generalizing 15, 17, and 19 into a 15–20 value. K-anonymity provides the balance between privacy and utility. It provides more flexibility to data publisher for choosing the desired level of privacy. Most importantly, the anonymized data can be used for processing for analytical data operations even after applying data anonymization technique. Bazai et al. (2017a) proposed an algorithm to use k-anonymity on k-NN classifier for MapReduce operations. The algorithm transformed the plaintext data into anonymized data and executed k-NN classifier on anonymized data. The results provide better data utility for veracious degrees of anonymity. Differential privacy approach has been widely used in statistical queries (Inan et al. 2010). Differential privacy ensures the privacy of individual by answering the query in such a way that the query result does not contain any information about individual's presence in

that data. Differential privacy (Dwork 2008) was formally presented by Dwork in 2006, the idea of adding carefully calibrated noise to the data. The noise level is controlled in such a way that if the records are correlated with other datasets, then an adversary is not able to trace the data subject. The addition of noise in the original data is calibrated so that the noisy data acquired must be usable for data processing in the same way as the original. The noise is not allowed to increase beyond a level where the noisy data becomes so different from the original data that its utilization (accuracy) is impractical. Differential privacy has many advantages over other privacy techniques. Firstly, the mathematical definition of differential privacy is based on two properties: sensitivity and privacy budget. The sensitivity focuses on record closeness to each other, and the privacy budget is calculated based on how much privacy is required for a given query. Secondly, also only unique to this technique, it does concern with adversary computational power and background knowledge (i.e., even if the adversary knows the individual's publicly available details and then uses it for de-anonymization of the query, the adversary cannot de-anonymize it because of random anonymization mechanism used by differential privacy). Thirdly, it maintains composability which ensures that it does not leak privacy even an adversary holds and combines two differentially private results. These properties free data providers from the concern of privacy leakage of their data. Vernica et al. describe KNN processing approach for computing set resemblances on textual documents (Vernica et al. 2010). Their focuses are with document processing rather than business data analytics, and they do not address any implication of privacy; therefore, no data anonymization strategies were mentioned.

In big data processing platforms, computation is done on data in different executions in plaintext; any information leakage while processing the data may disclose sensitive information. Bazai et al. (2017b) mainly focus on addressing this limitation and intended to explore how data anonymization techniques (k-anonymity and dif-

ferential privacy) can be applied in big data processing environment, using MapReduce, which provides a well-known basic set of big data processing architecture and infrastructure, to validate the proposed approach.

Big datasets usually contain many different data types; for example, information is stored in the textual data containing categorical and continuous value, while others are stored in the numerical data. Previous studies show (Fletcher and Islam 2017) that different data types impose different constraints when applying data anonymization techniques. This is true when each privacy parameter has a different impact on the data type. For example, k-group size provides the better utility and privacy with categorical values, while differential privacy works better with well-distributed numerical values (Blum et al. 2013). Many different approaches for using different privacy parameters have been found in the literature for categorical values and numerical data in traditional data processing approaches (Natwichai et al. 2006); however, these implementations do not support multi-node cluster.

Summary

Big data is a very popular term nowadays and has opened a big data era. Distributed and parallel applications are designed to process this huge data to drive new insights and knowledge. Although the design of these applications ensures the data security in a certain level, individual privacy is at a great risk. This chapter illustrates the privacy concern of big data processing platform and provides critiques for existing approaches that are supposed to prevent MapReduce privacy leakage. Although researchers are addressing the privacy concern with various approaches for data analytics in big data processing platforms with perturbation, cryptographic techniques, k-anonymity, and differential privacy, most of the studies are still are in early stages. The practical implementation of anonymity with data analytics will help number of privacy and security challenges.

Mapping

Definitions

Several data management tasks require to precisely establish associations between data structured under different schemas. Schema mappings allow the definition of semantic connections between schemas with structural differences. A schema mapping M is a

specification of a relation between instances of a source schema S and instances of a target schema T . Given a source instance I for S and a target instance J for T , they satisfy the mapping if $(I, J) \models M$. Schema mappings are used both for virtual and materialized integration, and they have been studied in many aspects, including their specification, semantics, and user-assisted generation.

Overview

There are many applications that need to exchange, correlate, and integrate heterogeneous data sources. These information integration tasks have long been identified as important problems, and unifying theoretical frameworks have been advocated by database researchers (Bernstein and Melnik 2007). To solve these problems, a fundamental requirement is that of manipulating *mappings* among data sources. The application developer is typically given two schemas – one called the source schema S and the other called the target schema T – that can be based on radically different models and structures. *Schema mappings* are logical expressions that specify the semantic connection between the instances for the source and the target schemas. Given a source instance I and a target instance J that satisfy the schema mapping, we can say that $(I, J) \models M$.

A mapping is usually represented as a triple $\langle S, T, M \rangle$, and its semantics is defined with respect to the setting where only the source instance I (for S) is given. Before introducing the semantics, it is useful to distinguish the two main problems for which mappings play a key role: *data exchange* (Fagin et al. 2005a) and *data integration* (Lenzerini 2002). The two problems share the same goal: support users in retrieving source data by posing queries on the target, which is also known as global or mediated schema in data integration. The main difference is in the way that such goal is achieved. *Data exchange* formally studies the semantics of generating an instance of a target database given a source instance, a mapping, and constraints on the target schema. It has formalized the notion of a *data exchange*

problem and has established a number of results about its properties. In data exchange, the source data is transformed into a materialized instance that conforms to the target schema. Users define queries on the target schema, and these are then answered by using the target instance. *Data integration* is the problem of combining data residing at different sources and providing the user with a unified view of these data. The main difference with data exchange is that the query is part of the input and only the answer to such query is materialized. The source data is queried in situ, i.e., the target queries are rewritten to compute answers using the source data only. Despite the differences in the execution, in both approaches the goal is to reason about the possible instances J such that $(I, J) \models M$.

The most popular logical specification for schema mappings are source-to-target tuple-generating dependencies (s-t TGDs), with the following form:

$$\forall x (\Phi_S(x) \rightarrow \exists y \Psi_T(x, y)) \quad (1)$$

where $\Phi_S(x)$ and $\Psi_T(x, y)$ are conjunctions of atomic formulas over S and T , respectively. Consider, for example, a source schema with two relations *Patient* (*SSN*, *Name*, *Phone*, *HosDate*) and *Surgery* (*PatName*, *Insurance*, *Treatment*, *Date*) and the target schema with two relations *Customer* (*Id*, *Name*, *Phone*, *BirthDate*, *Insurance*) and *Claim* (*CustId*, *Treatment*, *Date*). A s-t TGD defined over these two schemas is

$$\begin{aligned} \forall p, i, t, d \text{ } & \text{Surgery}(p, i, t, d) \rightarrow \\ & \exists Y_1, Y_2, Y_3 (\text{Customer}(Y_1, p, Y_2, Y_3, i) \wedge \\ & \text{Claim}(Y_1, t, d)) \end{aligned}$$

Assume the TGD above is the only constraint in our mapping M . Consider now a given instance I for the source schema, such as $I = \text{Surgery}(\text{Mark}, \text{Axa}, \text{Eyes}, 2/21/17)$, and three target instances:

$$\begin{aligned} J_0 = & \text{Customer}(10, \text{Mark}, 978, 3/3/79, \text{Axa}), \\ & \text{Claim}(20, \text{Eyes}, 2/21/17) \end{aligned}$$

$$J_1 = \text{Customer}(11, \text{Mark}, 978, 3/3/79, \text{Axa}),$$

$$\text{Claim}(11, \text{Eyes}, 2/21/17)$$

$$J_2 = \text{Customer}(12, \text{Mark}, 978, 3/3/79, \text{Axa}),$$

$$\text{Claim}(12, \text{Eyes}, 2/21/17) \quad (2)$$

It is easy to see that the pair of instances (I, J_0) does *not* satisfy the s-t TGD specification, because of the different values for the customer id. In this case, we say that J_0 is not a *solution* for the given I and mapping M . On the other hand, both instances J_1 and J_2 satisfy the TGD together with I . Since $(I, J_1) \models M$ and $(I, J_2) \models M$, we say that each of the two target instances is a solution for I . One may observe that these two target instances have different customer ids, but this is not in contradiction with neither the source instance, which does not have this information, nor the mapping, as the s-t TGD only states that the id value should be the same in the *Customer* and *Claim* relations.

The example represents a mapping that specifies what source data must be in the solutions, but does not specify what must not be in any solution. For example, a fourth target instance J_3

$$\text{Customer}(12, \text{Mark}, 978, 3/3/79, \text{Axa}),$$

$$\text{Claim}(12, \text{Eyes}, 2/21/17),$$

$$\text{Claim}(12, \text{Liver}, 10/1/2010) \quad (3)$$

is also a solution for I and M above. The s-t TGDs above are in fact called *open* mappings and compose the most studied class of mappings in the literature (Bernstein and Melnik 2007). These mappings always allow a solution and can be specified with no requirements on the target or other sources (i.e., other open mappings cannot conflict). However, there are more constrained settings where exact mappings have been studied (Fuxman et al. 2006b).

Another important characterization of schema mappings is with respect to their structure (Lenzerini 2002). This comes from data integration systems, which assumed that the schema mapping is a function, e.g., a view. In one setting, known as global-as-view (GAV), mappings have

one relation symbol in $\Psi_T(x, y)$ and no repeated variables. In the opposite modeling, each relation of the source schema is defined in terms of the target schema. In this setting, known as local-as-view (LAV), mappings have one relation symbol in $\Phi_S(x)$ and no repeated variables. GAV and LAV have been largely studied and adopted because of their tractable data complexity when answering queries in data integration systems.

Key Research Findings

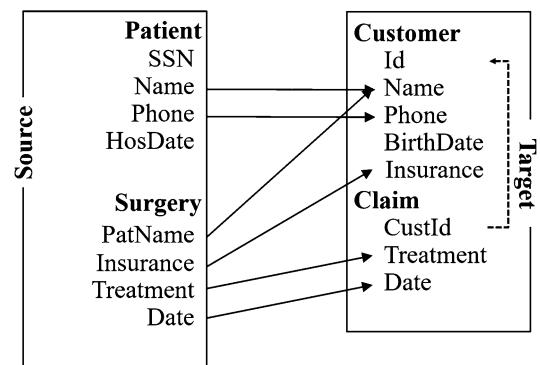

One important property of schema mappings is that they can be generated from graphical user interfaces (GUI). In fact, manually designing a schema mapping between schemas can be challenging. Even if the schemas represent similar data, they very often use different names and structures to describe the information. This is especially true when the schemas are independently designed. Manually crafting schema mappings is a difficult task, which requires technical experts that have deep understanding of both source and target schemas. When the size of the schemas increases, with dozens of relations and hundreds of attributes, it is also easy to make errors in the mappings, which can then lead to incorrect results in the ultimate application.

Since understanding the design of the schemas and manually writing schema mappings is time-consuming and prone to human errors, *mapping generation tools* have been created to make the process more abstract and user-friendly, thus easier to handle for a larger class of people. Most of these tools have been designed with data exchange in mind and directly compared to other solutions for the design of data transformation, such as ETL systems (Dessloch et al. 2008; Mecca et al. 2012). However, the same tools can be used to create schema mappings in data integration settings. Schema mapping generation tools include primarily Clio, which is the first tool able to generate logical mappings and corresponding scripts from high-level user input (Fuxman et al. 2006a; Haas et al. 2005;

Miller et al. 2000; Popa et al. 2002). Three main features characterize mapping generation tools.

High-level interface. The goal of simplifying the mapping specification was pursued by introducing a GUI that allows users to draw arrows, or *correspondences*, between schemas in order to define the desired transformation. Such correspondences can also be discovered and suggested to the users by schema matching algorithms (Bernstein et al. 2011). Correspondences represent associations between elements across different schemas in the form of attribute pairs and are discovered by profiling the attribute values and by mining the schema structures.

Consider the example shown in Fig. 1, with the relations described earlier and a foreign key from *Claim* to *Customer* in the target schema. Correspondences, represented as solid arrows in the figure, map atomic elements of the source schema to elements of the target schema, independently of the underlying data model or of the design choices. Due to the heterogeneity of the databases, the same concept could be represented differently across different schemas. At the same time, portions of the schemas with similar structure may actually model different entities. In the figure, the customer name in the target is encoded as the name of a patient in the source. However, multiple date attributes are present in both schemas, but they have different semantics across the relations, e.g., hospitalization date is

Schema Mapping, Fig. 1 Schema mapping scenario

different from birth year. While correspondences are easy to create and understand, they do not represent the full semantic relationship between source and target instances. In the example, the correspondences from the source relation *Surgery* to the target relations specify the constraint over the names and the treatments, but do not specify the relationship between the instances in relation *Customer* and *Claim*. This relationship is expressed explicitly by the foreign key and is part of the semantic specification, but it is lost in the attribute to attribute granularity of the correspondences. As we have seen in the schema mapping (2), a more complex formula is needed to capture precisely the semantic associations at the schema level. Correspondences are therefore taken as input by a schema mapping tool.

Automatic Mapping Generation. Based on value correspondences, mapping systems generate the logical dependencies that specify the mapping. In an operational interpretation, the resulting TGDs can be seen as a specification of how to *translate* data from the source to the target. It has been shown that the mapping generation is sound and complete with respect to the given correspondences, that is, all the relevant schema mappings are part of the output and none of them contradicts the correspondences (Fuxman et al. 2006a; Popa et al. 2002). Based on the correspondences drawn in Fig. 1, a mapping system would generate the following schema mapping with two dependencies:

SOURCE-TO-TARGET TGDS

$$\begin{aligned}
 m_1. & \forall s, n, p, h \text{ } Patient(s, n, p, h) \rightarrow \\
 & \exists Y_1, Y_2, Y_3 (\text{Customer}(Y_1, n, p, Y_2, Y_3)) \\
 m_2. & \forall p, i, t, d \text{ } Surgery(p, i, t, d) \rightarrow \\
 & \exists Y_1, Y_2, Y_3 (\text{Claim}(Y_1, p, Y_2, Y_3, i) \wedge \\
 & \quad \text{Account}(Y_1, t, d))
 \end{aligned} \tag{4}$$

Mapping Execution via Scripts. Given a source instance and a mapping, to produce a

target instance that is a solution, it suffices to execute the traditional *chase procedure* (Fagin et al. 2005a). The chase is a fixpoint algorithm which tests and enforces implication of data dependencies, such as TGDs, in a database. After the mappings had been generated, a schema mapping system translates the s-t TGDs under the form of an SQL script. When executed on any DBMS, the script implements the chase, i.e., it can be applied to a source instance I to create a new instance J that is a solution. Given a TGD, in order to chase it over I , we may see its $\Phi(x)$ as a first-order query Q_ϕ with free variables x over the source database. We execute $Q_\phi(I)$ using SQL in order to find all vectors of constants that satisfy the premise, and we then insert the appropriate tuple into the target instance to satisfy $\Psi(x, y)$. Skolem functions (Popa et al. 2002) are typically used to automatically generate new values for the existential variables y .

Given mappings written by users or generated from tools, a number of approaches have been proposed to *optimize* schema mappings in order to improve the efficiency of their execution and manipulation in real-world applications. In fact, schema mappings may present redundancy in their expressions, due, for example, to the presence of unnecessary atoms or unrelated variables, thus negatively affecting the data management process at hand (Fagin et al. 2008). The following efforts have aimed at optimizing such dependencies by identifying two kinds of equivalence aside from standard logical equivalence: the relaxed notions of data exchange (DE) equivalence and conjunctive query (CQ) equivalence. DE and CQ equivalences coincide with logical equivalence when the mapping scenario is made only of s-t TGDs, but differ on richer classes of equivalences, such as second-order TGDs, and scenarios with target constraints. Mapping rewriting has also been studied to compute a different class of data exchange solutions that reduces the redundancy in the target instances. Given a mapping scenario composed of s-t TGDs, these algorithms rewrite them to generate a runtime script that, on input instances, materializes compact solutions at scale (Mecca et al. 2009; Ten Cate et al. 2009). These works exploit the use of *negation*

in the premise of the s-t TGDs to rewrite them intercepting possible redundancy.

Schema mapping tools have proven to be effective in easing the burden of manually specifying TGDs and have been successfully transferred into commercial (Haas et al. 2005) and open-source systems (Marnette et al. 2011). Other commercial tools that generate some form of schema mappings from correspondences include Stylus Studio and Microsoft’s BizTalk Mapper and internal mapping modules in ETL systems. Given the large number of systems that have been proposed to create schema mappings, benchmarks for their systematic evaluation have been proposed (Alexe et al. 2008; Arocena et al. 2016).

Examples of Application

Schema mappings have been successfully adopted for data exchange and for data integration. They are popular because of their trade-off between expressiveness – as they can handle several real-world scenarios – and performance; formal results can be guaranteed with execution times that nicely scale over the size of the instances. However, many data management problems involve not only the design and execution of schema mappings but also their subsequent manipulation in a general framework (Bernstein and Melnik 2007). In this framework, other database applications, such as object-to-relational mappings and data warehousing, can be handled. This is achieved by introducing high-level algebraic operators that enable to build programs that directly manipulate schema mappings. One important application is *schema evolution*, where two of these operators play a key role. Consider a mapping M between schemas S and T , and assume that schema S evolves into a schema S' because of changes in the data organization or for performance reasons. The evolution can be expressed as a mapping M' from S to S' . Therefore, the relationship between the new schema S' and schema T can be obtained by first *inverting* the mapping M'

and then *composing* the result with the original mapping M . In this scenario inversion and composition are operators that take mappings as input and return new mappings. This high-level view of schema mappings exploits the intuition that they can be the building blocks for systems that save considerable effort to the final users.

Following this vision, the composition operator has been identified as one of the fundamental operators for the development of a framework for managing schema mappings, and its semantics has been studied (Fagin et al. 2005b). The main results show that first-order (FO) logic is not sufficient to express composition and that a second-order (SO) fragment of logic can be used as a mapping language for expressing this operator. Interestingly, SO TGDs can still be executed by means of scripts, and FO schema mappings can always be translated into this more general language, thus enabling composition. There are several other operators that have been defined for schema mappings, including several proposals on how to compute the inverse of a mapping (Arenas et al. 2009) and how to merge multiple mappings with the same target schema (Alexe et al. 2010).

Future Directions of Research

Emerging trends are encouraging the developing of more systems based on schema mappings. On one side, theoretical results are paving the way to the creation of innovative applications for which schema mappings show potential positive impact, such as data pipelines and graph data (Francis and Libkin 2017; Kolaitis et al. 2016). On the other side, new algorithms for the creation and optimization of schema mappings are widening the opportunities offered by such technology, with contributions such as mapping inference from data examples and probabilistic approaches (Ten Cate et al. 2017; Kimmig et al. 2017). These recent results show opportunities for enlarging the application of schema mappings to more data management tasks, including data fusion, data cleaning, and ETL scenarios.

Fribourg, Switzerland

Definitions

SciDB is a distributed database management system for managing and processing multidimensional arrays in scientific applications. It was first designed and developed by a group of academics led by Michael Stonebraker before being productized by Paradigm4.

Overview

The first XLDB workshop (1st Extremely Large Databases Workshop 2007) in 2007 brought together a group of scientists and industry members to discuss the capabilities of database management systems (DBMSs) at managing non-relational data at extreme scales. A number of

key shortcoming were identified, which were presented the following year at XLDB-2 (2nd Extremely Large Databases Workshop 2008). The lack of support for managing scientific data was in particular discussed. Consensus emerged that many Big Science projects presented unique challenges that could not be handled through generic DBMSs and would require a complete rewrite approach (Stonebraker et al. 2007).

As a result, a group of scientists led by Michael Stonebraker embarked on a new project to design and develop a new system for handling scientific arrays, as arrays represented a prominent data type for many science users (including astronomers, oceanographers, seismologists, or climate researchers). The resulting system, SciDB, was first presented at VLDB 2009 (Cudré-Mauroux et al. 2009). This first version supported a number of important features for science users, including:

1. native storage for nested, multidimensional arrays;
2. scientific operators built as user-defined functions (UDFs) to manipulate both the structure and the values of the arrays;
3. a shared-nothing design (Stonebraker 1986) allowing the system to scale out to many nodes and petabytes of data;
4. initial support for advanced features required by science users such as data versioning, provenance, and uncertainty.

The team continued the development of SciDB as an open source data management solution for Big Science projects. In 2011, Michael Stonebraker and Marilyn Matz co-founded Paradigm4 to further support the development of SciDB.

Architecture

SciDB is at its core a distributed array management system. The system takes as input large, multidimensional arrays potentially considering several values for each cell in the array. SciDB natively stores such arrays as a collection of *chunks*, each handling a portion of an array (e.g.,

a chunk or $10 \times 10 \times 5\text{ k}$ array cells). Chunks are typically of equal size (e.g., 64 MB) and store attribute values vertically (i.e., a chunk only stores the values of a given attribute).

Chunks partition the array spatially but can be overlapping to ease some operations like object detection, which would otherwise often involve stitching together multiple chunks. Chunks are written using various compression mechanisms on disk. The system adopts a *no-overwrite* storage strategy meaning that arrays cannot be updated in place (they can however be appended or updated by creating a new version of the array). A system catalog keeps track of the attributes and the spatial position of each chunk.

SciDB distributes the chunks among a set of worker nodes. Queries consist of a tree of operators over one or multiple arrays. Operators can modify both the structure of an array (e.g., its size or dimensions) as well as its contents (attribute values). The system comes with a number of standard operators such as *Filter*, which filters cell values based on a threshold, or *SJoin*, which combines attributes from different cells. The system is extensible and allows the definition of both user-defined types (UDTs) and user-defined functions (UDFs).

Many queries, such as *filter* or *object detection*, can be processed fully in parallel on each worker node. Specific operations might however require to exchange, share, or redistribute the chunks dynamically. SciDB defines a dedicated operator, called *ScatterGather*, to help support such cases. *Scatter/Gather* is a powerful operator allowing to dynamically redistribute the array over the nodes. Queries execution is orchestrated by a central node called the *coordinator*.

Academic Prototype

The first prototype of SciDB was developed as an open source project by a group of researchers from MIT, Brown University, SLAC, NIISI RAS, the University of Washington, Portland State University, and Microsoft. The group was led by Michael Stonebraker. The system was first demonstrated at VLDB in 2009 (Cudré-Mauroux et al. 2009).

This academic prototype adopted the architecture described above, with a non-overwrite, native array storage system and distributed query execution. It also featured initial support for array versioning, data provenance and uncertainty, as well as a simple query optimizer.

The main use case for this prototype was loosely modeled on an astronomy workload and was later extended to a full benchmark for scientific data management systems (Cudré-Mauroux et al. 2010). The use case considered the end-to-end ingestion and processing of raw data from a sensor system. It included three types of operations: (i) manipulation of raw imagery, including processing pixels to extract geo-spatial observations; (ii) manipulation of observations, including spatial aggregation and grouping into related sets; and (iii) manipulation of groups, including a number of relatively complex geometric operations in several dimensions.

The academic prototype was the basis of several research projects in array data management, including:

- A new storage manager to efficiently encode and access versioned arrays (Seering et al. 2012);
- A new storage manager for complex, parallel array processing implementing various partitioning and query execution strategies (Soroush et al. 2011);
- A hybrid analytic system for array-structured data integrating R and SciDB (Leyshock et al. 2013);
- A new structure to store and model multi-dimensional arrays supporting efficient inference processes (Ge and Zdonik 2010);
- Techniques to handle fine-grained lineage in scientific databases (Wu et al. 2013);
- Techniques to incrementally add nodes and to optimize data placement for n-dimensional array systems (Duggan and Stonebraker 2014).

Paradigm4 Development

In 2011, Michael Stonebraker and Marilyn Matz co-founded Paradigm4 to further support the development of SciDB (Paradigm4 2011).

The company hired Paul Brown to oversee the development of the system.

The system developed by Paradigm4 follows the architecture described above but adds a number of key features and libraries to SciDB (Stonebraker et al. 2011, 2013). It supports both a SQL-like, declarative language called *AQL* and a functional language (AFL). The system includes a full-fledged optimizer and an executor able to distribute queries to thousands of nodes. Support was also added for handling variable-size chunks, various encoding schemes (e.g., delta encoding, run-length encoding, or LZ encoding), uncertain data, and coarse-grained provenance.

A number of optimized operators come built-in with the system, including common linear algebra operators. The system also adds a number of dedicated operators for several vertical domain, e.g., for life sciences (to support genomic analysis, digital biomarker discovery, or biomedical images) and finance (for multifactor model generation or transaction cost analysis). Further use cases that have been explored include sensor analytics, insurance, and E-commerce.

Search and Query Processing

Search and query processing involves translation of high-level queries or user requests into low-level operations which can be executed on physical hardware to retrieve relevant results from a database. The process generally involves conversion of the high-level query into an intermediate representation, optimization of the intermediate representation to generate an optimal evaluation plan and finally the execution of the optimized plan on physical hardware to retrieve relevant results (Markl 2009). Figure 1 shows the major steps involved in query processing for relational databases.

The performance of search and query processing is essential for our daily life and work productivity. Besides relational databases, everyday applications of search and query processing range from simple Google search to complex deep learning systems. Other common examples include online shopping, supporting internal operations of organizations, and even simple file searches on personal computers.

Accelerators for Query Processing

Most current query processing systems made use of CPUs to evaluate queries submitted by users. However, the explosive growth in the amount of available data and the huge demand for high-throughput and low-latency query processing have resulted in the adoption of specialized hardware devices to accelerate query processing. These accelerators act as an add-on to CPUs and

Search and Query Accelerators, Fig. 1 Query processing steps

are used only for running specialized tasks like query processing. Some of the most common accelerators used for query processing include GPUs, FPGAs, and x86 based accelerators like Xeon Phi.

GPU

Graphics processing units (GPUs) were initially designed to accelerate the rendering of images for video editing and gaming. However more recently, GPUs have evolved as a powerful accelerator for processing huge amounts of data in parallel. There are already a number of query processing systems available for GPUs including GPUQP (Fang et al. 2007), Ocelot (Heimel et al. 2013), GPL (Paul et al. 2016), MapD (MapD 2016), and Voodoo (Pirk et al. 2016).

Hardware Design

Similar to CPUs, GPUs also contain processing cores, registers, multiple levels of cache, and a global memory unit (the equivalent of the main memory for CPUs). However, GPUs differ from CPUs in terms of the design of each one of these components. Instead of a small number of complex cores available on the CPUs, GPUs use a large number of relatively simpler cores that work in a SIMD fashion to process large amounts of data. For example, the latest Pascal GPUs from NVIDIA contain more than 3500 individual cores

which can work in parallel. This is more than 100 \times the number of cores in a modern CPU. GPUs are able to fit such a large number of cores in a single silicon die due to the relative simplicity of each individual core. These cores lack complex components such as branch prediction unit and even have much smaller cache than CPUs. However, they do have much larger number of registers and a higher bandwidth global memory unit, which is usually smaller (in size) than the main memory available on CPUs. The High Bandwidth Memory (HBM) units available in modern GPUs can provide close to 10 \times the bandwidth of the main memory accessible to CPUs. This high bandwidth and large number of cores help the modern Pascal GPUs from NVIDIA to achieve up to 9 TFLOPs of compute power using a single GPU. Figure 2 shows an overview of the internal architecture of the latest Pascal generation of GPUs from NVIDIA (2016).

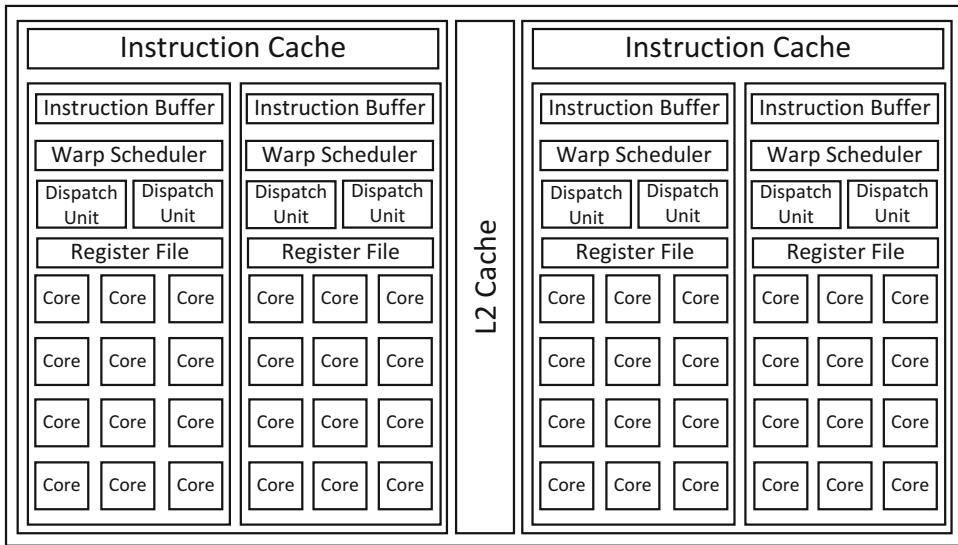

Most modern GPUs are available as a separate hardware unit which can be connected to the CPU over the PCIe bus. Any data that needs to be processed by the GPU needs to be first copied to the GPU global memory over the PCIe bus. However, the 16 GB/s memory bandwidth of the current generation of PCIe bus (3.0) has proved to be a bottleneck to processing large amounts of data on GPUs. Hence, vendors like NVIDIA have started looking into better interconnects like NVLink which is capable of providing up to 5x the bandwidth of the PCIe bus.

S

Advantages and Limitations

The main advantage of GPUs for query processing tasks comes in the form of the availability of large number of parallel cores which work in a SIMD fashion. This is mostly because query processing operations largely involve applying the same operation to a large number of data items in parallel. Further, the availability of larger number of registers and the much higher global memory bandwidth of GPUs ensure fast data access to the large number of parallel cores, thus making it possible to achieve much better throughput than CPUs.

However, the need to use specialized languages like CUDA or OpenCL to program the

Search and Query Accelerators, Fig. 2 GPU internal architecture

GPUs have proved to be a major limiting factor in ensuring widespread adoption of GPUs. This is because existing query processing systems need to be rewritten in these languages to take advantage of GPUs. Further, the low bandwidth of the PCIe bus also dampens the overall performance of GPU-based systems due to the high overhead of data movement between the CPU main memory and GPU global memory. This coupled with the relatively small size of GPU memory limits the performance gains achieved by addition of GPUs to large query processing systems.

FPGA

Field-programmable gate arrays (FPGAs) are specialized semiconductor devices that consist of a collection of logic blocks which can be connected together using programmable interconnects based on the operation that needs to be executed on the FPGA. Due to its unique hardware design, FPGAs can achieve significantly better energy efficiency than other hardware accelerators and even CPUs when performing most tasks. This has led to services like Microsoft Bing search adopting FPGAs in their servers (Allison Linn 2016).

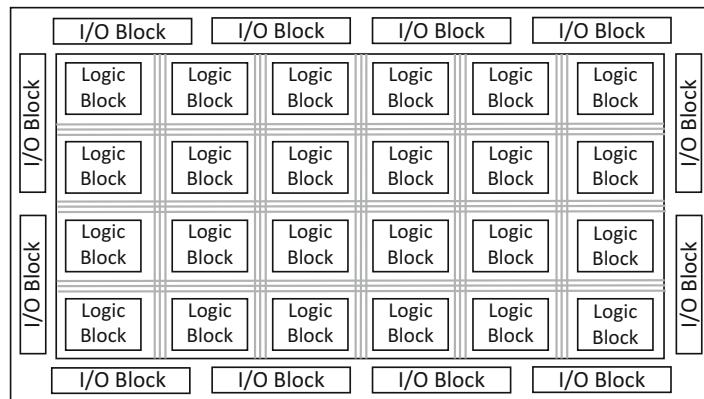

Hardware Design

An FPGA hardware consists of four main hardware units: logic blocks, registers, block RAM, and digital signal processors (DSPs). These hardware devices can be connected together based on the computation that needs to be executed on the FPGA. This means that FPGAs execute operations based on the interconnection in the hardware instead of decoding individual instructions as in the case of other hardware devices like CPUs or GPUs. Hence, FPGAs have the ability to process data more efficiently than other hardware devices making them significantly more energy efficient. FPGAs can be connected to CPUs over PCIe bus or Ethernet. Figure 3 shows an overview of architectural design of FPGAs.

In spite of being highly energy efficient, FPGA hardware usually falls behind other accelerators like GPUs when it comes to operating frequency and global memory bandwidth. Even though modern FPGAs have started adopting High Bandwidth Memory instead of traditional DDR RAM, these systems are still unable to achieve the same level of bandwidth as GPUs. FPGAs also lack additional on-chip cache which significantly impacts its performance when running programs written in high-level languages like OpenCL. Recent studies (Wang et al. 2016;

Search and Query Accelerators, Fig. 3

FPGA internal architecture

Woods et al. 2014) have demonstrated some promising results on accelerating query and search performance on FPGAs.

Advantages and Limitations

The major advantage of using FPGAs for query processing is its lower power consumption, which is very important in large data warehouses which spend a significant amount of money on power and cooling. Further, the use of hardware interconnections and the reliance on pipeline parallelism allow FPGAs to process data with much lower latency than other hardware devices like CPUs and GPUs. This is especially beneficial when querying data streams.

The major limitation of using FPGAs is the difficulty involved in programming them. Most FPGAs can be programmed only using low-level hardware description languages (HDLs) like Verilog or VHDL, making it extremely tedious to develop and maintain large-scale query processing systems on FPGAs. FPGA vendors have recently tried to address this issue by releasing OpenCL-based FPGAs which can be programmed using high-level languages like OpenCL. However, converting an operator written in OpenCL into an FPGA hardware implementation takes hours, and debugging these applications is extremely tedious. Further, the limited amount of resources available on the FPGA makes it difficult to fit a large number of operators on a single FPGA. All this makes it difficult to adopt FPGAs for systems that need to constantly adapt to user queries or changes in data streams.

Xeon Phi

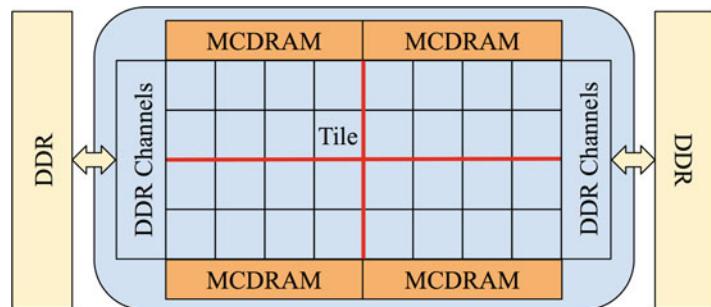

The Xeon Phi accelerator was first introduced in 2012 by Intel as an alternative to accelerators like GPUs. The attraction of Xeon Phi is the use of traditional x86 cores which allow the use of standard programming languages and APIs such as OpenMP. This means that most existing query processing implementations designed for CPUs can be ported over to the Xeon Phi accelerator without the need for any modification. Due to the use of traditional x86 architecture, the latest generation of Xeon Phi can even run an operating system and work without CPUs.

Hardware Design

The Xeon Phi follows a many-core design that uses the x86 architecture. The accelerator tries to offer a device which contains much larger number of cores than modern CPUs while being architecturally similar to existing CPUs. The recent release of Xeon Phi, known as Knights Landing (Avinash Sodani 2016), contains over 70 cores which make use of SIMD intrinsics to process large amounts of data in parallel. These cores are arranged in a 2D mesh and have access to L1 and L2 cache, but it lacks an L3 cache. Further, due to power and area limitations, each individual core has much lower operating frequency and a much simpler pipeline design when compared to modern CPUs. The Xeon Phi accelerator also has access to high-speed memory stacks integrated into the same silicon die. Figure 4 shows the

Search and Query Accelerators, Fig. 4

Xeon Phi internal architecture

architectural design of the Knights Landing processor.

Further, in addition to operating as a stand-alone device (without the need for a CPU), the Xeon Phi can also be used in conjunction with traditional CPUs by connecting it to the CPU over the PCIe bus. Recent studies have demonstrated significant performance improvement by tuning and optimization on those platforms (Jha et al. 2015; Cheng et al. 2017).

Advantages and Limitations

The major advantage of the Xeon Phi accelerator is the much larger number of x86 cores available for processing data in parallel. This design enables the execution of existing query processing systems on the Xeon Phi accelerator without any modification and at the same time makes it possible to achieve much higher levels of parallelism than traditional CPUs.

However, the simpler design and lower operating frequency of each individual core limit the performance of the accelerator when executing single-threaded workload. This is especially problematic due to the relatively low performance of individual cores. The lack of an L3 cache can also have a significant negative impact in such cases. Further, connecting the Xeon Phi to the CPU over PCIe bus leads to the PCIe interconnect becoming a bottleneck for data transfer.

Future Hardware

A recent trend in query processing hardware seems to be the development of coupled architectures which consist both CPUs and specialized accelerators in the same physical die or

on the same physical board. In such cases the accelerators are connected to CPUs using much faster interconnects like QPI or NVLink. Such a design allows the specialized hardware to access data residing in the system main memory without being bottlenecked by the lower-bandwidth PCIe bus. Some designs even allow the specialized hardware to access the L3 cache of CPUs, allowing for more fine-grained and faster movement of data between CPUs and hardware accelerators. Another recent trend in this area seems to be the emergence of database processing units (DPUs), which are specialized devices with hardware support for execution of relational operators (Wu et al. 2014).

Secure Big Data Computing in Cloud: An Overview

Sambit Kumar Mishra, Sampa Sahoo, and Bibhudatta Sahoo

National Institute of Technology Rourkela,
Rourkela, India

Definitions

Cloud computing: It is a system model that provides services on demand from a shared pool of

resources (CPU, main memory, secondary storage, bandwidth, etc.) without violating service level agreement (SLA) and maintaining a certain level of quality of service (QoS). *SLA:* The agreement done between the cloud service provider and cloud user before accessing the services.

Big data: It is an emerging area applied to store, manage, and analyze the data whose volume is large.

Virtualization: It is a technology that facilitates multiple virtual machines (VMs) over a single physical machine (host) with the help of a hypervisor or virtual machine monitor (VMM).

Virtual machine: A VM is a software program that emulates a real (physical) computing environment where an operating system is installed and can run different applications.

Introduction

The big data (explosion of data) problem aroused over the last 5–8 years as a result of the wide area network access, proliferation of next-generation applications, and advent of social media. Diverse sectors like finance, retail, smart sensor networks (IoT), physical and life science, etc., generate large data sets that need significant storage and computational implications. The bursty nature of data set spurred the use of cloud computing, where users can rent infrastructure on a “pay-as-you-go” basis. Virtualization technology, the basis of cloud computing, customized hardware and computational power of physical machines (PM), thus creating an illusion of several machines (virtual machines (VM)). Virtualization ensures the maximum of resource utilization and capital investment (Mishra et al. 2018b). A VM is a software application that emulates a physical computing environment, and multiple VMs can run on a single physical machine. Thus, virtualization reduces large capital infrastructure and maintenance cost. Cloud computing provides a scalable and cost-efficient solution to the big data challenge. Traditional computing (grid) technology had put a significant effort on resilience and robustness instead of solving the actual problem.

Modern big data technologies use scalable and cost-efficient methods to overcome such limitations.

The big data technology, though extremely powerful, was built for the technically savvy and needs applications to be parallelized in nature (ODriscoll et al. 2013). Big data with cloud technology makes several applications (e.g., biological problem) into reality to provide solutions. The implication of cloud computing to big data is due to the scalable and fault tolerance features of cloud computing toward big data computing. Addressing big data is a challenging and time-demanding task that requires a sizeable computational infrastructure to ensure reliable data processing and analysis. Since users are transmitting their data through the Internet, it gives rise to privacy issues, concerning profiling, stealing, and loss of control (Puthal et al. 2015). Although cloud computing transformed modern ICT technology, there exist security threats that can be elaborated by the volume, velocity, and variety of big data (Hashem et al. 2015).

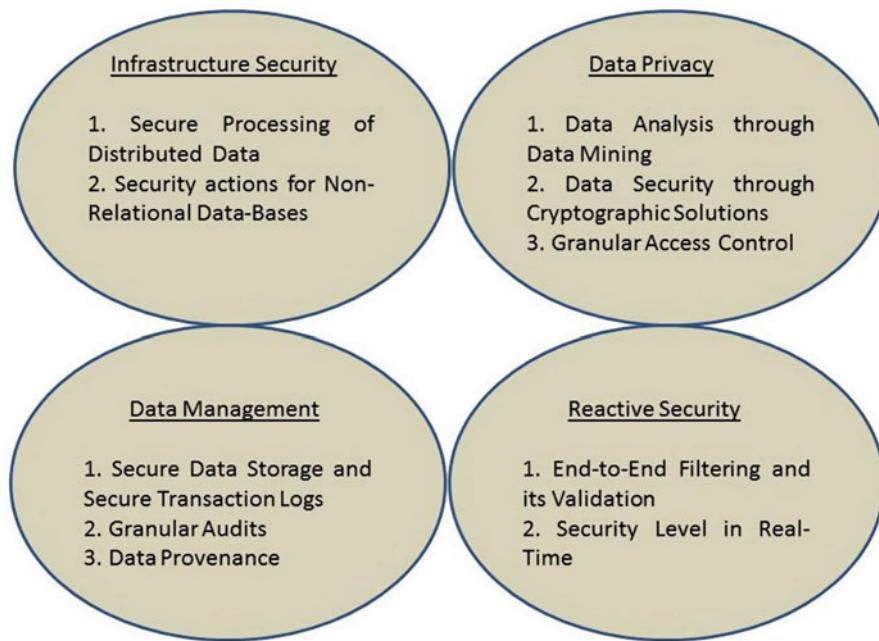

Some drawbacks associated with utilization of cloud computing are (1) data transfer rate: data from some applications may take long transmission time, even a week (e.g., genomic data) over the Internet. (2) Security and protection: Even though cloud computing is capable of handling big data sets, there is a loophole in terms of security and protection of data. Many applications such as cloud-based health-care system must provide enough security and protection of sensitive data from intruders. (3) Data tenancy: cloud infrastructures provide very little capability on data, application, and service back to an on-premise IT environment.

The big data processing capabilities of cloud computing generates a new area of computing system research. The requirement of secured big data computing in cloud is more essential due to the rise of the Internet of things (IoT). Gartner estimates that 26 billion of IoT devices (connected in mobiles, cars, TVs, security systems, etc.) will be installed by 2020 (Rivera and van der Meulen 2014). This will be responsible for a significant security challenge; however, it presents huge benefits for end users.

The big data not only deal with terabytes of data but also need to handle the issue of managing data under a traditional framework. The high-speed connectivity era permit movement of large sets of data that may contain sensitive information like credit/debit card numbers, addresses, and other details, raising data security concerns. Security issues in the cloud are a major concern for businesses and cloud providers today. The remaining of the paper is arranged as follows. The next section outlines an overview of secured challenges of big data computing in cloud; after that the next section reviews various solutions for security challenges in cloud followed by the conclusion and future direction.

Secured Challenges of Big Data Computing in Cloud

The complex infrastructure of cloud computing system increases various challenges for the IT industries and researchers. The volume of data collection, storage, and processing in the cloud system increases day by day, which brings new challenges in terms of the information security. Due to the stretching of security mechanisms out of the perimeter of the requirements, general firewalls cannot be used in the big data infrastructure (Kune et al. 2016). The challenges for secure big data computing may be organized into different big data aspects such as infrastructure security, data privacy, data management, and reactive security (Moura and Serrão 2016). Each of these mentioned security aspects face different security challenges as presented in Fig. 1. The security functions are compelled to operate over the heterogeneous composition using big data. Different technologies introduced abstraction that can enable the big data secure services on top of the heterogeneous infrastructure and separate the control from the system infrastructure. The production rate of data has been rising exponentially due to various sources like sensors. Thus, data privacy plays an important role due to the risk of erroneous data in every field. For example, the patient data; the content of patient medical record possess high-risk on the health-care system. The

Secure Big Data Computing in Cloud: An Overview, Fig. 1 Four different aspects of secure challenges of big data computing in cloud

big data computing has a set of risk areas that includes the ownership and classification of data, the process of creation, and collection of data. It would be more challenging in terms of research point of view to develop techniques to delegate encrypted data so that third parties can analyze it.

Some sensitive data require more security for the sake of the client; there should be an agreement (i.e., specified in SLA) upon the location of data, as its data may be considered illegal for others and lead to prosecution. Data encryption is required to solve security and privacy issues. Therefore, researchers have focused on the generation of new systems that must ensure the quick access of data where there is no effect of encryption on processing. To improve the system performance, various mechanisms (task allocation, VM consolidation, etc.) has to be improvised (Mishra et al. 2018a). To optimize the performance parameters like energy consumption, makespan, throughput, SLA violation, etc., the profit for the CSP as well as for the cloud user reduced (Mishra et al. 2018b). Due to the complexity of the system with the aim of optimizing various performance

parameters, the security level also has to be improved, which leads to a huge cost.

Solutions to the Security Challenge

For an efficient big data management and processing, the cloud system needs a high-speed transport mechanism that addresses two significant bottlenecks: (1) the degradation in the speed of WAN transfer that occurs over distance through traditional transfer protocols and (2) the last foot bottleneck caused by the HTTP interfaces in the cloud data center to the underlying object based cloud storage.

The new era of computing technology allows companies to store and analyze the vast amount of data (e.g., company, business, customer). So, it becomes a challenging task to make the data secure. To make the big data secure, various techniques are used for encryption, honeypot detection, logging, etc. The challenge of detecting and preventing advanced threats and malicious intruders must be solved using big data style analysis. With the rise in the use of big data,

companies must have to deal with both security and privacy issues. The big data issues are most acutely felt in certain industries, such as telecoms, web marketing and advertising, retail and financial services, and certain government activities. So, resource allocation and memory management algorithms used in the cloud for big data also have to be secure. Numerous data mining techniques can be used in the malware detection in cloud (Inukollu et al. 2014).

Kune et al. have elaborated the differences between the traditional data warehousing and big data and also discussed various solutions for the security issues in big data computing (Kune et al. 2016). Several areas of big data computing (i.e., scientific explorations, health care, governance) have been explained in Kune et al. (2016). The collected data from different sensors are extracted by analyzing those data for societal benefits.

Attackers also keep inventing new ideas of attacking to a secure system. Other issues like ransomware profoundly affect a company's reputation and resources, denial of service attacks, phishing attacks, and cloud abuse. Globally, 40% of businesses experienced a ransomware incident during the past year. Both clients and cloud providers have their own share of risks involved when agreeing on cloud solutions. Insecure interfaces and weak APIs can give away valuable information to hackers, which can be misused. Fraud detection patterns, encryptions, and smart solutions are immensely valuable to combat attackers. At the same time, it is the responsibility of the user to own data and keep it safe while looking for intelligent answers that can assure a steady ROI (return on investment) as well (Riaz 2017).

Conclusion and Future Directions

This chapter presents some of the most significant security and privacy issues that affect big data computing in cloud environment and also discusses the information security, methodologies, and tools to provide security and privacy to the system. It also presents some relevant solutions for these security issues.

This chapter does not point to directions and technologies that contribute to solve some of the relevant security issues.

Definitions

Access control is a mechanism used to restrict access to data or systems, based on rules that grant *subjects* (e.g., individuals, groups, roles) *access rights* to *resources* (e.g., data or systems) (Sandhu and Samarati 1994). Enforcement is usually broken into two stages: *authentication* and *authorization*. Authentication involves the verification the data subjects identity or attributes, whereas authorization is a mechanism used to determine if the requester (i.e., the subject) has the access rights necessary to carry out the request.

Encryption is an effective means of ensuring the confidentiality and integrity of information stored locally or transferred over a network (Menezes et al. 1996). Encryption involves the translation of data into an unintelligible form through the use of a secret key. Decryption is the process of restoring data to its original form through the use of a key (which may or may not be the same as the key used to encrypt the data). Encrypted data is referred to as cipher or cipher text, whereas unencrypted data is commonly known as plain text.

Trust mechanisms are used to verify the validity of a claim (e.g., the identity/attributes of an individual or the correctness of data). The most widely used trust mechanisms include *policies* and *reputation* (Artz and Gil 2007). Policies are used to govern the exchange of credentials that are often certified by trusted third parties. Reputation mechanisms take the form of provenance information and metrics that are calculated from previous actions and behaviors. Where no such data is available, trust may be established via referral from other trusted parties.

Anonymization involves the removal of personally identifiable information from datasets. One of the most well-known anonymization techniques, k-anonymity, involves the use of suppression (i.e., masking sensitive data) and generalization (i.e., choosing broader classification terms for sensitive data), in order to group individuals into equivalence classes, whereby each individual in a class is indistinguishable from *k-1* other individuals (Samarati and Sweeney 1998).

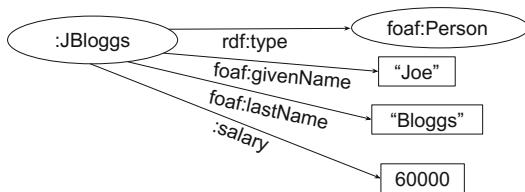

Overview

The Resource Description Framework (Manola and Miller 2004) is designed to facilitate data integration and reuse by representing distributed data in a machine-readable format. RDF *vocabularies* (otherwise known as *ontologies*) are collections of RDF triples that can be used to describe both schema and instance data. Each triple, which is composed of a *subject-predicate-object* expression, asserts a binary relationship between two pieces of information. *Internationalized Resource Identifiers (IRIs)* and *literals* are used to represent information, which can be either physical or abstract in nature. The *RDFSchema* (RDFS) ontology (Brickley and Guha 2014) is composed of a set of classes and properties commonly used to describe RDF data. RDFS does not describe the structure of an RDF graph but rather provides a framework that can be used to denote classes, properties, and relations. Vocabularies are often placed in a common *namespaces*, referenced via *prefixes*. In the examples that follow, the default prefix `:` is used to denote an example enterprise ontology `<http://example.org/ex/>`. In addition, well-known `rdf` and `foaf` prefixes are used for the RDF built-in vocabulary and FOAF social network ontology, respectively. Example 1 demonstrates how RDF can be used to represent information pertaining to Joe Bloggs.

Example 1 (RDF triples) The following triples state that the entity `:JBloggs` is a person whose first name is `Joe`, last name is `Bloggs`, and salary is `60,000`:

```
:JBloggs rdf:type foaf:Person.  
:JBloggs foaf:givenName "Joe".  
:JBloggs foaf:lastName "Bloggs".  
:JBloggs :salary 60000.
```

An *RDF graph* is a finite set of RDF triples, with subjects and objects represented as nodes and predicates represented as edges. Figure 1 demonstrates how the triples in Example 1 converge to form a graph, with IRIs represented as ovals and literals represented as rectangles. A collection of RDF graphs, which can include a

Security and Privacy Aspects of Semantic Data, Fig. 1
Triples represented as an RDF graph

default graph and one or more named graphs, is known as an RDF dataset.

In a recent survey by Fernandez Garcia et al. (2016), the authors analyzed topics appearing in papers that were published in Semantic Web conference proceedings and journals from 2006 to 2015 inclusive. The results of the conducted text analysis confirmed that traditional Semantic Web topics, such as knowledge representation, data management, system engineering, searching, browsing and exploration, and data integration, dominated the field up to 2015.

According to Fernandez Garcia et al. (2016), although topics relating to security and privacy have shown a minor increase over the years, the topics remain under-represented in comparison to traditional topics.

Much of the early research on security and privacy in the context of the Semantic Web focused on using RDF to represent existing access control models and standards and demonstrating how the technology could be used to develop general policy languages. Later the focus moved to the development of access control strategies for RDF and the Semantic Web. Other popular topics over the years include demonstrating how existing encryption mechanisms can be used to protect RDF data and establishing trust mechanisms for the Semantic Web. More recently, the landscape has broadened to include the encryption and anonymization of RDF data.

Key Research Findings

The goal of this section is to introduce the reader to key research findings in relation to Semantic Web security and privacy, and as such it focuses

on the predominant topics within the community, namely, access control, encryption, trust, and anonymization.

Access Control

Access Control (AC) for the RDF data model has predominately focused on using patterns to specify authorizations, enabling inference based on semantic relations between policy entities, and demonstrating how RDF can be used to form general policy languages.

Reddivari et al. (2005) demonstrate how access control rules can be used to manage access to an RDF store. Two predicates permit and prohibit are used to grant and deny access rights based on common database actions (e.g., INSERT, DELETE, SELECT) to one or more triples using triple patterns (cf. Example 2). A triple pattern is composed of an RDF triple with optionally a variable (denoted by a ?) in the subject, predicate, and/or object position.

Example 2 (AC rules with triple patterns) The following rule states that a subject Alice can create instances of any class (denotes as ?y) if there is an assertion that subject Alice created that class.

```

permit (INSERT(Alice,
(?x,rdf:type,?y)))
:- createdNode(Alice,?y)
  
```

Jain and Farkas (2006) build on the approach proposed by Reddivari et al. (2005), by demonstrating how RDFS entailment rules can be used to derive authorizations for inferred triples. While Kirrane et al. (2013) demonstrate how authorizations based on quad patterns (where the fourth element denotes the named graph) can be used to enforce Discretionary Access Control (DAC), where users can pass their access rights on to other users. Like Jain and Farkas (2006), the authors derive access rights for derived data using RDFS entailment rules.

When it comes to access control enforcement, typical enforcement strategies involve filtering unauthorized data based on access control policies and executing queries against the

filtered dataset or using query rewriting techniques to inject access control filters into queries.

Dietzold and Auer (2006) and Gabillon and Letouzey (2010) demonstrate how graph patterns (i.e., sets of triple patterns) constrained by a WHERE clause can be used to create a new dataset that only contains data the subject is permitted to access. The authorized dataset is created using SPARQL the standard query language for RDF (Seaborne and Prud'hommeaux 2008). Essentially, authorizations contain filters that refer to sparql CONSTRUCT queries that are used to generate the authorized dataset. In Gabillon and Letouzey (2010) a rule such as Permit(Alice, SELECT, foafview.txt) can be used to permit subject Alice, access right SELECT on resource foafview.txt. The resource foafview.txt simply contains a CONSTRUCT query such as that presented in Example 3). When a requester submits a query, a new dataset is created based on the matched authorizations. The query is executed against the new dataset, which only contains data that the requester is permitted to access.

Example 3 (Construct view) The following query creates a dataset that contains all data relating to people with Bloggs as a last name.

```
CONSTRUCT {?x ?p ?y}
WHERE {
?x ?p ?y .
?x foaf:lastName "Bloggs"}
```

An alternative enforcement strategy proposed by Abel et al. (2007) uses query rewriting to create bindings for variables that are subsequently added to the query WHERE clause. In the case of negative authorizations, the bindings are added to a MINUS clause, which is appended to the query. A simple SPARQL SELECT query is presented in Example 4, and sample rewritten queries containing positive and negative filters are presented in Examples 5 and 6, respectively. When a requester submits a query, the enforcement framework rewrites the query according to the matching authorizations, and the rewritten query is

subsequently executed against the new dataset, ensuring that the requester is only returned data that they are permitted to access.

Example 4 (SELECT query) The following query returns all data.

```
SELECT *
WHERE { ?s ?p ?o }
```

Example 5 (Positive filter) The following query, which contains a positive filter, only returns the information for :JBloggs.

```
SELECT *
WHERE { ?s ?p ?o .
FILTER ( ?s = :JBloggs ) }
```

Example 6 (Negative filter) The following query, which contains a negative filter, returns everything except the :salary information.

```
SELECT *
WHERE { ?s ?p ?o .
MINUS { ?s ?p ?o .
FILTER ( ?p = :salary ) }}
```

In addition to the access control mechanisms described above, there have been a number of standardization initiatives that could be used to limit access to RDF data. *Web Identity and Discovery (WebID)* (Sporny et al. 2011) is a mechanism that can be used to uniquely identify and authenticate a person, company, organization, or other entity, by means of a Uniform Resource Identifier (URI), while *Web Access Control (WAC)* W3C (n.d.) is an RDF vocabulary and access control framework that can be used for policy specification and enforcement. Both Villata et al. (2011) and Sacco and Passant (2011) extend WAC to cater for access control over the RDF data model. Using the extended vocabularies, it is possible to associate access control with individual RDF resources (subjects, predicates, and objects) and also collections of RDF resources (named graphs). In addition, the authors extend the vocabulary to cater for a broader set of access privileges.

An alternative policy language, called the Open Digital Rights Language (ODRL) (Iannella

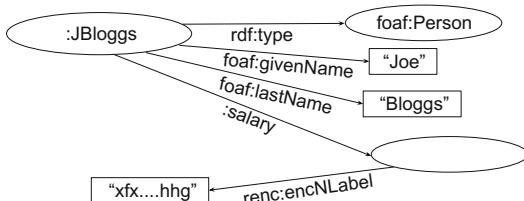

and Villata 2018), is a general rights language that can be used to define rights for limiting access to digital resources. When it comes to ODRL and RDF, primary research efforts to date focus on demonstrating how ODRL can be used to express a variety of access policies (Steyskal and Polleres 2014; Steyskal and Kirrane 2015) and using ODRL vocabularies to specify RDF licenses (Cabrio et al. 2014).

A comprehensive survey of existing access control strategies for RDF is presented in Kirrane et al. (2017).

Encryption

Encryption techniques for RDF have received very little attention to date, with work primarily focusing on the partial encryption of RDF data, the querying of encrypted data, and the signing of RDF graphs.

Giereth (2005) demonstrates how public-key encryption can be used to partially encrypt RDF fragments (i.e., subjects, objects, or predicates). The ciphertext and the corresponding metadata (algorithm, key, hash, etc.) are represented using a literal that they refer to as an encryption container. When only the object is encrypted, the object part of the triple is replaced with a blanknode (i.e., an anonymous resource), and a new statement is created with the blanknode as the subject, the encryption container as the object, and a new `renc:encNLabel` as the predicate (cf. Fig. 2). The treatment of encrypted subjects is analogous. The encryption of predicates is a little more difficult, as reification (a technique used to make statements about resources) is needed

Security and Privacy Aspects of Semantic Data, Fig. 2
Partially encrypted RDF graph

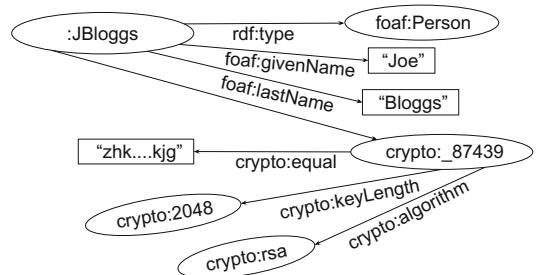

to associate the new blanknode with the relevant subject, object, and encryption container.

Rather than simply storing the encrypted data and metadata in a literal, Gerbracht (2008) discusses how the metadata that can be represented using multiple triples using their crypto ontology. The encrypted element or subgraph is replaced with a new unique identifier, and new statements are added for the encrypted data and the corresponding metadata (cf. Fig. 3).

Kasten et al. (2013) in turn focus on querying encrypted data. In the proposed framework, each triple is encrypted eight times according to the eight different triple pattern binding possibilities. The proposed approach allows for graph pattern queries to be executed over the ciphertext, at the cost of storing multiple ciphers for each statement. An alternative approach by Fernández et al. (2017) demonstrates how functional encryption can be used to generate query keys based on triple patterns, whereby each key can decrypt all triples that match the corresponding triple pattern. Other work by Kasten et al. (2014) investigates enabling of the signing of graph data at different levels of granularity.

Trust

In 2007, Artz and Gil (2007) conducted a survey of existing trust mechanisms in computer science in general and the Semantic Web in particular. The authors highlight that traditional approaches focused primarily on authentication via assertions by third parties; however, in later years, the topic evolved to include historical interaction data, the transfer of trust from trusted entities,

Security and Privacy Aspects of Semantic Data, Fig. 3
Partially encrypted RDF graph and metadata

and decentralized trust mechanisms (e.g., voting mechanisms or other consensus decision-making mechanisms).

Existing work on trust and semantic data focuses primarily on demonstrating how existing trust metrics can be applied to Semantic Web Data, the development of policy languages to support trust and negotiation, and the identification of trust architectures and frameworks.

Ding et al. (2003, 2005) discuss how various trust mechanisms can be combined in order to determine the reliability of information published on the Semantic Web. The proposed trust mechanism combines historical data, information obtained directly from trusted semantic agents, and information based on referrals from trusted agents.

The PeerTrust policy language and framework (Gavriloaie et al. 2004) demonstrate how together semantic annotations and access control rules can be used to support automated trust negotiation and access control. An alternative policy language called Protune is described in Bonatti and Olmedilla (2005, 2007). Although Protune is in fact a general policy language, the authors focus primarily on trust negotiation and policy explanations.

Bizer and Oldakowski (2004) propose a trust architecture that combines reputation, content, and context-based trust mechanisms. The *information integration layer* aggregates data from several sources and adds the relevant provenance metadata. The *repository layer* is used to store the information and associated metadata in named graphs. The *query and trust evaluation layer* uses trust policies to make trust decisions. Here the authors rely on a query language TriQL.P that is used to return the query results together with a justification tree that can be used to understand how the query results fulfill the trust requirement. Finally the *application and explanation layer* receives requests and provides the trust decision together with the relevant explanations.

More recently, Laufer and Schwabe (2017) propose a framework that can be used to describe the trust process. Inputs to be considered include the data and associated metadata and contextual

information relating to the action that needs to be taken, together with trust policies specified by the agent. Like Ding et al. (2003), the trust process relies on historical data, along with direct and indirect sources of information.

Anonymization

The anonymization of RDF data has recently emerged as a popular research topic, with work to date focusing on the application of k-anonymity (Samarati and Sweeney 1998) or differential privacy (Dwork 2006) to RDF data.

Radulovic et al. (2015) propose a framework called k-RDFanonymity, which includes an anonymization model, generalization and suppression operations, and distortion metrics that are specifically tailored for the anonymization of RDF data. The authors highlight the fact that RDF differs from tabular data as identifiers, quasi-identifiers, and sensitive attributes can appear in the subject, predicate, and object positions. Additionally the anonymization needs to be able to handle data represented as literals and IRIs. In the proposed model, generalization involves the replacement of resources (i.e., literals or IRIs) with more general resources based on domain hierarchies, while suppression involves either the removal or replacement of resources.

Heitmann et al. (2017) build on this work to ensure protection against neighborhood attacks. The proposed approach, which is known as k-RDF-Neighborhood anonymity, ensures that one-hop neighbors of an anonymized resource are indistinguishable from k-1 one-hop neighbors of other resources.

Other work in relation to RDF anonymization includes adopting graph or statistical database approaches. Lin (2016) takes inspiration from existing graph isomorphism-based anonymization techniques, discussing their suitability for RDF data from both a security and a computational complexity perspective. Whereas, Silva et al. (2017) explore the application of existing differential privacy mechanism to RDF data and propose a framework that can be used to compute differential privacy parameters.

Examples of Application

Semantic Web technologies have a solid foundation in open standards as evidenced by the various World Wide Web Consortium (W3C) recommendations; however, the layers of the Semantic Web technology stack (Berners-Lee 2000) that relate to security and privacy (i.e., unifying logic, proof, trust, and cryptography) are still very immature. Although the application of the key research findings described in the previous section is still very exploratory, several of the articles are guided by real-world use cases and practical applications.

For instance, the Protune policy language (Bonatti and Olmedilla 2005, 2007), which was developed by the Research Network of Excellence on Reasoning on the Web, known as REWERSE, was tasked with building the foundations for the advanced of Web systems and applications by developing inter-operable reasoning languages.

Fernández et al. (2017) are motivated by a real word use case that involves the combination of open and closed data in a data market scenario. In order to demonstrate the suitability of the proposed encryption mechanism, the authors conduct a performance evaluation over two real-world datasets: Jamendo a large dataset containing licensed music and the AEMET metereological dataset.

Although the initial evaluation of the trust framework proposed by Ding et al. (2003) was conducted using simulated data, the authors later discussed how trust mechanisms could be used in the context of homeland security, in order to identify suspicious individuals, relationships, activities, or events (Ding et al. 2005). Similarly, Laufer and Schwabe (2017) describe how the proposed trust framework can be used to evaluate the trustworthiness of claims in relation to political agents in Brazil coming from a variety of public sources (e.g., news stories, tweets, social media postings).

Existing work on anonymization appears to be less applied than the other topics with authors simply motivating their work by referring to privacy concerns in domains, such as healthcare and energy (cf. Radulovic et al. 2015).

Future Directions for Research

From a community perspective, it is well known that privacy is a multidisciplinary research area, which brings with it the need for closer collaboration between computer scientists, humanities, and social scientists and legal scholars. Although initiatives such as the *Society, Privacy and the Semantic Web – Policy and Technology* (PrivOn) workshop, which was collocated with the International Semantic Web Conference (ISWC) from 2013 to 2017, provides a forum for multidisciplinary research, stronger collaboration between different research communities is still needed.

From a technical perspective, there is a need for more applied work and a focus on attacker models across all privacy and security topics. Additionally there are many open research questions concerning the topics presented in this paper, several of which are outlined below.

When it comes to information security, there is still no standard access control strategy for the Semantic Web. Considering the array of access control specification and enforcement mechanisms proposed to date, a necessary first step is to develop a framework that can be used to evaluate existing offerings in terms of correctness, completeness, and robustness.

As for encrypted RDF, it is still not possible to execute complex queries and computations over encryption RDF data. One interesting avenue for future work is the application of homomorphic encryption to RDF; however, it brings with it performance and scalability issues that still need to be tackled. Another open research topic is the simplification of key management for multiple datasets, federated querying over encrypted data, and providing support for the revocation of existing keys.

In terms of trust, a recent article by Beek et al. (2016) highlights several issues with respect to the quality of existing data and datasources, claiming that the Semantic Web is neither traversable nor machine-processable and consequently arguing that the Semantic Web needs centralization. A counterargument, which is more in keeping with the goals of the Semantic

Web, would be to argue for the application of trust mechanisms into the fabric of the Semantic Web, which could be brought about by the realization of the upper layers and vertical layers of the Semantic Web technology stack.

Anonymization is a relatively new topic within the Semantic Web community with works primarily focusing on k-anonymity. However, it is well known that k-anonymity is prone to homogeneity and background knowledge attacks. Common extension mechanisms include l-diversity (Li et al. 2007), which ensures that sensitive attributes within an equivalence class are suitably different, and t-closeness, which ensures that the distribution of each equivalence class is representative of the distribution of the entire dataset (Machanavajjhala et al. 2006).

Other promising privacy and security research directions that remain underdeveloped and as such have not been presented in this article include usage control, which is defined as an extension of access control that enables data publishers to dictate not only who can access their data but also what they are permitted to do with this data (Bonatti et al. 2017). Related topics include transparency, which involves being open with respect to data processing and sharing, and accountability, which involves making data consumers responsible for their actions. Here, interesting avenues for future work include the adoption and extension of non-repudiation and fair exchange protocols.

Security and Privacy for the Resource Description Framework

► Security and Privacy Aspects of Semantic Data

Security and Privacy in Big Data Environment

Shekha Chenthara, Hua Wang, and Khandakar Ahmed

Institute for Sustainable Industries and Liveable Cities, VU Research, Victoria University, Melbourne, Australia

Synonyms

Attribute-based access control (ABAC); Authentication, authorization, and accounting (AAA); Availability; Confidentiality; Distributed denial of service (DDoS); Electronic health data (EHD); Electronic health records (EHR); Integrity; Privacy, Authentication, Integrity, Nonrepudiation (PAIN); Ramp secret sharing scheme (RSSS); Role-based access control (RBAC)

Format Definition

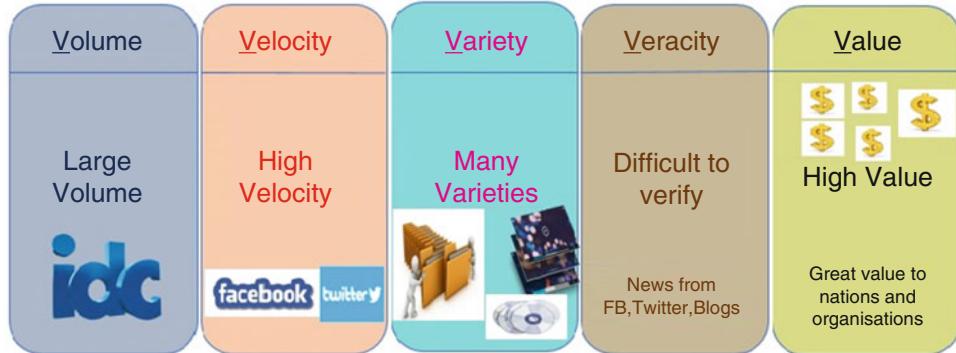

We come across data in every possible form, whether through social media sites, sensor networks, digital images or videos, cell phone GPS signals, purchase transaction records, weblogs, medical records, archives, military surveillance, e-commerce, complex scientific research, and numerous fields. This amount could reach to some quintillion bytes of data! This data is what we call ... BIG DATA! (Venkatram and Geetha 2017). “Big data is nothing but an assortment of huge

and complex data that it becomes very tedious to capture, store, process, retrieve and analyze with the help of on-hand database management tools or traditional data processing techniques.” We live in the Age of Big Data where everything that surrounds us is connected to a data source and everything is captured digitally (Matturdi et al. 2014). In the past few years, the total amount of data created by human has been exploded (McCune 1998). From 2005 to 2020, the amount of data is predicted to increase 300 times, from 130 exabytes to 40,000 exabytes (Gantz and Reinsel 2012). These data are generated by scientific research, finance and business informatics, government, Internet search, social networks, document, photography, audio, video, logs, click streams, mobile phones, sensor networks, and so on, and Big Data is the result of this dramatic increase of data.

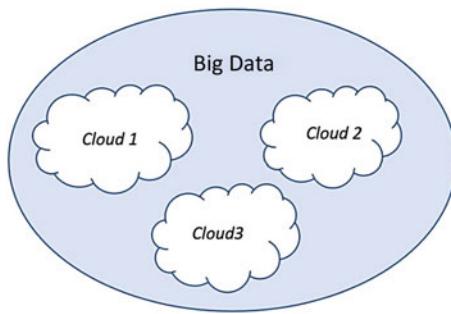

Overview of Big Data

Big Data can be represented by 5Vs – volume, velocity, variety, veracity, and value (Kadhiwala 2017). It is defined by five characteristics of Big Data, including five levels of meaning. Initially, volume refers to huge amount of data. Secondly, velocity refers to fast processing speed. Thirdly, variety refers to different varieties of data categories. Big Data is taken from multiple data sources, and data types contain structured, semi-structured, and unstructured data, such as network log, video, pictures, geographic location information, and so on. Fourthly, veracity refers to the authenticity of data. Finally, value refers to the worth of Big Data (Fang et al. 2017) (Fig. 1).

As the amount of data is increasing day by day, *cloud* has become a perfect solution to store data by providing virtually unlimited storage that can be accessed over the Internet. By outsourcing large volume of data to cloud storage, such as Google Drive, Dropbox, and Amazon Simple Storage Service, users can simplify their data management and reduce data maintenance costs through the pay-as-you-use model (Shu et al. 2018). Cloud services provide the necessary infrastructure by reducing the cost of storing, processing, and updating information with improved

Security and Privacy in Big Data Environment, Fig. 1 5 V features of Big Data

Security and Privacy in Big Data Environment, Fig. 2
An overview of Big Data

efficiency and quality. However, privacy of Big Data is a major hurdle while outsourcing private data in third-party *cloud* as there is a possibility of leaking/sharing sensitive information contained in Big Data with unauthorized entities. As most of the data is sensitive and strictly confidential, security of stored data is a major concern in Big Data environment. Since Big Data often contains sensitive information that needs to be protected from unauthorized access, therefore release of several techniques has to be devised immediately to protect it (Fig. 2).

The content of the chapter is enumerated as follows: Section “Format Definition” describes an overall view of big data. Section “Historical Background” describes challenges and issues of big data security and privacy. Section “Need for Data Security” reveals the need for big data security via some real examples. Section “Key Applications” describes one of the applications

related to big data security and privacy and some solutions to enforce big data security and privacy. Section “Future Research Directions” briefly introduces future research areas, and finally, Section “Conclusion” concludes this chapter.

Historical Background

The term “Big Data” is used to indicate the exponential growth and availability, the variety of data, and the speed at which the data is produced and transferred. The rise of Big Data contributes enormous opportunities for individuals, organizations, and society (Huang et al. 2017). An important notion is privacy for Big Data, since it contains sensitive information about individuals. Several privacy models, such as k-anonymity (Sweeney 2002), l-diversity (Machanavajjhala et al. 2007), t-closeness (Li et al. 2007), and differential privacy (Dwork 2011), can be used to anonymize data. It also raises some privacy and ethical issues. Big Data brings some challenges such as heterogeneity, data life cycle management, data processing, scalability, data visualization, security and privacy, etc.

Challenges of Big Data Security and Privacy

Undoubtedly the most challenging and concerned problem in Big Data is security and privacy. Governmental agencies, healthcare industry, biomedical researchers, and private businesses invest enormous resources into the collection, aggre-

gation, and sharing of large amounts of personal data for the tremendous benefit of Big Data. Many facts [section 3] show that Big Data will harm the user's privacy if it is not properly handled (Matturdi et al. 2014). The security and privacy issues which should be concerned in Big Data context include: "1. The personal information of a person when combined with external large data sets, leads to the inference of new facts about that person whereby these facts about the person are sometimes secretive and the person might not want the data owner to know or any person to know about them; 2. Information regarding the users (people) is collected and exploited in order to add value to the business of any organization. This is done by creating insights into their lives which they are unaware of; 3. Another consequence is of Social stratification where a literate person would be taking advantages of the Big data predictive analysis whereas the illiterate/ underprivileged will be worse off if it is high in developing countries where 'Digital Divide' is very much prevalent; 4. Big Data used by law enforcement will increase the chances of certain tagged people to suffer from adverse consequences who never have the ability to defend nor have the knowledge of being discriminated against" (Katal et al. 2013). The field of privacy in Big Data which contains a host of challenges involves interaction with individuals, re-identification attacks, probable and provable results, and economic effects (Jensen 2013; Zhang et al. 2014).

Privacy and Security Issues of Big Data

Data is the most crucial part in *Big Data*. Hence, assuring data security and privacy during either data transition or data storage is the core need of Big Data (Kadhiwala 2017; Zhang et al. 2017). Generally, data is treated as secure, when *confidentiality, integrity, and availability*, i.e., the CIA triad model, are satisfied (Xu and Shi 2016). *PAIN* is another measure to ensure data security and privacy benchmark (Sudarsan et al. 2015; Sun et al. 2011a). Hence, favoring literature studies, the main security and privacy issues of Big Data are confidentiality, integrity,

availability, monitoring and auditing, key management, and data privacy (Cheng et al. 2017).

Data Confidentiality:Research Directions

Confidentiality relates to applying some rules and restrictions to data against illegal disclosure. Confidentiality can be assured by limiting access to the data and also by employing various cryptographic techniques. There are three different ways to ensure confidentiality in typical security mechanism as follows (Sudarsan et al. 2015):

- Data is encrypted during transition and stored as plaintext.
- Authentication is used on stored plaintext data to grant access.
- Data is encrypted when stored and decrypted when in use.

Several data confidentiality techniques exist, and the most significant techniques among those are access control and encryption. Both techniques have been widely investigated (Bertino et al. 2011; Nabeel et al. 2013; Shang et al. 2010), and both are needed to assure data confidentiality. Confidentiality can also be assured using authentication, one of the AAA security concepts (Li et al. 2011; Ulusoy et al. 2014). Authentication is referred as user identity establishment, whereas authorization is used to grant resource access to the authenticated user. Access control refers to enforcing resource access permission for authorized use to authenticated users. Several access control mechanisms such as mandatory access control (MAC) (Balamurugan et al. 2015), RBAC (Balamurugan et al. 2015; Wang et al. 2005), and ABAC (Ruj 2014) can be used to ensure data privacy.

Integrity

Data integrity provides protection against altering of data by an unauthorized user in an unauthorized manner. Hardware errors, user errors, software errors, or intruders are main reasons for data integrity issues (Sudarsan et al. 2015). Salami attacks, data diddling attacks, trust relationship attacks, man in the middle attack, and

session hijacking attacks are most well-known attacks on data integrity (Types of Network Attacks against Confidentiality, Integrity and Availability 2017). Integrity can be maintained using data provenance, data trustworthiness, data loss, and data deduplication. Data provenance is related to information about creation process as well as sources of data through which it is transformed. It is the process to check all states of data from initial state to current state. Debugging, security, and trust models are various applications of data provenance (Azmi 2015; Glavic 2014). Without data provenance information, the user never comes to know from where the data came and what and which transformations have applied to data. This affects the value or originality of data (Alguliyev and Imamverdiyev 2014).

Availability

Data availability ensures that data must be available for use whenever authorized users require it. However, the emergence of cloud computing has narrowed down issues of data availability for Big Data due to high uptime of cloud. Denial of service (DoS) attack, DDoS attack, and SYN flood attack are known attacks to breach data availability; therefore, there is a need of revised solutions (Types of Network Attacks against Confidentiality, Integrity and Availability 2017).

Key Management

Key management and key sharing between users, servers, and data centers are emerging security issues for Big Data. Wen et al. (Jeong and Shin 2016) have explained various approaches for key management such as secret sharing, server-aided approach, and encryption with signature. In key management with RSSS, users do not need to maintain any key on their own, but instead, they have to share secrets among multiple servers. Key can be reconstructed using a minimum defined number of secrets using RSSS.

Data Privacy

Data privacy intends to assure personally identifiable information (PII) should not be shared without informed assent of related data owner (Kabir et al. 2012; Sun et al. 2011b). In some

cases, even though receiving user's consent to use and share the data, the use of PII could be restrained for a specific reason. For example, to develop effective treatment or medicine, the study of patient's medical record is essential. Hence, PII of the patient must be anonymized to protect privacy. In order to ensure data privacy, several encryption techniques and access control mechanisms can be employed.

Need for Data Security: Looking at the Bigger Picture

With the proliferation of data, cyber attacks and data breaches are increasing exponentially (Shen et al. 2017). The growing spate of incidents due to the proliferation and careless handling of data increases the vulnerability of data leakage. With the advent of *cloud*, the data has become more vulnerable to cyber attacks. With the growth of data and its insensitive management, it has come under various sorts of threats that compromise the privacy and security of nations in general and individuals in particular. Recent happenings across the world revealed the vulnerability of data to threats and greater ramifications that followed. Nowadays, no sector is free from data threats and breach. From US presidential elections (where private server of the presidential candidate was hacked) to the recent attack on UIDAI (Unique Identity Development Authority of India) which allots UIN (unique identity number for its citizens), the threat on Big Data is continuing. The incident that shook the conscience of global cyber community was the Ransomware attack that threw bare computers and systems across more than 150 countries at the mercy of cyber thieves. Though some breaches such as "WikiLeaks" and "Panama Papers" expose various irregularities in public domain, these are viewed as great thefts in the literature of data security which put the privacy and security of nations and individuals at stake. Hence there is an imminent need to develop a comprehensive and full proof mechanism to secure the Big Data from unauthorized intrusions.

Key Applications

There are diverse privacy and security concerns in various sectors such as social media, banking sectors, healthcare systems, energy industries, and other online database systems. In this study, we discuss one of the research applications related to Big Data in healthcare or EHD that explains how to enforce privacy and security of Big Data.

Application of Privacy and Security in Electronic Health Data (EHD)

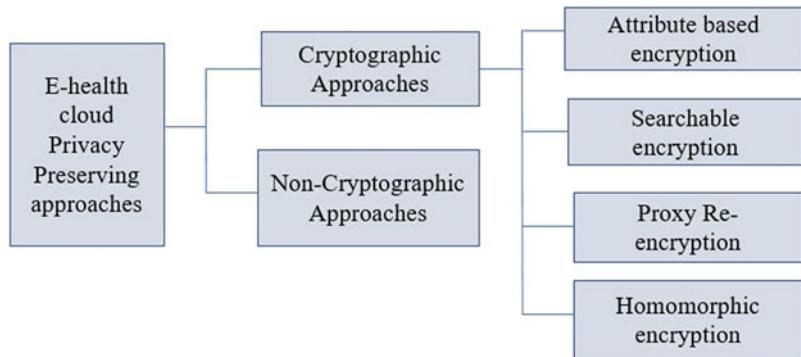

EHD (also known as electronic health records, EHR) is a systematic collection of electronic health information about individual patients or populations (Yi et al. 2013). Such records include a whole range of data including demographics, medical histories, medication and allergies, immunization status, laboratory test results, radiology images, billing information, and all sensitive patient information. According to a national survey, 94% of providers report that their EHR makes records readily available at point of care, 88% report that their EHR produces clinical benefits for the practice, and 75% of providers report that their EHR allows them to deliver better patient care (Clemens et al. 2017). However, the transition from paper-based to EHR systems poses some unique challenges for privacy and confidentiality, security, data integrity, and availability. As *cloud computing* is emerging as a new computing paradigm in healthcare sector (Griebel et al. 2015), it not only facilitates the exchange of electronic medical records among healthcare providers or organizations but also acts as a medical record storage center (Li et al. 2016). *Cloud* services provide the infrastructure to healthcare providers and patients by reducing the cost of storing, processing, and updating information with improved efficiency and quality. As computerized medical records are integrated into one place, data can be accessed from different places by different users, and this increases the risk of invasion of privacy. Since most of the data are sensitive and strictly confidential and stored on a third-party server where the owner doesn't have direct access, it demands serious threats in

terms of data privacy and security (Abbas and Khan 2014; Vimalachandran et al. 2017). This work focuses on identifying the most appropriate method to share private information between multiple healthcare providers in the patient's care team and the patient and their family or carers in the *cloud* environment.

Hence, EHR in healthcare is facing problems with privacy breaches and unauthenticated record access in the recent years, and the most prime one is related to privacy and security of medical data (Abbas and Khan 2014). The issues range from malware attacks that compromise the integrity of systems and privacy of patients to distributed denial of service (DDoS) which can disrupt facilities' ability to provide patient care. In healthcare systems, for instance, cyber attacks like Ransomware can have ramifications beyond financial loss and breach of privacy (Ahmed and Ullah 2017). Earlier this year, hackers broke into the databases of Community Health Systems (CHS), one of the largest hospital groups in the United States, and accessed personal health information, name, address, and personal data including social security numbers from around 4.5 million patients. Hackers from Internet vigilante group Anonymous also targeted several hospitals, launching a DDoS attack on the hospital website as an act of "hacktivism" (AbuKhousa et al. 2012).

Therefore, there is an indispensable need to protect the privacy, security, confidentiality, integrity, and availability of sensitive information pertaining to individuals' data in general. In this context, cybersecurity is utmost required to prevent, detect, and act on unauthorized access to a health system and its information. Therefore, the primary aim is to strengthen the security infrastructure by providing a strong protection mechanism in "e-healthcare" aiming toward patients' confidence and thereby providing security and privacy (Wu et al. 2012) to electronic health data. Therefore, in order to protect the privacy of patient data, access control mechanisms and encryption techniques will be a better solution. Some of the cryptographic approaches are mentioned in Fig. 3. Narayan et al. (2010) proposed an attribute-based infrastructure for the

Security and Privacy in Big Data Environment,
Fig. 3 Taxonomy of the privacy-preserving approaches in the e-Health cloud

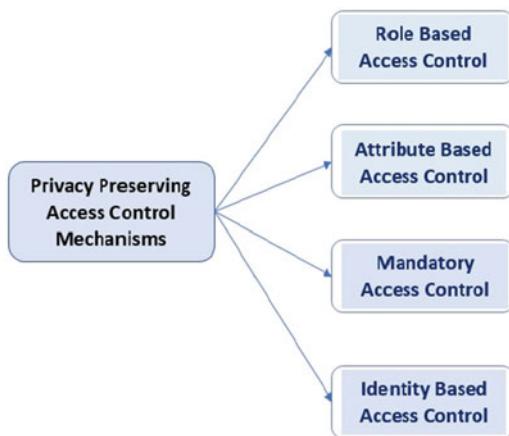

EHR where the patients encrypt their EHR files using the bABE. This approach solves the key management issues by using the users' attribute for data encryption allowing every user to have only one private key for their attribute set for decryption. This approach also allows users to carry and healthcare providers to perform keyword-based searches on the encrypted patients' records without revealing the keywords or partial matches to the cloud system. The keyword search functionality is provided by combining the bABE and the public key encryption with keyword search (PEKS). Ibraimi et al. (2009) proposed a multi-authority scheme for protecting EHD (electronic health data) across different domains. The limitation of the work is that they are not designed for database federations of many medical organizations.

Narayan et al. (2010) proposed a patient-centric cloud-based EHR system by incorporating symmetric key cryptography, public key cryptography, and an attribute-based architecture. This method includes encrypting the patient health data being encrypted by the patient using a symmetric key and also a metadata file which includes a description of the file, attribute-based access policy, and location information encrypted using broadcast CP-ABE and stored in a cloud platform. This method supports direct revocation without re-encryption of data but has a higher computational cost on the patient end where all re-encryption and updating of access policies are handled by the patient side (Narayan et al. 2010). Another downside is that the Trusted Authority can access all the

encrypted files. Barua et al. (2013) used the mechanisms of proxy re-encryption and ABE to develop a more sophisticated cloud-based solution. However it does not require external party for key distribution; it leads to a single point of failure and also creates key escrow while managing all attributes with a single authority. In order to resolve the issue, Li et al. (2013) introduced a cloud-based health record sharing scheme using both KP-ABE and MA-ABE schemes. This solution exerts some level of computational cost on the user side.

In EHR systems as most of the data are strictly confidential and stored in a third-party *cloud*, *access control mechanisms* are equally ineludible and vital as *encryption techniques* (Zhang et al. 2015). Access control is a fundamental security barrier for data privacy in a healthcare information system, which limits who can access and operate the documents in an EHR system (Wang et al. 2005, 2009; Zhang et al. 2014). Some access control mechanisms are mentioned in Fig. 4.

Several access control mechanisms such as RBAC and its variants are currently used, and newer approaches such as ABAC have been proposed in healthcare domain to restrict access to electronic health data (Khalil et al. 2007, Wang et al. 2002). However, both of these have few inherent inadequacies as an individual approach. However, by combining the advantages of both RBAC and ABAC, a new approach can be proposed (Alshehri and Raj 2013). This dual-layer access control model being proposed integrates attributes with roles combining the strength of RBAC and ABAC and thereby aims at assuring

Security and Privacy in Big Data Environment, Fig. 4
Basic access control schemes

two fundamental security properties, confidentiality and integrity, of the sensitive data in the healthcare domain. Several research aspects of privacy and security in EHD are categorized and discussed in this study. However, among several encryption techniques, ABE and combination of several access control mechanisms are profoundly important for enforcing security and privacy to EHD.

Future Research Directions

Privacy and security of Big Data is gaining momentum in research community due to emerging technologies like cloud computing, analytics engines, and social networks. There are a number of open problems and future research perspectives related to privacy and security of Big Data (Cuzzocrea 2014, Wang et al. 2015).

1. Privacy-Preserving Big Data Analytics – Big Data are valuable because they are treasured source of knowledge that is useful for decision making and prediction purposes. It possesses challenging research hurdles, because analytics process huge volumes of Big Data, and hence privacy of target data sets is not preserved yet.
2. Privacy-Preserving Social Network Mining – Social network data are the most reliable

sources of real-life Big Data, with well-known web social networks like Facebook, Twitter and Instagram. Here, data mining is of primary interest, but the need for privacy and security very often limits the real impact of these tasks.

3. Privacy-Preserving Electronic Health Data – Electronic health data stores sensitive and confidential patient information in large datasets. Hence, there is a high need to preserve the privacy and security of stored data sets to protect the confidentiality of patient.
4. Security Issues of (Big) Outsourced Databases – In cloud infrastructures, databases are often outsourced based on the DaaS (Database as a Service) approach. This elevates more problematic security concern as query-processing procedures may easily access sensitive data sets and determine privacy breaches.

Conclusion

Privacy and security of Big Data is gaining prominence nowadays due to its high proliferation and utility as a result of recent developments in information and communication technology (ICT) such as social networking, IoT (Internet of things), Big Data analytics, and cloud computing. Big Data is a treasure trove of knowledge due to its potential for large-scale use and utility across various fields. This paper discusses scopes, challenges, and various techniques employed to secure privacy and security of Big Data. There is ample scope for further research in Big Data security and privacy of which few areas are discussed under the heading “[Future Research Directions](#)” of this write-up. However, in light of existing bottlenecks in data privacy and security, future research directions call for deliberate attention and immense contribution of research scholars and practitioners.

Semantic Interlinking

Gianluca Demartini

The University of Queensland, St. Lucia, QLD, Australia

Definitions

Semantic interlinking is defined as the establishment of links and relations between multiple structured datasets.

Overview

Motivation

The exponential growth of data is becoming pervasive across different areas of business and science. Despite its wide availability in large amounts, data is typically stored in standalone silos where different datasets are represented using different formats, stored and indexed within different system architectures, and maintained following different business processes. For example, in certain organizations it is possible to encounter customer databases, technical reports, product images, and other datasets that need to be used in conjunction. Such data integration problems are a long-standing open research challenge in the data management area. The recent rise of big data with its volume and variety dimensions has magnified already existing issues.

Similar challenges are also often present in Open Data where datasets are published and made freely available (typically by governmental organizations) without paying much attention at data quality issues such as the lack of appropriate data format usage and the provision of datasets out of their context.

These situations make data integration an open challenge. *Semantic data interlinking* can be generally defined as the establishment of links and relations between multiple structured datasets. This entry presents an overview of semantic techniques for the interlinking of big data.

Linked Open Data

An important application domain of semantic interlinking is Linked Open Data (LOD) where the goal is to publishing data openly, in a structured format, and interlinked together (Bizer et al. 2007). The aim of the LOD initiative is to fix the challenges that open data comes with, by means of using a common data representation model and by interlinking datasets together.

Tim Berners-Lee suggested a 5-star model for LOD (<http://5stardata.info>) where he claims that data shared on the Web should ideally be (1) available under an open license, (2) provided as structured data, (3) published using nonproprietary formats, (4) described using unique resource identifiers (URIs), and (5) linked to other data to provide context.

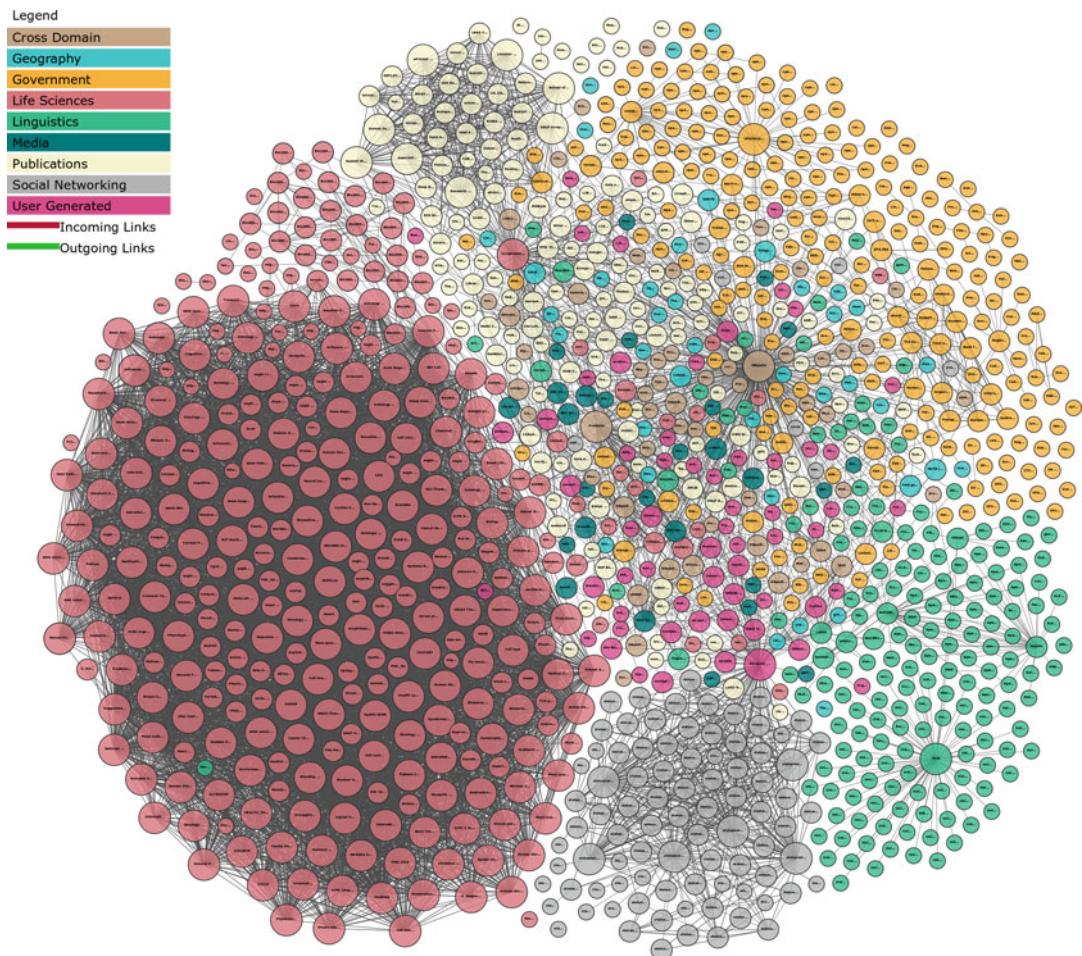

Existing datasets that have been published following such principles are depicted in the LOD cloud (see Fig. 1) where each bubble represents a dataset following LOD principles and edges between nodes represent links across items described in the datasets.

Other than domain-specific datasets (many of which are in the biomedical field), popular datasets in the LOD cloud include DBpedia (Auer et al. 2007) and Wikidata (Vrandečić and Krötzsch 2014).

DBpedia is a structured dataset automatically extracted from Wikipedia infoboxes that contains factual statements about notable entities described in Wikipedia. On the other hand, Wikidata is a crowdsourcing effort aiming at creating a knowledge base of facts. The original motivation to start Wikidata was to supply a central repository for the structured information to be displayed in Wikipedia infoboxes.

Key Research Findings

Research in the area of semantic interlinking focuses on different problems: First, given two datasets to be interlinked, there is the need to align the underlying ontologies used to describe the instances present in the datasets; Next, there is the need to align the instances described in the two datasets, that is, to identify which entities

Semantic Interlinking, Fig. 1 Linking Open Data cloud diagram 2017, by Andrejs Abele, John P. McCrae, Paul Buitelaar, Anja Jentzsch and Richard Cyganiak. <http://lod-cloud.net/>

referred to are the same across the datasets. This section first discusses these two problems and present some methods proposed in the literature designed to address them. It then presents the more specific problem of entity linking, that is, performing semantic interlinking between a document and a structured dataset. Finally, it introduces more recent human-in-the-loop approaches.

Semantic Schema Alignment

The problem of schema alignment (also known as ontology matching Shvaiko and Euzenat 2013) consists in identifying which schema elements of a datasets are equivalent to those of a different

dataset. This is a classic problem in the area of semantic interlinking for which a large number of approaches have been proposed.

For example, Jain et al. (2010) focus on methods to find alignments between ontologies used by different LOD datasets. The approach they propose is based on using the Wikipedia category hierarchy to bootstrap the schema alignment process. Similarly, Parundekar et al. (2010) align different ontologies used in different LOD datasets. Their approach is based on existing equivalence statements at the instance level on which they reason about possible schema alignments. To evaluate such methods, standard benchmarks exist. The most popular and commonly used ones

have been created in the context of the Ontology Evaluation Alignment Initiative (Euzenat et al. 2011).

Semantic Record Linkage

Record linkage is defined as the identification of the same real-world entity mentioned across different datasets. In the semantic interlinking domain, this translates into identifying which instances in two LOD datasets refer to the same object.

Approaches for this problem include, for example, Rong et al. (2012) who look at this as a binary classification problem (i.e., a candidate pair of instances matches or not) and solve it using standard supervised machine learning models.

The main challenge of record linkage is scalability: When aiming at identifying duplicates across two datasets, it would be necessary to perform a quadratic number of comparisons to check every possible pair of instances. In a big data context, where the volume of data is prohibitive, performing all possible comparisons is not a scalable option. To deal with this challenge, a number of indexing techniques to make more efficient comparisons have been proposed (Christen 2012). Another common approach to deal with this is *blocking* where the idea is to first use computationally inexpensive methods to create groups of similar objects based on approximate methods (e.g., by means of clustering) and then to perform all possible comparisons using a computationally expensive similarity measure only for the members of a group thus removing a large number of false positives (Bilenko et al. 2006; Papadakis et al. 2013).

Entity Linking

A third problem related to the two main semantic interlinking problems described above is that of *entity linking* (Rao et al. 2013). This is defined as uniquely disambiguating an entity mentioned in a textual document by linking it to a background knowledge graph (Shen et al. 2015). For example, given a document mentioning the entity "Tom Cruise," the goal is to create a link from it to the URI of an instance of a LOD dataset (e.g., DBpedia).

Common approaches for entity linking include, for example, graph-based approaches (Moro et al. 2014) able to look at the coherence of linking decisions based on sub-graph density.

When run at scale, entity linking can benefit from collection features like, for example, entity frequency as an indicator of linking accuracy (Lin et al. 2012). That is, an entity which appears several times in a coherent document collection is likely to be referring to the same concept. It is also easier to use contextual information (e.g., all the sentences where an entity appears) to better decide about which instance of the knowledge graph to link to.

Human-in-the-Loop Semantic Interlinking

A more recent family of approaches to semantic interlinking makes use of the *crowdsourcing* methodology. This implies the development of *human-in-the-loop systems* that leverage machine-based computation to scale interlinking to large datasets but make also use of crowdsourcing to solve difficult cases where humans outperform machine-based algorithms.

An early approach to crowd-based schema alignment was presented by Sarasua et al. (2012) where they compared a human-in-the-loop approach with purely machine-based schema alignment methods showing significant improvements in alignment effectiveness.

For the problem of entity linking, human-in-the-loop solutions include ZenCrowd by Demartini et al. (2012) where authors propose to, given a document and background LOD dataset, collect entity linking decisions from algorithms and from a crowdsourcing platforms. Then, they propose a factor graph model to effectively combine the machine-based and human-based decisions. Again, experimental results show that such combined approach results in better quality entity linking.

A similar human-in-the-loop approach has been proposed by Demartini et al. (2013) for semantic record linkage where the crowdsourcing step is used last after the machine-based blocking and alignment methods described above. For the same problem of semantic record linkage, Wang et al. (2012) investigated the use of grouping

record linkage crowdsourcing tasks together showing how crowd workers perform better as compared to when they are presented with individual record linkage tasks.

Examples of Application

Potential applications where semantic interlinking can provide benefits include information extraction, information retrieval, and knowledge base population.

Applications domains where LOD datasets and semantic interlinking have been used successfully include cultural heritage (Knoblock et al. 2017), manufacturing (Petersen et al. 2017), smart cities (Egami et al. 2016), and others.

Future Directions for Research

As this entry has shown, research in the area of semantic interlinking has been focusing on a number of diverse problems (i.e., semantic schema alignment, semantic record linkage, and entity linking). The current focus of the research community is on the scalability of such approaches to large heterogeneous datasets (e.g., by means of blocking and indexing techniques) and on improving interlinking accuracy by means of human-in-the-loop systems.

Future work should be looking at issues like, for example, semantic interlinking for dynamic LOD datasets (i.e., datasets that are not considered static but rather evolving over time) for which already existing interlinking decisions may need to be updated as ontologies used by the LOD datasets may change (Kuhn et al. 2017).

Semantic Search

Philippe Cudre-Mauroux
eXascale Infolab, University of Fribourg,
Fribourg, Switzerland

Definitions

Semantic Search regroups a set of techniques designed to improve traditional document or knowledge base search. Semantic Search aims at better grasping the context and the semantics of the user query and/or of the indexed content by leveraging

natural language processing, Semantic Web, and machine learning techniques to retrieve more relevant results from a search engine.

Overview

Semantic Search is an umbrella term regrouping various techniques for retrieving more relevant content from a search engine. Traditional search techniques focus on ranking documents based on a set of keywords appearing both in the user's query and in the indexed content. Semantic Search, instead, attempts to better grasp the semantics (i.e., meaning) and the context of the user query and/or of the indexed content in order to retrieve more meaningful results.

Semantic Search techniques can be broadly categorized into two main groups depending on the target content:

- techniques improving the relevance of classical search engines where the query consists of natural language text (e.g., a list of keywords) and results are a ranked list of documents (e.g., webpages);
- techniques retrieving semi-structured data (e.g., entities or RDF triples) from a knowledge base (e.g., a knowledge graph or an ontology) given a user query formulated either as natural language text or using a declarative query language like SPARQL.

Those two groups are described in more detail in the following section. For each group, a wide variety of techniques have been proposed, ranging from natural language processing (to better grasp the contents of the query and data) to Semantic Web (to guide the search process leveraging declarative artifacts like ontologies) and machine learning (typically to learn models from large quantities of data).

Main Approaches

We give below an overview of the various techniques that have been proposed in the context of Semantic Search for improving document search

as well as knowledge base search. A number of surveys delve into more detail in this context: Mangold (2007) focuses on natural language queries on RDF knowledge bases or ontologies. Madhu et al. (2011) and Mäkelä (2005) are two brief surveys covering both topics. Bast et al. (2016) is an extensive survey covering Semantic Search in its broadest sense.

Document Search

Classical search engines take as input a user query formulated as a list of keywords and return as output a ranked list of documents relevant to those keywords. A number of Semantic Search methods have been suggested in that context.

Natural language processing (NLP) techniques have long been applied to better grasp the semantics of the query or documents. Often, Part-of-Speech (POS) tagging is first applied on the textual content in order to assign grammatical tags (such as *noun*, *conjunction*, or *verb*) to individual words. Such assignment is highly accurate for well-formed sentences (Manning 2011) but much more challenging for short texts such as queries (Hua et al. 2015). POS tags can then be used to better discriminate textual keywords, for example, for named-entity recognition (NER), where the task is to identify which keywords correspond to real-world entities, or for co-reference resolution, where the task is to identify all keywords referring to the same entity in the text. Sentence parsing takes NLP analyses to the next level by aiming at capturing the overall structure of sentences, typically through a dependency parse tree.

NLP methods are often combined with lexical resources or third-party sources to retrieve more relevant results. The main idea in this context is to identify entities in the textual query or content and to match them to their counterpart in a third-party resource to improve the search results. Voorhees (1993) proposed an early approach in the sense that leverages WordNet to disambiguate word senses and hence improve search results. Pehcevski et al. (2008) analyze the structure of Wikipedia to better rank relevant entities in response to a search request. Kaptein

et al. (2010) use Wikipedia to better characterize and identify entities when searching for entities in document collections, while Schuhmacher et al. (2015) combine different features from the documents, the entity mentions, and Wikipedia using a learning-to-rank approach to improve the search results.

Conceptually similar approaches have been proposed in the context of the Semantic Web, by leveraging the structure or contents of a knowledge base to better grasp the context of queries or entities appearing in textual documents. Tran et al. (2007), for instance, propose an ontology-based interpretation of natural language queries for Semantic Search. The authors translate a keyword query into a description logic, conjunctive query that can then be evaluated with respect to an underlying knowledge base. Schuhmacher and Ponzetto (2013) exploit entities and semantic relations from the DBpedia knowledge base to cluster the results of a search engine into more meaningful groups. Prokofyev et al. (2015) leverage an ontology to better resolve co-references in textual documents for Semantic Search tasks.

Machine learning techniques are often used for Semantic Search, to power some of the approaches described above but also to capture the context and semantics of the words or entities appearing in documents. One of the main intuitions in this context is that words that occur in similar contexts are likely to be semantically similar. Early approaches leveraging this observation built high-dimensional matrices capturing the co-occurrence of words in a certain context (e.g., within a window of a few words) and hence the similarity between words (Lund and Burgess 1996). Each word is in that case represented by a sparse vector in a high-dimensional space. Lower-dimensional embeddings can then be created by applying standard matrix factorization techniques like principal component analysis.

More recently, Mikolov et al. (2013) suggested a new word embedding technique to generate dense vector representations of words

efficiently. The method works by maximizing the co-occurrence probability of words appearing within a certain context window using a relatively simple neural network. This opened the door to numerous applications, by efficiently generating vector representations of words from large text corpora and feeding them into subsequent machine learning models. Approaches to improve entity recognition (Siencnik 2015), web search query expansion (Grbovic et al. 2015), or web search ranking (Nalisnick et al. 2016) have, for example, been explored in the context of Semantic Search.

Knowledge Base Search

A number of Semantic Search approaches target large and declarative knowledge bases (a.k.a ontologies or knowledge graphs) instead of document collections. Such knowledge bases can be expressed in many different ways that are typically derived from Semantic Web standards such as RDF or OWL. Google’s Knowledge Graph, DBpedia (Bizer et al. 2009), Yago (Rebele et al. 2016), or Wikidata (Vrandecic and Krötzsch 2014) are well-known examples of that trend. Users can express their queries through two main modalities in this case: either as structured (e.g., SPARQL) queries or as natural language (e.g., keyword) queries.

Horrocks and Tessaris (2002) introduced an early formal approach to answer structured queries posed against ontologies. Their algorithm returns sound and complete results to conjunctive queries leveraging reasoning techniques and description logics. Stojanovic et al. (2003) present a method to rank results in ontology-based search. The authors consider conjunctive queries and combine logical inference with an analysis of the contents of the knowledge base to retrieve more relevant results. Maedche et al. (2003) introduce a meta-ontology and a registry to improve search queries targeting ontologies. Their solution leverages WordNet to match entities appearing in the ontology to lexical entries and to guide the search process.

Pound et al. (2010) introduce the ad hoc object retrieval task for searching for resources (e.g., entities, types, or relations) over knowledge bases

using natural language queries. The authors also propose a baseline technique for answering such queries based on term frequencies as well as an evaluation methodology. Tonon et al. (2012) propose an improved search technique for ad hoc object retrieval exploiting sequentially an inverted index to answer keyword queries and a graph database to improve the search effectiveness by automatically generating declarative queries over an RDF graph.

Hybrid approaches leveraging both textual and structured contents have also been suggested. Rocha et al. (2004), for instance, combine a traditional search engine with graph exploration techniques to answer keyword queries on an ontology. Zhang et al. (2005) suggest a new model to search semantic portals, where both documents and structured data are available. Their method is based on creating textual representations for all entities in the structured repository such that they can also be indexed and searched through classical information retrieval techniques.

Word embedding techniques (see above) have also been adapted to power Semantic Search on knowledge bases. RDF2Vec (Ristoski and Paulheim 2016), for instance, learns vectorial representations of entities in RDF graphs. Wang et al. (2017) provide a survey of embedding approaches for knowledge bases and classify the models into two main families: translation-based techniques, which interpret relations in the knowledge base as a translation vector between the two entities connected by the relation, and semantic matching models, which exploit similarity-based scoring functions to create the embeddings.

Systems

Leading industrial search engines, such as Bing, Yandex, or Google, all implement Semantic Search in one way or another but typically do not describe in detail the techniques they leverage. A number of Semantic Search systems have been described or open-sourced, however, and are summarized below.

TAP (Guha et al. 2003) is an early Semantic Search framework. TAP focuses on entity search queries expressed as keywords and augments traditional results (documents) with semi-structured data returned from a knowledge base. The knowledge base is also used to better filter and sort the list of returned documents in that context.

A number of Semantic Search systems focusing on RDF and ontologies have been proposed. Swoogle (Ding et al. 2004) offers semantic search over a knowledge base represented in RDF thanks to an inverted index and a database storing metadata about all entities. SWSE (Hogan et al. 2011) follows the typical architecture of a search engine but operates on RDF data also. SWSE results are ranked by running a classical PageRank algorithm on a graph connecting the URIs appearing in the RDF triple to their source on the web.

SemSearch (Lei et al. 2006) is a search engine for the Semantic Web that hides the complexity of the underlying RDF data to the user. SemSearch accepts keyword queries from the user, translates the user queries into formal queries by exploiting the labels of the entities in the knowledge base, runs the resulting query in the knowledge base, and finally ranks the results by taking into account the number of keywords the search results satisfy. Sindice (Oren et al. 2008) is a Semantic Search engine and look-up service that focuses on scaling to very large quantities of semi-structured data. It supports keyword and URI-based search as well as structured queries.

SHOE (Heflin and Hendler 2000) is an early Semantic Search system collecting semi-structured annotations from the web and storing them in a knowledge base. It offers a GUI to formulate ontology-based structured queries to find webpages. The Watson system (d'Aquin and Motta 2011) works similarly by collecting, analyzing, and giving access to ontologies and semantic data available online. It supports both keyword and SPARQL search queries.

SCORE (Sheth et al. 2002) is a platform supporting the creation and maintenance of large knowledge bases. It supports ontology-driven Semantic Search capabilities by extracting facts

and metadata from web sources via text mining techniques.

Nordlys (Hasibi et al. 2017) is an open-source toolkit for Semantic Search. The toolkit supports a number of features including detecting entities in natural language queries, cataloging entities from a knowledge base (by default DBpedia), interlinking entities, and retrieving entities.

Schema.org (Mika 2015), finally, is not a system per se but rather a standardization effort founded by leading search engines (including Google, Microsoft, Yahoo, and Yandex). Its mission is to create and promote schemas to embed semi-structured data in web documents (and beyond) in order to facilitate Semantic Search capabilities online.

Synonyms

RDF stream processing; Stream reasoning

Definitions

Semantic stream processing (SSP) refers to a set of models, principles, and techniques for analyzing and processing stream data by exploiting semantic structures which are explicitly or implicitly embedded in stream data elements. Such “semantic streams” are represented as sequences of temporal graphs linking human-machine understandable semantics and computational primitives. Semantic stream processing approaches leverage reasoning capabilities through formally defined rules to automate and optimize their continuous processing flows formulated in high-level abstract concepts and relationships.

Overview

Billions of sensors being distributed across the globe are continuously streaming data about the physical world around us. The stream data generated by networks of sensors enables us to detect and identify a multitude of things, from simple phenomena to complex events and situations. However, the lack of integration and communication between these networks and the lack of contextual information and background knowledge often isolate important data streams and intensify the existing problems of too much data and not enough knowledge about implicit meaning of such data and user intentions. As a potential remedy for such problems, Whitehouse et al. (2006) proposed the concept of “semantic streams” that

represent stream data associated with logic rules. Such logic rules represented in Prolog allow users to pose declarative queries over semantic interpretations of sensor data. Interestingly, the Prolog-based query model of Whitehouse et al. (2006) from the wireless sensor network community is adopted itself from the semantic Web services paradigm. This paradigm is similar to the concept of “semantic sensor Web” Sheth et al. (2008a) from the semantic Web community. Sheth et al. (2008a) claimed that sensors annotated with semantic metadata will increase interoperability and provide contextual information which is essential for situational knowledge.

As a result, sensor data published as semantic data sources (in RDF models) along with dynamic web data sources (social network, web blogs, etc.), which can be viewed as a variant of sensor data, introduced several research challenges in addressing their highly dynamic and low-latency processing nature. This then opened a new research trend in the semantic Web community, called RDF stream processing (RSP) or Linked Data stream processing (Le-Phuoc et al. 2012b), dealing with heterogeneous stream data sources that can be modeled by means of the RDF model. The choice of RDF as the data model, in combination with ontological profiles for representing stream data elements, offers not only interoperability but also well-understood semantics based on Datalog, Description Logics (DLs), and Answer Set Programming (ASP). Following this design choice, several RSP engines were built by extending existing semantic Web software stacks, e.g., triple storage and SPARQL query engines. Consequently, minimizing differences to “static” RDF and “static” SPARQL became the common goal for a majority of approaches in this line of work. Despite a significant amount of work dedicated to modeling stream data in RDF- and SPARQL-like continuous query languages in the last 10 years, none of them can provide a comprehensive, clean, and sound theoretical foundation along with a robust implementation.

However, amid the disagreement on a unified data model and query language, there are a lot of parallel efforts in building applications and processing engines in this domain. This movement

has started a new research trend of trying to realize reasoning features as offered in conventional RDF engines also for streams, called stream reasoning (Margara et al. 2014; Dell’Aglio et al. 2017). This research domain advocates stream reasoning as the common theme for enabling logic entailment profiles (RDFS, OWL, etc.) of RSP engines as well as other kinds of reasoning over RDF streams, e.g., statistical reasoning. There are few attempts toward this direction, however. The stream reasoning research area remains vastly unexplored, both from a theoretical point of view and also from the perspective of systems and tools supporting it. Notably, the implementations often are done before having a sound theoretical foundation.

In our context, a stream may consist of any kind of raw data with the restriction of discrete elements, e.g., we do not consider “normal” video or audio streams, but discrete pieces of such data. The same holds true for any other data which is discrete in nature, e.g., sensor readings. Semantic streams consist of such discrete elements which are semantically annotated. These annotations can be done manually or by way of automatic annotation through data analysis or hybrid approaches, e.g., the stream and its characteristics are described manually, whereas the individual stream elements are annotated by software. An example for this is monitoring of parking spaces with a camera, where the raw data is not interesting but only if a parking space is occupied or not. Thus the data is “lifted,” and this process is called semantic lifting which benefits greatly from the broad availability of machine learning tools, e.g., object recognition with convolution neural networks and entity extraction with natural language processing (NLP) tools. In fact, semantic lifting can tap into a wide range of semantic computing pipelines (Sheu et al. 2010) that has been around more than a decade. It is important to question whether it is trivial to seamlessly integrate these two types into a single processing pipeline. The constituting parts of stream reasoning are grounded in well-understood formal semantics and can usually be expressed via straightforward sets of rules. As such, they do not exhibit the complexity and the

opacity of artificial intelligence approaches that are based on machine learning and neural models.

In semantic stream processing, meaning and relationships do not have to be predefined and “hardwired” into data formats and the application program code at design time. Semantic technology enables encoding and extracting meaning separately from stream data elements and stream sources and separately from application code. With the interlinked nature of semantic data associated with stream data, a software agent can directly search topics, concepts, and associations that span a vast number of stream data sources linked with knowledge graphs. This automatic discovery capability fosters the dynamic composable in a semantic stream processing pipeline. Hence, adding, changing, and implementing new relationships or interconnecting sub-stream processing pipelines in a different way can be done on the fly at run-time after deploying the application logic. In this fashion, a semantic stream processing pipeline can be federated across autonomous processing agents which expose their self-describing stream sources and processing capabilities. Via automatic discovery, the software agent does not have to have full a priori knowledge about input data sources to deploy its application logic. For instance, an autonomous vehicle can continuously discover stream data sources available via its current network connections without knowing them or their types in advance. It can then subscribe the corresponding continuous queries to the relevant stream sources, e.g., to get notifications about traffic jams on the roads and junctions nearby its locations without having to hard-code the data sources and queries.

Key Research Findings

The most consolidated group of research findings on semantic stream processing includes contributions from RSP engines and stream reasoners. These contributions aim at enabling the semantic integration of heterogeneous stream data sources with (large) static datasets stored

in relational databases or triple stores through declarative continuous queries based on RDF and SPARQL. By adding window operators to SPARQL and extending the RDF model to capture temporal aspects of stream elements, RSP engines such as C-SPARQL (Barbieri et al. 2010b), CQELS (Le-Phuoc et al. 2011) and SPARQL_{stream} (Calbimonte et al. 2010) integrate the features of data stream management systems (DSMSs) and SPARQL engines. For their implementation, different approaches were chosen based on the features or performance criteria of interest. In the top-down approach, query features are broken down for delegation to the underlying processing engines. The extreme case following the top-down approach is rewriting a continuous query in SPARQL form to SQL queries on traditional relational database or relational data stream management systems. This approach is called ontology-based data access (ODBA), and ODBA-based engines (Calbimonte et al. 2010; Kharlamov et al. 2017) use the ontologies as the semantic guidelines for rewriting their queries to a targeted database schema. EP-SPARQL (Anicic et al. 2010) is another variant of this rewriting approach which translates its unified language for event processing and reasoning as logic expressions to Prolog rules. These are then executed in a Prolog engine. In contrast to this, the bottom-up approach builds or reuses physical query operators to construct execution engines which coordinate and control the query execution process. It takes considerably more effort to build query engines of this kind, e.g., CQELS and C-SPARQL. However, it is easier to improve the performance and add more features as the implementation is under full control. For example, C-SPARQL extended reasoning features, and CQELS implemented more efficient data structures to improve processing throughput.

To offer a high processing throughput, the system implementers need to spend significant engineering efforts on optimizing and tuning physical data structures (Le-Phuoc 2017; Ren et al. 2017) and query executors (Le-Phuoc et al. 2013; Ren et al. 2017; Bazoobandi et al. 2017) tailored to the

RDF graph nature of stream elements. To scale out the processing to multiple processing nodes, generic cloud-based stream platforms are used: For example, CQELS Cloud (Le-Phuoc et al. 2013) uses Apache Storm and Strider (Ren et al. 2017) uses Apache Spark. The scaling strategy of Strider offers a good solution for handling computationally expensive operations like continuous reasoning on RDFS+ profiles.

In the continuous query setting, the incremental reasoning approach is the obvious choice for materializing the logic entailments of the RDF data within a window. With the observation that deletions can be foreseen and are not random, expiration time annotations are associated with all the axioms involved in the materialization, and such information is exploited to identify only the facts to be deleted. Sparkwave (Komazec et al. 2012) makes use of the RETE (Forgy 1982) algorithm to maintain RDFS entailments with sliding windows defined in C-SPARQL whereby RDFS axioms are encoded as RETE rules and organized in a network. A different approach is adopted by INSTANS (Rinne et al. 2016) which adopts SPARQL 1.1 with an extension to its query evaluation model to continuously query data streams. The implementation of INSTANS also relies on the RETE algorithm: Tasks are expressed as networks of queries and compiled in RETE-like structures to evaluate the results. When new facts are added to the system, they are matched against these rules.

When stream reasoning started to take off in the scientific community, various efforts tried to unify the query language primitives to promote a query model with a sound formalization which can generalize existing query languages such as C-SPARQL, CQELS-QL, and EP-SPARQL. For example, Dell’Aglio et al. (2014) targeted unifying query languages for RSP engines and extended the support for CEP (Dell’Aglio et al. 2016). In parallel, Beck et al. (2015) proposed the LARS framework as a unified way to express stream reasoning primitives under ASP foundations. LARS was later implemented in Laser (Bazoobandi et al. 2017). From a Datalog perspective, windowing operators are just a special case of temporal Datalog variants, so Ronca et al.

(2018) recently proposed a Datalog-based logic framework for stream reasoning with a comprehensive complexity analysis.

An additional and noteworthy extension to logic-based reasoning is presented in Barbieri et al. (2010a) where the authors focus on inductive stream reasoning. Inductive stream reasoning involves mining of large portions of data and applying statistical and machine learning techniques to extract new knowledge. The authors propose combining inductive reasoning with deductive reasoning to increase accuracy of the inductive reasoning. The technique has been applied and validated on a real scenario derived from social media analysis, showing the accuracy of the reasoning algorithm in this context. In a similar effort, Chen et al. (2017) showed that DL-based reasoning can integrate efficiently with online streaming mining for traffic data.

Benefiting from the semantic Web adoption, Le-Phuoc et al. (2012a) and Arias Fisteus et al. (2014) proposed middleware solutions transforming and enriching unstructured data streams or raw sensory data to RDF streams by reusing existing tools from the semantic Web stack. Together with other trends on exposing IoT streams using ontologies (Barnaghi et al. 2012), the research community is working very actively on defining suitable ontologies for capturing semantics of sensor data and its contextual information. Examples are the W3C Semantic Sensor Network Ontology (Haller et al. 2017) and the Thing Description (Kaebisc and Kamiya 2018) and Time Ontology (Cox and Little 2017). This lays a solid foundation for semantic lifting which can use available tools for detecting semantic events (Rea et al. 2004; Wang et al. 2006; Chang et al. 2015) and extracting semantic relationships, e.g., from video scenes (Baier et al. 2017), to generate semantic streams.

Examples of Application

Internet of Things (IoT) and Smart Cities: IoT and smart cities have an extremely wide application range where the ideas of semantic sen-

sor Web (Sheth et al. 2008b) and semantic sensor stream (Barnaghi et al. 2013) can be applicable for various applications. In smart cities, most of the applications try to process and understand information relevant for the life of people in a city and use it to make the city more efficient, friendly to the environment, etc. Such applications have access to a huge amount of heterogeneous stream sensor sources. For example, traffic events from social streams (Anantharam et al. 2015) and event streams of big cities (Anantharam et al. 2016), traffic streams (Chen et al. 2017; Eiter et al. 2017), and other IoT streams (Puschmann et al. 2017) are extremely dynamic data sources which demand efficient and scalable algorithms for processing data in near-real-time at the semantic level. In this context, the semantic stream processing must provide enough expressiveness to abstract and derive high-level concepts from low-level and time-annotated data. Moreover, smart cities require the large-scale integration of different data types and sources: As an example, traffic information can be retrieved from sensors, through tracking cell phones in GSM cells, as well as from navigation systems, or posts on social networks.

Another interesting concept is **citizen sensing** which is social sensing enabled by mobile sensors and human computing whereby humans and their devices act as “sensors” and share their observations and views using mobile devices and Web 2.0 services (Sheth 2009). Together with live social semantics (Alani et al. 2009) and social media stream (Balduini et al. 2012), the applications of this type requires semantic analysis of social media by extending traditional analysis based on graphs enriching the connections between people and concepts with semantic annotations. One of the goals of the analysis of social media is to capture hidden relations between people and concepts. Some experiments on the use of social media analysis have been reported in Balduini et al. (2013), where the authors focus on the processing of Twitter posts to extract new information, e.g., how the mood changes during the day, which are the trending topics, etc., during large-scale events (London Olympic Games 2012 and Milano Design Week 2013).

Predictive Maintenance: Sensing devices allow industrial applications to actively and constantly monitor machines to predict maintenance cycles. Such applications include a large number of sensor sources with a wide variety of sensing platforms and types of measurements, not to mention large enterprise knowledge bases, that need to be correlated with stream data to enrich such time series data. For instance, in Kharlamov et al. (2016) the data processing task requires to extract, aggregate, and correlate static data about turbine structure, streaming data produced by up to 2,000 sensors installed in different parts of the turbine, and historical operational data of the reference sensors stored in multiple data sources. Similarly, the application scenarios from Siemens Energy (Kharlamov et al. 2017) and the DEBS challenge 2017 (Gulisano et al. 2017) need efficient and scalable semantic stream processing pipelines to detect abnormal behavior in manufacturing machines and provide actionable insights based on the observations in time.

Future Directions for Research

As an increasing number of semantic streams is made available for a new generation of applications, practitioners are building more and more engines supporting SSP or integrate SSP into current stream engines or RDF stores. To comprehensively support all features of current RSP engines, CEP, and stream reasoning engines, a top-down approach would provide the theoretical foundations associated with feasible implementations for a new generation of SSP engines in the years to come. As shown in the surveys of Margara et al. (2014) and Dell’Aglio et al. (2017), a unified data model associated with well-formulated semantic processing primitives is a vital prerequisite for building a generic execution framework for SSP. The analysis of computational complexity of the resulting processing models should be done at a fine-grain level to give effective guidelines for designing and implementing the underlying engines.

The first challenging problem in generalizing the data model for stream elements or atomic events is capturing their order in the most generic way. As shown in Margara et al. (2014) and Dell’Aglio et al. (2017), current time models based on logical timestamps have their own shortcomings in terms of expressivity and practical implementations. A solution for enforcing causal order in both windowing operators and sequence patterns of events has to be seamlessly integrated with soft-orders entailed by semantic rules. This solution has to take into account out-of-order streams/events, distributed settings, and imprecise timestamps and imprecise clocks. Then the uncertainty properties need to be captured along with semantic relationships and concepts, especially, since there are more and more symbolic values/entities generated by machine learning algorithms from discrete noisy data as semantic streams. Uncertainty can be modeled together with other provenance information which can be represented as ontological contextual information.

Together with accommodating traditional computing primitives from CEP, SPARQL, DSMS, etc., interleaving reasoning primitives without violating the decidability of the whole processing pipeline is a challenging research problem in designing a declarative query language or domain-specific languages (DSLs) for SSP. Some proposals (Barbieri et al. 2010a; Chen et al. 2017) have started investigating the use of inductive and/or statistical reasoning. Also, recent developments in natural language understanding and computer vision have paved the way for a new generation of semantic query capabilities over stream data, e.g., social streams and video streams. Specifically, the visual reasoning capabilities as proposed in Johnson et al. (2017) and Jang et al. (2017) enable the integration of visual question answering (VQA) query fragments into a SSP pipeline. Interestingly, there are various potential links among VQA and NLP and semantic Web. For instance, to improve some state-of-the-art techniques of VQA, Baier et al. (2017) model scene descriptions through RDF triples

which are used to answer the queries about visual relationships in human language form as specified in the Visual Genome dataset (Krishna et al. 2016). It is worth noting that the data and queries of the Visual Genome can be naturally expressed in RDF graphs and SPARQL queries, respectively. On the other hand, there are plenty of works on question answering in human language form for RDF or knowledge graphs, e.g., Unger et al. (2012) and Bordes et al. (2014). The aforementioned features are quite appealing for developers amid the rise of transfer learning with a plethora of free pretrained models, but the computational complexity implications need to be investigated thoroughly as well, as they are not yet well understood.

Increasing the expressiveness of how to define a query or a processing pipeline on semantic streams will incur further research and engineering challenges as achieving good performance, and scalability will be necessary and the progress in this domain is rather modest at the moment. For improving performance, the research problems are not limited to designing more efficient algorithms for certain types of computation primitives, e.g., incremental reasoning in windowing data collections, but also include the execution settings such as processing load, resource constraints, and parallelization and coordination assumptions. For instance, continuous optimization considering several dynamic processing aspects such as multiple queries, volume of static data, and input rates is rather challenging even with traditional relational data stream processing. On top of that, a common assumption of processing stream data is that the processing state can be completely loaded into main memory. This might be overly optimistic, and standard techniques like storing to disks or shifting the data and processing to other computing nodes should be considered as optimization strategies. This new working assumption is advocated by the edge computing paradigm which matches the distributed nature of a majority of stream applications. Also and in particular, the federated processing model of RSP will bring new challenges for current information systems, such as the Web. Uniform parallel

computing settings like cloud/private clusters and high-performance computing nodes with large numbers of CPUs and GPUs will play an important role for continuously handling intensive workloads triggered by stream data at Web scale. This provides more options and capabilities along with technical and research challenges in realizing them.

Similarity Sketching

Rasmus Pagh

Computer Science Department, IT University of Copenhagen, Copenhagen S, Denmark

Synonyms

Distance estimation; Similarity estimation; Similarity summarization

Overview

Similarity between a pair of objects, usually expressed as a *similarity score* in [0, 1], is a key concept when dealing with noisy or uncertain data, as is common in big data applications.

The aim of *similarity sketching* is to estimate similarities in a (high-dimensional) space using fewer computational resources (time and/or storage) than a naïve approach that stores unprocessed objects. This is achieved using a form of lossy compression that produces succinct representations of objects in the space, from which similarities can be estimated. In some spaces, it is more natural to consider *distances* rather than similarities; we will consider both of these measures of proximity in the following.

Definitions

Formally, consider a space X of objects and a function $d : X \times X \rightarrow \mathbf{R}_+$. We refer to d as a *distance function* for X . Similarity sketching with respect to (X, d) is done by using a sketching function $c : X \rightarrow \{0, 1\}^s$ such that for every pair of objects $x_1, x_2 \in X$, the distance $d(x_1, x_2)$ can be approximated from the knowledge of $c(x_1)$ and $c(x_2)$. Most forms of similarity sketching are *randomized* and produce an estimate $\hat{d}(c(x_1), c(x_2))$ such that with probability $1 - \delta$, it holds that:

$$\begin{aligned} (1 - \varepsilon) d(x_1, x_2) &\leq \hat{d}(c(x_1), c(x_2)) \\ &\leq (1 + \varepsilon) d(x_1, x_2), \quad (1) \end{aligned}$$

where $\varepsilon, \delta > 0$ are user-specified parameters. Often $c(x)$ itself represents an object in X , intuitively one that is close to x , and \hat{d} is just distance function evaluation. In some cases, it is not possible to achieve the kind of *multiplicative* error guarantee as in (1), and it is instead the case that $\hat{d}(c(x_1), c(x_2))$ differs from $d(x_1, x_2)$ by an additive constant in $[-\varepsilon, \varepsilon]$.

If X is finite, we note that the probability that some distance in X is *not* within the interval (1) is at most $\binom{|X|}{2}\delta$. If this probability is strictly less than 1, it is possible to fix a choice of sketching function c such that all distances estimated fulfill (1). In the case where X is a data set of interest, *data-dependent* similarity sketching methods can improve performance when estimating distances in X ; we do not describe such methods here – for more information, see Wang et al. (2017).

Key Techniques

Quantization

In signal processing, an object x from a large or infinite space X can be mapped to a nearby object $c(x)$ in a smaller, finite subset of the space, to enable a succinct representation. Such a mapping, referred to as *quantization*, can be used for similarity sketching by estimating $d(x, y)$ simply as

$d(c(x), c(y))$. An efficient quantization method for Euclidean and angular distances is *product quantization* by Jégou et al. (2011).

MinHash

An early form of similarity sketching targeted *Jaccard similarity* of sets. The technique, now known as *MinHash*, was introduced in Broder et al. (1997) and Broder (1997). It works as follows: For a random permutation $r : X \rightarrow X$, map a set S to the “MinHash value” $h_r(S) = \min_{x \in S} r(x)$, where the minimum is over an arbitrary, fixed ordering of X . In practice it is hard to construct random permutations, so instead one uses a hash function $r : X \rightarrow R$ where R is a large range (e.g., the 64-bit integers) ensuring that collisions in S are unlikely.

It can be shown that if sets S_1 and S_2 have Jaccard similarity J , the probability that $h_r(S_1) = h_r(S_2)$ (i.e., that the MinHash values collide) is J . MinHash is a so-called locality-sensitive hash function (LSH) for which collision probability depends on similarity (or distance). Computing h_r independently k times, with different hash functions r , we expect that the number t of collisions is close to kJ with high probability. Thus, we can estimate J well as $\hat{J} = t/k$, with precision that grows with k .

Improvements. MinHash can be improved in several ways. First of all, the space usage can be reduced by a method called *b-bit MinHash*, which consists of storing a b -bit hash signature rather than the MinHash value itself, yielding collision probability $J + (1 - J)/2^b$. The larger collision probability can be taken into account to derive an unbiased estimator for J . Ultimately, b -bit MinHash has greater precision at the same space usage compared to MinHash; see Li and König (2011).

The value of b used in practice is often 1 or 2, with space typical usage of $k = 32$ or $k = 64$ bits. Larger values of b are relevant when estimating Jaccard similarities close to 0. For $b = 1$, it is particularly efficient to compute the number of hash collisions, using bitwise exclusive or in conjunction with a `popcnt` that computes the

number of nonzero bits. When the Jaccard similarity of interest is above 0.8, there are methods that are more precise than b -bit MinHash, for example, *Odd Sketch* due to Mitzenmacher et al. (2014).

The time required for computing k MinHash values (or b -bit MinHash values) can be reduced by the so-called *one-permutation* method that works by initially splitting the set S into k parts and then computing a MinHash value for each part as described by Li et al. (2012). Another approach is *bottom-k sampling*, where the k smallest hash values of a single hash function are used to select a sample; see Thorup (2013) and its references. These methods have been further improved by Dahlgaard et al. (2017).

LSHable Distance Measures

Jaccard similarity is an example of an *LSHable* similarity measure, namely, it allows a random hash function r such that the collision probability equals the similarity. In fact, the MinHash method extends to any LSHable similarity measure by simply replacing the hash function r . An important LSHable distance measure is *angular distance* as shown by Charikar (2002). Angular distance, in turn, can be used to estimate *coseine similarity*. For more discussion of LSHable similarity measures, see Chierichetti and Kumar (2015).

For distance measures that allow an LSH, a similar result can be achieved since the probability of an LSH collision $r(x) = r(y)$ is a decreasing function of $d(x, y)$. The highest accuracy is achieved around distances for which the collision probability is not far from 1/2, say, in the range [1/3, 2/3]. Functions of this form, for example, for Hamming distance or Euclidean distance, are usually found in the literature on search data structures using locality-sensitive hashing; see, e.g., Andoni and Indyk (2008) and its references.

We observe that these similarity sketches can be efficiently computed in a *streaming* setting where only a single element of S is considered at a time. More information on approximate computing for stream analytics can be found elsewhere in this volume.

Dimension Reduction and Embeddings

A special case of similarity sketching is *dimension reduction*: mapping objects to a lower-dimensional space, reducing the representation size, while approximately preserving distances. We refer to the article on dimension reduction in this encyclopedia for more details.

We mention a particular form of dimension reduction called *kernel approximations* where distances after the embedding reflect a distance measure (called a *kernel*) on the original space. Such mappings are possible for a wide class of distance measures defined on Euclidean space; see, e.g., Rahimi and Recht (2007).

Some spaces X' can be *embedded* into a space X for which similarity sketching is possible, generally introducing a distortion of distances. For example, Manhattan (or ℓ_1) distances on $[0, 1]^d$ can be embedded into Hamming space by unary encoding of (quantized) coordinate values; see, e.g., Gionis et al. (1999). An embedding implies a similarity sketch on X' obtained by combining the embedding with a similarity sketch for X . Of course, the precision that can be obtained in this way is limited by the precision of the embedding.

Applications

Similarity sketching is used, for example:

- in situations where exact distance computation is not possible for reasons of space (e.g., main memory indexes supporting near neighbor search, where the set of vectors is too large to fit in the memory),
- when exact computation is undesirable for reasons of time (e.g., when considering a large set of candidate very high-dimensional objects in an algorithm for nearest neighbor search),
- as a preprocessing step in machine learning applications where it serves to reduce dimensionality as well as data size.

Since similarity sketching distorts distances, it will generally change the output compared to an exact algorithm and might introduce false positives as well as false negatives in search applications.

Software Libraries

Similarity sketching is often implemented as part of a particular application, and as such there does not seem to be many general-purpose libraries available. For Euclidean distances among a fixed set of points, the QuadSketch C++ library (<https://github.com/talwagner/quadsketch>) provides state-of-the-art performance with a data-dependent mapping. The DataSketch library (<https://github.com/ekzhu/dataskeetch>) provides Python implementations of variants of MinHash.

Definitions

An *aggregation* is a function from a collection of data items to an aggregate value. In *sliding-*

Sliding-Window Aggregation Algorithms, Fig. 1
Sliding-window aggregation definitions

window aggregation, the input collection consists of a window over the most recent data items in a stream. Here, a *stream* is a potentially infinite sequence of data items, and the decision on which data items are *most recent* at any point in time is given by a window policy. A *sliding-window aggregation algorithm* updates the aggregate value, often using incremental-computation techniques, as the window contents change over time, as illustrated in Fig. 1.

Overview

Sliding-window aggregation summarizes a collection of recent streaming data, capturing the most recent happenings as well as some history. Including some history provides context for decisions, which would be missing if only the current data item were used. Using the most recent data helps identify and react to present trends, which would be diluted if all data from the beginning of time were included.

Aggregation is one of the most fundamental data processing operations. This is true in general, not just in stream processing. Aggregation is versatile: it can compute counts, averages, or maxima, index data structures, sketches such as Bloom filters, and many more.

In databases, it shows up as a basic relational algebra operator called group-by-aggregate and denoted γ (Garcia-Molina et al. 2008). In spreadsheets, it shows up as a function from a range of cells to a summary statistic (Sajaniemi and Pekkanen 1988). In programming languages, it shows up as a popular higher-order function called `fold` (Hutton 1999). In MapReduce, it shows up as `reduce` (Dean and Ghemawat 2004), which has been leveraged in many tasks, including computations that do not diminish the volume of data.

In stream processing, aggregation plays a similarly central role. But unlike the abovementioned cases, which focus on data at rest, streaming aggregation must handle data in motion. In particular, sliding-window aggregation must handle inserting new data items into the window as they arrive and evicting old data items from the window as they expire. Supporting this efficiently poses algorithmic challenges, especially for non-invertible aggregation functions such as `max`, for which there is no way to “subtract off” expiring items. From an algorithmic perspective, handling sliding windows with both insertion and eviction is more challenging than handling just insertion. Yet, there are two cases where eviction does not matter: unbounded and tumbling windows. Unbounded windows appear, for instance, in CQL (Arasu et al. 2006). Because they grow indefinitely, it is sufficient to update aggregations upon `insert` and not keep the data item itself around; they never need to call `evict`. Tumbling windows are more common; because they clear the entire contents of the window at the same time, there is no need to call `evict` on individual elements of the window.

Sliding windows are most commonly first-in, first-out (FIFO), resembling the behavior of a queue. What to keep in a sliding window and how often the aggregation is computed are controlled by policies, catalogued elsewhere (Gedik 2013); they may be count-based (e.g., the past 128 elements) or time-based (e.g., the past 12 min), among others. Regardless of policies, FIFO sliding-window aggregation (SWAG) can be formulated as an abstract data type with the following operations:

- `insert(v)` appends the value v to the window.
- `evict()` removes the “oldest” value in the window.
- `query()` returns the aggregation of the values in the window.

Metrics of interest in SWAG implementations are throughput, latency, and memory footprint. SWAG implementations also differ in generality: to enhance efficiency, aggregation operations, when feasible, are applied incrementally – that is, modifying a running sum of sort in response to data items arriving or leaving the window. To what extent this can be exploited depends on the nature of the aggregation operation.

Past work (Gray et al. 1996; Tangwongsan et al. 2015) cast most aggregation operations as binary operators, written \oplus , and has categorized them based on algebraic properties. Table 1 lists common aggregation operations with their properties and groups them into categories. An aggregation operator is *invertible* if there exists some function \ominus such that $(x \oplus y) \ominus y = x$ for all x and y . Using \ominus , SWAGs can implement eviction as an undo. A function is *associative* if $x \oplus (y \oplus z) = (x \oplus y) \oplus z$ for all x , y , and z . SWAGs can take advantage of associativity by applying \oplus at arbitrary places inside the window. Without associativity, SWAGs are restricted to applying \oplus only at the end, upon insertion. A function is *commutative* if $x \oplus y = y \oplus x$ for all x and y . SWAGs are able to ignore the insertion order of data items for commutative aggregation operators. An aggregation operator is *rank-based* if it relies upon an ordering by some attribute of each data item, for instance, to find the i th-smallest.

Table 2 presents an overview of the SWAG algorithms presented in this article, with their asymptotic complexity, space usage, and restrictions. The most straightforward SWAG algorithm is called **Recalc**, since it always recalculates all values. Upon any `insert` or `evict`, Recalc walks the entire window and recomputes the aggregation value by using all available elements. Its performance is obviously $O(n)$, where n is

the current number of elements in the window. Recalc serves as the baseline comparison for all other SWAG algorithms. **Subtract-on-evict** (SOE) is a $O(1)$ algorithm, but it is not general: it can only be used when the aggregation is invertible. Upon every `insert`, SOE updates the current aggregation value using \oplus , and upon every `evict`, SOE updates that value using \ominus . The **order statistics tree** (OST) adds subtree statistics to the inner nodes of a balanced search tree (Hirzel et al. 2016). Values are put in both a queue and the tree, making both `insert` and `evict` $O(\log n)$. But `query` calls for aggregations such as the median or p th percentile become $O(\log n)$ because such information can be derived by traversing a path that is no longer than the height of the tree.

This section gave a brief overview with background and some simple aggregation algorithms. In general, research into SWAG algorithms tries to avoid $O(n)$ costs (unlike Recalc) but maintain generality (unlike SOE and OST). The next section will discuss the more sophisticated algorithms from Table 2 that offer improvements toward this goal.

Key Research Findings

The most successful techniques in speeding up sliding-window aggregation have been data structuring and algorithmic techniques that yield asymptotic improvements. They are the most effective when the aggregation function meets certain algebraic requirements. For instance, there are important aggregation operations that are associative, but not necessarily invertible nor commutative.

Pre-aggregation of data items that will be evicted at the same time is a technique that can be applied together with all SWAG algorithms discussed in this article. When data items are co-evicted, the window need not store them individually but can instead store partial aggregations, reducing the effective window size n in Table 2. Pre-aggregation algorithms include paned windows (Li et al. 2005), paired windows (Krishnamurthy et al. 2006), and Cutty

Sliding-Window Aggregation Algorithms, Table 2

Summary of aggregation algorithms and their properties, where n is the window size and n_{\max} is the size of the smallest contiguous range that contains all the shared windows

	Algorithmic complexity		Restrictions
	Time	Space	
Recalc	Worst-case $O(n)$	$O(n)$	None
Subtract-on-Evict (SOE)	Worst-case $O(1)$	$O(n)$	Sum-like or collect-like
Order Statistics Tree (OST) (Hirzel et al. 2016)	Worst-case $O(\log n)$	$O(n)$	Median-like
Reactive Aggregator (RA) (Tangwongsan et al. 2015)	Average $O(\log n)$	$O(n)$	Associative
DABA (Tangwongsan et al. 2017)	Worst-case $O(1)$	$O(n)$	Associative, FIFO
B-Int (Arasu and Widom 2004)	Shared $O(\log n_{\max})$	$O(n_{\max})$	Associative, FIFO
FlatFIT (Shein et al. 2017)	Average $O(1)$	$O(n)$	Associative, FIFO

windows (Carbone et al. 2016). Windows are sometimes coarsened to enable pre-aggregation, improving performance at the expense of some approximation.

B-Int (Arasu and Widom 2004), designed to facilitate sharing across windows, stores a “shared” window S that contains inside it all the windows being shared. To facilitate fast queries, B-Int maintains pre-aggregated values for all base intervals that lie within S . *Base intervals* (more commonly known now as dyadic intervals) are intervals of the form $[2^\ell k, 2^\ell(k+1)-1]$ with $\ell, k \geq 0$. The parameter ℓ defines the level of a base interval. This allows a query between the

i -th data item and j -th data item within S to be answered by combining at most $O(\log |i-j|)$ pre-aggregated values, resulting in logarithmic running time.

The **Reactive Aggregator** (RA) (Tangwongsan et al. 2015) is implemented via a balanced tree ordered by time, where internal nodes hold the partial aggregations of their subtrees, and offers $O(\log n)$ amortized time. Instead of the conventional approach to implementing balanced trees by frequent rebalancing, RA projects the tree over a complete perfect binary tree, which it stores in a flat array. This leads to higher performance than other

tree-based SWAG implementations in practice, since it saves the time of rebalancing as well as the overheads of pointers and fine-grained memory allocation.

For latency-sensitive applications, the aggregation algorithm cannot afford a long pause. **DABA** (Tangwongsan et al. 2017) ensures that every SWAG operation takes $O(1)$ time in the worst-case, not just on average. This is accomplished by extending Okasaki’s functional queue (Okasaki 1995) and removing dependencies on lazy evaluation and automatic garbage collection. **FlatFIT** (Shein et al. 2017) is another algorithm that achieves $O(1)$ time although in the amortized sense. This is accomplished by storing pre-aggregated values in a tree-like index structure that promotes reuse, reminiscent of path compression in the union-find data structure.

There are a number of other generic techniques that tend to apply broadly to sliding-window aggregation. Window partitioning is sometimes used as a means to maintain group-by aggregation and obtain data parallelism through fission (Schneider et al. 2015). When stream data items arrive out of order, a holding buffer can be used to reorder them before they enter the window (Srivastava and Widom 2004). Alternatively, in the case that the stream is formed by merging multiple sub-streams, out-of-order streams may be solved by pre-aggregating each data source separately and consolidating partial aggregation results as late as possible when doing an actual query (Krishnamurthy et al. 2010).

Examples of Application

Many applications of stream processing depend heavily upon sliding-window aggregation. This section describes concrete examples of applying sliding-window aggregation to real-world use cases. Understanding these examples helps appreciate the problems and guide the design of solutions.

Medical service providers want to save lives by getting early warnings when there is a high likelihood that a patient’s health is about to de-

teriorate. For instance, the Artemis system analyzes data from real-time sensors on patients in a neonatal intensive care unit (Blount et al. 2010). Among other things, it counts how often the blood oxygen saturation and the mean arterial blood pressure fall below a threshold in a 20-s sliding window. If the counts exceed another threshold, Artemis raises an alert.

Financial agents engaged in algorithmic trading want to make money by buying and selling stocks or other financial instruments. Treleaven et al. review the current practice for how that works technologically (Treleaven et al. 2013). Streaming systems for algorithmic trading make their decisions based on predicted future prices. One of the inputs for these predictions is a moving average of the recent history of a price, for example, over a 1-hour sliding window.

Road traffic can be regulated using variable tolling to implement congestion-pricing policies. One of the most popular benchmarks for streaming systems, linear road, is based on variable tolling (Arasu et al. 2004). The idea is to regulate demand by charging higher tolls for driving on congested roads. To do this, the streaming system must determine whether a road is congested. This works by using sliding-window aggregation to compute the number and average speed of vehicles in a given road segment and time window.

The above list of use cases is by no means exhaustive; there are many more applications of sliding-window aggregation, for instance, in phone providers, security, and social media.

Future Directions for Research

Research on sliding-window aggregation has focused mainly on aggregation functions that are associative and on FIFO windows. Much less is known for other nontrivial scenarios. Is it possible to efficiently support associative aggregation functions on windows that are non-FIFO? Besides associativity and invertibility, what other properties can be exploited to develop general-purpose algorithms for fast sliding-window aggregation? How can SWAG algorithms take better advantage of multicore parallelism?

University of Michigan, Ann Arbor, MI, USA

Introduction

An increasing number of enterprise applications, particularly those in financial trading and IoT (Internet of Things), produce mixed workloads with all of the following: (1) continuous stream processing, (2) online transaction processing (OLTP), and (3) online analytical processing (OLAP). These applications need to simultaneously consume high-velocity streams to trigger real-time alerts, ingest them into a write-optimized transactional store, and perform analytics to derive deep insight quickly. Despite a flurry of data management solutions designed for one or two of these tasks, there is no single solution that is apt for all three.

SQL-on-Hadoop solutions (e.g., Hive, Impala/Kudu and SparkSQL) use OLAP-style optimizations and columnar formats to run OLAP queries over massive volumes of static data. While apt for batch processing, these systems are not designed as real-time operational

This article is based on Mozafari et al. (2017), authored by Barzan Mozafari, Jags Ramnarayan, Sudhir Menon, Yogen Mahajan, Soubhik Chakraborty, Hemant Bhanawat, Kishor Bachhav

databases, as they lack the ability to mutate data with transactional consistency, to use indexing for efficient point accesses, or to handle high-concurrency and bursty workloads.

Hybrid transaction/analytical processing (HTAP) systems, such as MemSQL, support both OLTP and OLAP queries by storing data in dual formats (row and columns) but need to be used alongside an external streaming engine (e.g., Storm (Toshniwal et al. 2014), Kafka, Confluent) to support stream processing. They also lack approximation features required for interactive-speed analytics or visualization workloads (Park et al. 2016).

Finally, there are numerous academic (Chandrasekaran et al. 2003; Mozafari et al. 2012; Thakkar et al. 2011) and commercial (Apache Samza; Toshniwal et al. 2014; TIBCO; Akidau et al. 2013) solutions for stream and event processing. Although some stream processors provide some form of state management or transactions (e.g., Samza (Apache Samza), Liquid (Fernandez et al. 2015), S-Store (Meehan et al. 2015)), they only allow simple queries on streams. However, more complex analytics, such as joining a stream with a large history table, need the same optimizations used in an OLAP engine (Liarou et al. 2012; Braun et al. 2015; Thakkar et al. 2011). For example, streams in IoT are continuously ingested and correlated with large historical data. Trill (Chandramouli et al. 2014) supports diverse analytics on streams and columnar data but lacks transactions. DataFlow (Akidau et al. 2015) focuses on logical abstractions rather than a unified query engine.

Consequently, the demand for mixed workloads has resulted in several composite data architectures, exemplified in the “lambda” architecture, which requires multiple solutions to be stitched together – a difficult exercise that is time-consuming and expensive.

In capital markets, for example, a real-time market surveillance application has to ingest trade streams at very high rates and detect abusive trading patterns (e.g., insider trading). This requires correlating large volumes of data by joining a stream with (1) historical records, (2) other streams, and (3) financial reference

data which can change throughout the trading day. A triggered alert could in turn result in additional analytical queries, which will need to run on both ingested and historical data. In this scenario, trades arrive on a message bus (e.g., Tibco, IBM MQ, Kafka) and are processed by a stream processor (e.g., Storm) or a homegrown application, while the state is written to a key-value store (e.g., Cassandra) or an in-memory data grid (e.g., GemFire). This data is also stored in HDFS and analyzed periodically using a SQL-on-Hadoop or a traditional OLAP engine.

These heterogeneous workflows, although far too common in practice, have several drawbacks (D1–D4):

D1. Increased complexity and total cost of ownership: The use of incompatible and autonomous systems significantly increases their total cost of ownership. Developers have to master disparate APIs, data models, and tuning options for multiple products. Once in production, operational management is also a nightmare. To diagnose the root cause of a problem, highly paid experts spend hours to correlate error logs across different products.

D2. Lower performance: Performing analytics necessitates data movement between multiple non-colocated clusters, resulting in several network hops and multiple copies of data. Data may also need to be transformed when faced with incompatible data models (e.g., turning Cassandra's ColumnFamilies into Storm's domain objects).

D3. Wasted resources: Duplication of data across different products wastes network bandwidth (due to increased data shuffling), CPU cycles, and memory.

D4. Consistency challenges: The lack of a single data governance model makes it harder to reason about consistency semantics. For instance, a lineage-based recovery in Spark Streaming may replay data from the last checkpoint and ingest

it into an external transactional store. With no common knowledge of lineage and the lack of distributed transactions across these two systems, ensuring exactly once semantics is often left as an exercise for the application ([Exactly-once processing with trident](#)).

Challenges

SnappyData's goal is to reduce complexity and improve performance by offering streaming, transaction processing, and interactive analytics in a single cluster (Ramnarayan et al. 2016). Realizing this goal involves overcoming several challenges. The first challenge is the drastically different data structures and query processing paradigms that are optimal for each type of workload. For example, column stores are optimal for analytics, transactions need write-optimized row-stores, and infinite streams are best handled by sketches and windowed data structures. Likewise, while analytics thrive with batch processing, transactions rely on point lookups/updates, and streaming engines use delta/incremental query processing. Marrying these conflicting mechanisms in a single system is challenging, as is abstracting away this heterogeneity from programmers.

Another challenge is the difference in expectations of high availability (HA) across different workloads. Scheduling and resource provisioning are also harder in a mixed workload of streaming jobs, long-running analytics, and short-lived transactions. Finally, achieving interactive analytics becomes nontrivial when deriving insight requires joining a stream against large historical data ([Makin' Bacon and the Three Main Classes of IoT Analytics](#)).

Approach Overview

To support mixed workloads, SnappyData carefully fuses Apache Spark, as a computational engine, with Apache GemFire, as a transactional store.

Through a common set of abstractions, Spark allows programmers to tackle a confluence of different paradigms (e.g., streaming, machine learning, SQL analytics). Spark's core abstraction, a

Resilient Distributed Dataset (RDD), provides fault tolerance by efficiently storing the lineage of all transformations instead of the data. The data itself is partitioned across nodes and if any partition is lost, it can be reconstructed using its lineage. The benefit of this approach is twofold: avoiding replication over the network and higher throughput by operating on data as a batch. While this approach provides efficiency and fault tolerance, it also requires that an RDD be immutable. In other words, Spark is simply designed as a computational framework and therefore (i) does not have its own storage engine and (ii) does not support mutability semantics. (Although `IndexedRDD` ([Indexedrdd for apache spark](#)) offers an updatable key-value store ([Indexedrdd for apache spark](#)), it does not support colocation for high-rate ingestions or distributed transactions. It is also unsuitable for HA, as it relies on disk-based checkpoints for fault tolerance.)

On the other hand, Apache `GemFire` ([Apache Geode](#)) (a.k.a. Geode) is one of the most widely adopted in-memory data grids in the industry, which manages records in a partitioned row-oriented store with synchronous replication. It ensures consistency by integrating a dynamic group membership service and a distributed transaction service. GemFire allows for indexing and both fine-grained and batched data updates. Updates can be reliably enqueued and asynchronously written back out to an external database. In-memory data can also be persisted to disk using

append-only logging with offline compaction for fast disk writes ([Apache Geode](#)).

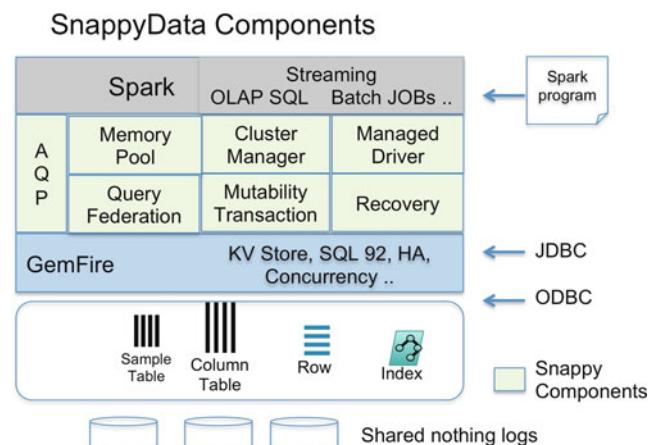

Best of two worlds – To combine the best of both worlds, SnappyData seamlessly integrates Spark and GemFire runtimes, adopting Spark as the programming model with extensions to support mutability and HA (high availability) through GemFire’s replication and fine-grained updates. This marriage, however, poses several nontrivial challenges. For instance, when ingesting a stream, SnappyData processes the incoming stream as a batch, avoids replication, and replays from the source on a failure. To avoid a tuple-at-a-time replication, the processed state can be written to the store in batches. Recovery from failure will thus be limited to the time needed to replay a single batch.

Architecture

Figure 1 depicts SnappyData’s core components (the original components from Spark and GemFire are highlighted).

SnappyData’s hybrid storage layer is primarily in-memory and can manage data in row, column, or probabilistic stores. SnappyData’s column format is derived from Spark’s RDD implementation. SnappyData’s row-oriented tables extend GemFire’s table and thus support indexing and fast reads/writes on indexed keys. In addition to

SnappyData, Fig. 1
SnappyData’s core components

these “exact” stores, SnappyData can also summarize data in *probabilistic* data structures, such as stratified samples and other forms of synopses. SnappyData’s query engine has built-in support for approximate query processing (AQP), which can exploit these probabilistic structures. This allows applications to trade accuracy for interactive-speed analytics on streams or massive datasets.

SnappyData supports two programming models – SQL (by extending SparkSQL dialect) and Spark’s API. Thus, one can perceive SnappyData as a SQL database that uses Spark’s API as its language for stored procedures. Stream processing in SnappyData is primarily through Spark Streaming, but it is modified to run in situ with SnappyData’s store.

SQL queries are federated between Spark’s Catalyst and GemFire’s OLTP engine. An initial query plan determines if the query is a low-latency operation (e.g., a key-based lookup) or a high-latency one (scans/aggregations). SnappyData avoids scheduling overheads for OLTP operations by immediately routing them to appropriate data partitions.

To support replica consistency, fast point updates, and instantaneous detection of failure conditions in the cluster, SnappyData relies on GemFire’s P2P (peer-to-peer) cluster membership service ([Apache Geode](#)). Transactions follow a two-phase commit protocol using GemFire’s Paxos implementation to ensure consensus and view consistency across the cluster.

A Unified API

Spark offers a rich procedural API for querying and transforming disparate data formats (e.g., JSON, Java Objects, CSV). Likewise, to retain a consistent programming style, SnappyData offers its mutability functionalities as extensions of SparkSQL’s dialect and its DataFrame API. These extensions are backward compatible, i.e., applications that do not use them observe Spark’s original semantics.

A DataFrame in Spark is a distributed collection of data organized into named columns. A DataFrame can be accessed from

a SQLContext, which itself is obtained from a SparkContext (a SparkContext is a connection to Spark’s cluster). Likewise, much of SnappyData’s API is offered through SnappyContext, which is an extension of SQLContext. Listing 1 is an example of using SnappyContext.

```

1 // Create a SnappyContext from a SparkContext
2 val spContext = new org.apache.spark.
3   SparkContext(conf)
4 val sncContext = org.apache.spark.sql.
5   SnappyContext(spContext)
6
7 // Create a column table using SQL
8 sncContext.sql("CREATE TABLE MyTable (id int,
9   data string) using column")
10
11 // Append contents of a DataFrame
12   into the table
13 someDataDF.write.insertInto("MyTable");
14
15 // Access the table as a DataFrame
16 val myDataFrame: DataFrame = sncContext.
17   table("MyTable")
18 println(s"Number of rows in MyTable = {
19   myDataFrame.count()}")

```

Listing 1 Working with DataFrames in SnappyData

Stream processing often involves maintaining counters or more complex multidimensional summaries. As a result, stream processors today are either used alongside a scale-out in-memory key-value store (e.g., Storm with Redis or Cassandra) or come with their own basic form of state management (e.g., Samza, Liquid (Fernandez et al. 2015)). These patterns are often implemented in the application code using simple get/put APIs. While these solutions scale well, most users tend to modify their search patterns and trigger rules quite often. These modifications require expensive code changes and lead to brittle and hard-to-maintain applications.

In contrast, SQL-based stream processors offer a higher-level abstraction to work with streams but primarily depend on row-oriented stores (e.g., [IBM](#); [TIBCO](#); Meehan et al. (2015)) and are thus limited in supporting complex analytics. To support continuous queries with scans, aggregations, top-K queries, and joins with historical and reference data, some of the

same optimizations found in OLAP engines must be incorporated in the streaming engine (Liarou et al. 2012). Thus, SnappyData extends Spark Streaming to allow declaring and querying streams in SQL. More importantly, SnappyData provides OLAP-style optimizations to enable scalable stream analytics, including columnar formats, approximate query processing, and co-partitioning (SnappyData 2016).

Hybrid Store: Row and Column Tables

Tables can be partitioned or replicated and are primarily managed in memory with one or more consistent replicas. The data can be managed in Java heap memory or off-heap. Partitioned tables are always partitioned horizontally across the cluster. For large clusters, SnappyData allows data servers to belong to one or more logical groups, called “server groups.” The storage format can be “row” (either partitioned or replicated tables) or “column” (only supported for partitioned tables) format. Row tables incur a higher in-memory footprint but are well suited to random updates and point lookups, especially with in-memory indexes. Column tables manage column data in contiguous blocks and are compressed using dictionary, run-length, or bit encoding (Xin and Rosen).

SnappyData extends Spark’s column store to support mutability. Updating row tables is trivial. When records are written to column tables, they first arrive in a *delta row buffer* that is capable of high write rates and then age into a columnar form. The delta row buffer is merely a partitioned row table that uses the same partitioning strategy as its base column table. This buffer table is backed by a conflating queue that periodically empties itself as a new batch into the column table. Here, conflation means that consecutive updates to the same record result in only the final state getting transferred to the column store. For example, inserted/updated records followed by deletes are removed from the queue. The delta row buffer itself uses copy-on-write semantics to ensure that concurrent application updates do not cause inconsistency (Abadi et al. 2013). SnappyData extends Spark’s Catalyst optimizer

to merge the delta row buffer during query execution.

Probabilistic Store

Achieving interactive response time is challenging when running complex analytics on streams, e.g., joining a stream with a large table (Mozafari and Zaniolo 2010). Even OLAP queries on stored datasets can take tens of seconds to complete if they require a distributed shuffling of records or if hundreds of concurrent queries run in the cluster (Agarwal et al. 2012). In such cases, SnappyData’s storage engine is capable of using probabilistic structures to dramatically reduce the volume of input data and provide approximate but extremely fast answers. In this regard, SnappyData can be seen as the first full-fledged commercial AQP engine (see Mozafari (2017) for why the adoption of AQP has not previously slowed). SnappyData’s probabilistic structures include uniform samples, stratified samples, and sketches (Mozafari and Niu 2015). Unlike VerdictDB (Park et al. 2018; He et al. 2018) and Database Learning (Park et al. 2017), which are agnostic of the underlying query engine, SnappyData’s probabilistic store is tightly integrated into its query processing logic. SnappyData’s approach is also different from other AQP engines (Zeng et al. 2014a; Agarwal et al. 2012; Zeng et al. 2014b), in the way that it creates and maintains these structures efficiently and in a distributed manner. However, given these structures, SnappyData uses off-the-shelf error estimation techniques (Agarwal et al. 2014). SnappyData’s sample selection and maintenance strategies are discussed next.

Sample selection – Unlike uniform samples, choosing which stratified samples to build is a nontrivial problem. The key question is which sets of columns to build a stratified sample on. Prior work has used skewness, popularity, and storage cost as the criteria for choosing column sets (Agarwal et al. 2012, 2013). SnappyData extends these criteria as follows: for any declared or foreign-key join, the join key is included in a stratified sample in at least one of the participating relations (tables or streams). However,

SnappyData never includes a table’s primary key in its stratified sample(s). Furthermore, SnappyData uses an open-source tool, called `WorkloadMiner`, which automatically analyzes past query logs and reports a rich set of statistics ([CliffGuard](#)). These statistics guide SnappyData’s users through the sample selection process. `WorkloadMiner` is integrated into `CliffGuard`. `CliffGuard` guarantees a robust physical design (e.g., set of samples), which remains optimal even if future queries deviate from past ones ([Mozafari et al. 2015](#)).

Once a set of samples is chosen, the challenge is how to update them, which is a key differentiator between SnappyData and previous AQP systems that use stratified samples ([Chaudhuri et al. 2007](#); [Agarwal et al. 2013](#); [Zeng et al. 2015](#)).

Sample maintenance – Previous AQP engines that use offline sampling update and maintain their samples periodically using a single scan of the entire data ([Mozafari and Niu 2015](#)). This strategy is not suitable for SnappyData with streams and mutable tables for two reasons. First, maintaining per-stratum statistics across different nodes in the cluster is a complex process. Second, updating a sample in a streaming fashion requires maintaining a reservoir ([Vitter et al. 1985](#); [Al-Kateb and Lee 2010](#)), which means the sample must either fit in memory or be evicted to disk. Keeping samples entirely in memory is impractical for infinite streams unless the sampling rate is perpetually decreased. Likewise, disk-based reservoirs are inefficient as they require retrieving and removing individual tuples from disk as new tuples are sampled.

To solve these problems, SnappyData always includes timestamp as an additional column in every stratified sample. Uniform samples are treated as a special case with only one stratified column, i.e., timestamp. As new tuples arrive in a stream, a new batch (in row format) is created for maintaining a sample of each observed value of the stratified columns. Whenever a batch size exceeds a certain threshold (1M tuples by default), it is evicted and archived to disk (in a columnar format), and a new batch is started for that stratum.

Treating each micro-batch as an independent stratified sample has several benefits. First, this allows SnappyData to adaptively adjust the sampling rate for each micro-batch without the need for internode communications in the cluster. Second, once a micro-batch is completed, its tuples never need to be removed or replaced, and therefore they can be safely stored in a compressed columnar format and even archived to disk. Only the latest micro-batch needs to be in-memory and in row format. Finally, each micro-batch can be routed to a single node, reducing the need for network shuffles.

State Sharing

SnappyData hosts GemFire’s tables in the executor nodes as either partitioned or replicated tables. When partitioned, the individual buckets are presented as Spark RDD partitions, and their access is therefore parallelized. This is similar to the way that any external data source is accessed in Spark, except that the common operators are optimized in SnappyData. For example, by keeping each partition in columnar format, SnappyData avoids additional copying and serialization and speeds up scan and aggregation operators. SnappyData can also colocate tables by exposing an appropriate partitioner to Spark.

Native Spark applications can register any DataFrame as a temporary table. In addition to being visible to the Spark application, such a table is also registered in SnappyData’s catalog – a shared service that makes tables visible across Spark and GemFire. This allows remote clients connecting through ODBC/JDBC to run SQL queries on Spark’s temporary tables as well as tables in GemFire.

In streaming scenarios, the data can be sourced into any table from parent stream RDDs (DStream), which themselves could source events from an external queue, such as Kafka. To minimize shuffling, SnappyData tables can preserve the partitioning scheme used by their parent RDDs. For example, a Kafka queue listening on Telco CDRs (call detail records) can be partitioned on `subscriberID` so that Spark’s DStream and the SnappyData table ingesting these records will be partitioned on the same key.

Locality-Aware Partition Design

A major challenge in horizontally partitioned distributed databases is to restrict the number of nodes involved in order to minimize (i) shuffling during query execution and (ii) distributed locks (Helland 2007; Zamanian et al. 2015). In addition to network costs, shuffling can also cause CPU bottlenecks by incurring excessive copying (between kernel and user space) and serialization costs (Ousterhout et al. 2015). To reduce the need for shuffling and distributed locks, SnappyData’s data model promotes two fundamental ideas:

- 1. Co-partitioning with shared keys** – A common technique in data placement is to take the application’s access patterns into account. SnappyData pursues a similar strategy: since joins require a shared key, it co-partitions related tables on the join key. SnappyData’s query engine can then optimize its query execution by localizing joins and pruning unnecessary partitions.
- 2. Locality through replication** – Star schemas are quite prevalent, wherein a few ever-growing fact tables are related to several dimension tables. Since dimension tables are relatively small and change less often, schema designers can ask SnappyData to replicate these tables. SnappyData particularly uses these replicated tables to optimize joins.

Dynamic rebalancing of data – When access is non-uniformly distributed across the keys, a load imbalance occurs where a few servers end up performing most of the work. For instance, when tracking users’ browsing behavior on a website, a few popular pages will dominate the rest. SnappyData provides metrics on which nodes are being accessed heavily and also provides administrative APIs that can be used to move “hot buckets” of data to a different node. If the imbalance is a memory usage imbalance, admin APIs can be used to trigger a rebalance which is a non blocking operation that moves buckets of data to less loaded nodes in the background and restores memory balance. Used effectively,

rebalancing prevents hotspots from developing in the system and avoid performance bottlenecks.

Hybrid Cluster Manager

Spark applications run as independent processes in the cluster, coordinated by the application’s main program, called the driver program. Spark applications connect to cluster managers (YARN or Mesos) to acquire executor nodes. While Spark’s approach is appropriate for long-running tasks, as an operational database, SnappyData’s cluster manager must meet additional requirements, such as high concurrency, high availability, and consistency.

High Availability

To ensure high availability (HA), SnappyData needs to detect faults and be able to recover from them instantly.

Failure detection – Spark uses heartbeat communications with a central master process to determine the fate of the workers. Since Spark does not use a consensus-based mechanism for failure detection, it risks shutting down the entire cluster due to master failures. However, as an always-on operational database, SnappyData needs to detect failures faster and more reliably. For faster detection, SnappyData relies on UDP neighbor ping and TCP ack timeout during normal data communications. To establish a new, consistent view of the cluster membership, SnappyData relies on GemFire’s weighted quorum-based detection algorithm ([Apache Geode](#)). Once GemFire establishes that a member has indeed failed, it ensures that a consistent view of the cluster is applied to all members, including the Spark master, driver, and data nodes.

Failure recovery – Recovery in Spark is based on logging the transformations used to build an RDD (i.e., its lineage) rather than the actual data. If a partition of an RDD is lost, Spark has sufficient information to recompute just that partition (Zaharia et al. 2012). Spark can also checkpoint RDDs to stable storage to shorten

the lineage, thereby shortening the recovery time. The decision of when to checkpoint, however, is left to the user. GemFire, on the other hand, relies on replication for instantaneous recovery but at the cost of lower throughput. SnappyData merges these recovery mechanisms as follows:

1. Fine-grained updates issued by transactions avoid the use of Spark’s lineage altogether and instead use GemFire’s eager replication for fast recovery.
2. Batched and streaming micro-batch operations are still recovered by RDD’s lineage, but instead of HDFS, SnappyData writes their checkpoints to GemFire’s in-memory storage, which itself relies on a fast P2P (peer-to-peer) replication for recovery. Also, SnappyData’s intimate knowledge of the load on the storage layer, the data size, and the cost of recomputing a lost partition allows for automating the choice of checkpoint intervals based on an application’s tolerance for recovery time.

Hybrid Scheduler and Provisioning

Thousands of concurrent clients can simultaneously connect to a SnappyData cluster. To support this degree of concurrency, SnappyData categorizes incoming requests as low- and high-latency operations. By default, SnappyData treats a job as a low-latency operation unless it accesses a columnar table. However, applications can also explicitly label their latency sensitivity. SnappyData allows low-latency operations to bypass Spark’s scheduler and directly operate on the data. High-latency operations are passed through Spark’s fair scheduler. However, among the low-latency operations, SnappyData still relies on a simple FIFO policy (other systems, such as MariaDB or MySQL, use more sophisticated algorithms for transaction scheduling, e.g., VATS (Huang et al. 2017) or MySQL’s CATS (Tian et al. 2018)). For low-latency operations, SnappyData attempts to reuse their executors to maximize their data locality (in-process). For high-latency jobs, SnappyData dynamically expands their compute resources while retaining the nodes caching their data.

Consistency Model

SnappyData relies on GemFire for its consistency model. GemFire supports “read committed” and “repeatable read” transaction isolation levels using a variant of the Paxos algorithm (Gray and Lamport 2006). Transactions detect write-write conflicts and assume that writers rarely conflict. When write locks cannot be obtained, transactions abort without blocking ([Apache Geode](#)).

SnappyData extends Spark’s `SparkContext` and `SQLContext` to add mutability semantics. SnappyData gives each SQL connection its own `SQLContext` in Spark to allow applications to start, commit, and abort transactions.

While any RDD obtained by a Spark program observes a consistent view of the database, multiple programs can observe different views when transactions interleave. An MVCC mechanism (based on GemFire’s internal row versions) can be used to deliver a single snapshot view to the entire application.

In streaming applications, upon faults, Spark recovers lost RDDs from their lineage. This means that some subset of the data will be replayed. To cope with such cases, SnappyData ensures the exactly once semantics at the storage layer so that multiple write attempts are idempotent, hence relieving developers of having to ensure this in their own applications. SnappyData achieves this goal by placing the entire flow as a single transactional unit of work, whereby the source (e.g., a Kafka queue) is acknowledged only when the micro-batch is entirely consumed and the application state is successfully updated. This ensures automatic rollback of incomplete transactions.

S

Conclusion

SnappyData is a unified platform for real-time operational analytics, which supports OLTP, OLAP, and stream analytics in a single integrated solution. SnappyData’s approach is a deep integration of a computational engine for high-throughput analytics (Spark) with a scale-out in-memory transactional store (GemFire). SnappyData extends SparkSQL and Spark Streaming APIs

with mutability semantics and offers various optimizations to enable colocated processing of streams and stored datasets. SnappyData has integrated approximate query processing for enabling real-time operational analytics over large (stored or streaming) data. Overall, SnappyData's goal is to yield a significantly lower TCO for mixed workloads compared to using disparate products that are managed, deployed, and monitored separately.

Definitions

SQL is a highly scalable and efficient relational processing engine with ease-to-use APIs and mid-query fault tolerance. It is a core module of Apache Spark, which is a unified engine for distributed data processing (Zaharia et al. 2012). Spark SQL can process, integrate, and analyze the data from diverse data sources (e.g.,

Hive, Cassandra, Kafka, and Oracle) and file formats (e.g., Parquet, ORC, CSV, and JSON). The common use cases include ad hoc analysis, logical warehouse, query federation, and ETL processing. It also powers the other Spark libraries, including structured streaming for stream processing, MLlib for machine learning (Meng et al. 2016; Michael et al. 2018), GraphFrame for graph-parallel computation (Dave et al. 2016), and TensorFrames for TensorFlow binding. These libraries and Spark SQL can be seamlessly combined in the same application with holistic optimization by Spark SQL.

Overview

Spark is a general purpose big data processing system. It was originally developed in the AMPLab at UC Berkeley and donated to Apache Software Foundation in 2013. Now, Apache Spark is one of the most popular open-source projects in data analytics and query processing. Spark SQL (Armbrust et al. 2015) (its predecessor, Shark (Xin et al. 2013)) was introduced in 2014 and became the core of Apache Spark ecosystem. It enables Spark to perform efficient and fault-tolerant relational query processing with analytics database technologies. The relational queries are compiled to Resilient Distributed Dataset (RDD) transformations and actions, which are executable in Spark.

Spark SQL follows the classic query processing and federation architecture with adoption of the recent research (e.g., whole-stage code generation). Through the user-facing APIs (SQL, DataFrame, and Dataset), the user queries are converted to unresolved abstract syntax trees (called unresolved logical plans). The plans are then analyzed using the session-specific temporary view manager, and the cross-session cache manager and catalog. Logical optimizer and physical planner optimize the resolved plans by applying heuristics-based and cost-based transformation rules. During the query planning phase, the sub-plans are pushed down to the underlying data sources for more

efficient processing, if possible; the logical plans are converted to the executable physical plans consisting of transformations and actions on RDDs with the generated Java code. The code is compiled to Java bytecode, executed at runtime by JVM and optimized by JIT to native machine code at runtime.

Declarative APIs

Prior to Spark SQL, Spark offers low-level procedural APIs for operating RDDs and building DAGs that are executable in Spark. Spark SQL introduces three declarative APIs (DataFrame, Dataset, SQL language), which are complementary to the low-level Spark APIs (i.e., RDD APIs). It facilitates tight integration of relational queries and complex procedural processing.

The SQL API is based on ANSI SQL:2003 standard with full compliance to Hive query language (HiveQL). For the existing Hive users, the compliance facilitates migration to Spark SQL. Spark SQL also provides language-integrated and lazily evaluated DataFrame-/Dataset APIs. The DataFrame API provides untyped relational operations, while the Dataset API provides a typed version for better type safety. The DataFrame API is available in Scala, Java, Python, and R. The Dataset API is only available in Scala and Java since Python and R are dynamically typed languages.

Compared with SQL, DataFrame/Dataset APIs provide richer and user-friendly interfaces, since the APIs are not limited by ANSI SQL compliance and also fully integrated with the programming languages (Java/Scala/Python/R). Using DataFrame/Dataset APIs, a complex data-flow logic can be split to multiple simpler modular host-language functions and then build up a single logical plan for holistic query optimization. All these three APIs are internally represented by the same Catalyst logical plans. They can be mixed, combined, optimized, and executed holistically, thanks to the lazy execution. The execution is triggered until users call the action APIs (e.g., collect, save, and show).

Query Optimization

Spark SQL optimizes the plans using the stratified search strategy that are widely used in the commercial database vendors (e.g., Oracle and DB2). First, the optimizer rewrites the query plans using heuristics-based rules. The typical transformation rules include predicate pushdown, column pruning, outer join elimination, constraint propagation, and predicate inference. Then, the cost-based plan enumeration and method selection are executed. The cost-based optimizer framework is initially shipped with Spark 2.2 and still rapidly evolving. Histogram was introduced for cardinality estimation in Spark 2.3. More accurate cost model, demand-driven enumerators, and adaptive query optimization are in the road map.

Spark SQL optimizer is extensible. Custom optimizer rules can be injected. For example, the users can add extra optimization rules for pushing more operators into the external data source systems or supporting the new data types.

Query Execution

Memory and CPU, rather than disk and network I/O, are the major performance bottlenecks of query execution in Apache Spark (Ousterhout et al. 2017), thanks to the progress in related hardware and data compression. The project Tungsten speeds up query execution by optimizing the efficiency of CPU and memory. The major focuses include off-heap memory management and runtime code generation.

Memory Management

The overhead of JVM objects and GC are significant for data intensive Java applications. Apache Spark leverages the application semantics to explicitly manage the memory using the *sun.misc.Unsafe* feature. This feature provides the C-style direct access to off-heap memory. The memory managed by Spark is invisible to the garbage collector. Tuning

GC for higher performance is not needed. The compiled/interpreted operations directly manipulate the binary data represented in the Tungsten specialized format. Compared with JVM objects, it has less memory footprint and thus reduces the processing time.

Runtime Code Generation

On the driver, Spark generates Java source code specialized to each query. On the executors, the generated code is compiled to Java bytecode by a lightweight Java compiler, which runs directly on the JVM and can be further compiled to native code by the just-in-time (JIT) compiler in the JVM. It strikes a good balance between performance and readability (and thus debuggability) of generated code.

Runtime code generation is performed on two levels: (1) expressions are generated into straightforward Java code to reduce interpretation overhead, and (2) where possible, multiple adjacent physical plan operators, along with the expressions involved, are fused together using a push-based model and generated into a single code generation unit (called a stage). Compared with the original iterator-based pull model (Volcano), this reduces the overhead of virtual function calls and materialization of intermediate results between operators, improves data locality, and enables further specialization with the context of multiple operators.

The same code generation framework is also used to speed up serialization/deserialization. As a unified data processing framework, Spark SQL supports flexible use of UDFs and type-safe Dataset APIs, both of which involve conversions between domain objects and Spark SQL internal data representations.

Data Sources

Spark separates computation and storage. The data sources are autonomous and can be shared with the other processing engines. The data schema is dynamic. The schema is just a virtual view that can be predefined or derived when reading it. For example, the built-in file source

connectors, including JSON, CSV, Parquet, and ORC, offer read-time schema inference. All the inferred or predefined schemas can be stored in a global persistent catalog, which is Hive metastore by default. The Hive metastore can also be shared with the other engines (e.g., Hive).

Thanks to the rich interoperability with external data sources, Spark SQL can read from, integrate with, and write to a variety of data sources. Users can use the built-in connectors and also plugin other third-party connectors. Through the data source APIs, third parties can build customized connectors to access the data stores.

Highly efficient vectorized readers are provided for columnar file sources (e.g., Parquet and ORC). Such complicated I/O operations are not fused into the whole-stage codegen. Bulk reading and processing can reduce the per-tuple interpretation overhead and leverage compiler optimization. The built-in cache mechanism is also columnar. The external sources and intermediate results can be explicitly cached in memory or local disk for reuse.

Conclusion

Since the initial release, Apache Spark has quickly become the largest open-source community in big data. It is the work of over 1000 contributors from over 250 companies. Spark SQL is the most active component in Apache Spark. Spark SQL brings end-to-end optimization in the sophisticated applications, which use one or multiple Spark libraries (e.g., SQL, MLlib, and structured streaming). More breakthroughs are expected in the coming years, as Spark SQL is growing to be a compiler of the unified analytics engine.

SparkBench

John Poelman and Emily May Curtin
IBM, New York, USA

Synonyms

[Apache Spark benchmarking](#); [Spark-Bench](#); [CODAIT/spark-bench](#)

Overview

SparkBench is a flexible framework for benchmarking, simulating, comparing, and testing ver-

sions of [Apache Spark](#) and Spark applications. It provides users three levels of parallelism and a variety of built-in data generators and workloads that allow users to finely tune their setup and get the benchmarking results they need.

Definitions

A framework for benchmarking Apache Spark.

Historical Background

Apache Spark began in 2010 as a research project by Matei Zaharia and others in the Berkeley AMPLab. Following the landmark success of *Resilient Distributed Datasets: A Fault-Tolerant Abstraction for In-Memory Cluster Computing* by Zaharia et al. (2012), Spark continued to gain popularity and usage as its performance gains over traditional MapReduce workflows became evident. Spark continued to grow as well, introducing Python and R APIs, machine learning, graph computation, SQL, and streaming computation.

In 2015, a group of researchers at IBM identified a need in the growing Spark ecosystem for a benchmarking solution that focused specifically on Spark. While benchmarking systems such as the [AMPLab Big Data Benchmark](#) and Intel's [HiBench](#), to name just two, focused primarily on comparisons of Spark to other big data compute engines, the researchers at IBM chose to focus more specifically on Spark. In their 2015 paper *SPARKBENCH: A Comprehensive Benchmarking Suite For In Memory Data Analytic Platform Spark*, they wrote,

While Spark has been evolving rapidly, the community lacks a comprehensive benchmarking suite specifically tailored for Spark. The purpose of such a suite is to help users to understand the tradeoff between different system designs, guide the configuration optimization and cluster provisioning for Spark deployments. Existing big data benchmarks... are either designed for other frameworks such as Hadoop or Hive, or are too general to provide enough insights on Spark workload characteristics. (Li et al. 2015)

SparkBench Versus Other Tools

Intel's HiBench and other similar tools benchmark select Spark algorithms against implementations in other frameworks. These tools focus on a small selection of algorithms that are run in the style of traditional benchmarks. They are not focused specifically on Apache Spark, nor do they claim to be. Instead, they are useful for differentiating Spark against frameworks such as MapReduce, Storm, Hive, and others. SparkBench was designed to exercise various subsystems of Spark in a detailed way, not to compare Spark against other frameworks.

There are a number of projects that provide detail profiling information on Spark performance in a particular job. These, in most cases, can be combined with SparkBench to great effect by using SparkBench to build the simulation or benchmark in question and also drive the profiler. Some projects in this category include [CODAIT/spark-tracing](https://github.com/CODAIT/spark-tracing) (<https://github.com/CODAIT/spark-tracing>) and the commercially available [YourKit](http://spark.apache.org/developer-tools.html#profiling) (<http://spark.apache.org/developer-tools.html#profiling>).

Many production users of Spark have also observed the need for a production-grade Spark job scheduling tool. Some examples include Airflow by Airbnb and Azkaban by LinkedIn. While SparkBench provides the ability for users to compose suites of jobs to simulate use cases, it is not a production tool. [Airflow](#) and [Azkaban](#) provide feature-filled DAG schedulers and production monitoring for Spark jobs. They may be used as drivers for SparkBench to further enable complex simulation of real-world Spark use cases.

SparkBench Version 1.x Structure

The first version of SparkBench included a suite of individually compiled Spark applications. Each contained an application for generating data and an application containing the implementation of the algorithm in question. These applications were largely written in a mix of Java and Python and stitched together through a plethora of bash scripts that provided configuration and coalescing of results. The applications were designed to be individually compiled and run one at a time on a given cluster.

Key to the design of SparkBench 1.0 was the breadth of applications. In 2015, some of the now more widely used components of Spark including Spark SQL and Streaming were only just debuting. The authors of SparkBench 1.0 were careful to include representative workloads for each major piece of Apache Spark.

The source code for the first version of SparkBench was released on Bitbucket. It was eventually ported to GitHub under the umbrella of the CODAIT organization where contributors continued to update the code for subsequent releases of Apache Spark.

Motivation for Rewrite

Since the initial release of SparkBench in 2015, the adoption and number of use cases for Spark have continued to grow at a rapid pace. Notebooks now provide data scientists and analysts new ways of collaborating; cloud services provide businesses new ways of leveraging and accessing the cluster compute power of Spark; and Apache Spark itself has gone from version 1.4.0 to version 2.x in just 2 short years.

In 2017, a team at IBM working on performance improvements to core components of Apache Spark realized the need for a benchmarking tool that could do more than benchmarking. A simple run of traditional algorithms could not capture the complex nature of multiuser user cases that were the focus of the new improvements. To that end, Scala developer Emily May Curtin embarked on a major rewrite of SparkBench.

S

Project Structure

The new version of SparkBench (2.x) is a complete, ground-up rewrite of version 1.x. While version 1.x was a series of individually compiled Java or Scala programs with their own main() functions, the new version is a single Scala framework compiled using one SBT build file. Rather than algorithm implementations living alone in their own jar stitched together through bash, each is an implementation of the abstract workload class. All configurations are done in a single configuration file rather than a series of scattered variables in various bash scripts.

	Old version	New version
Project design	Series of shell scripts calling individually built jars	Scala project built using SBT
Build/release	Built manually, released manually	SBT, Travis CI, auto-release to GitHub releases on PR merge
Configuration	Scattered in shell script variables	Centralized in one configuration file with many new capabilities
Parallelism	None	Three different levels
Custom workloads	Requires writing a new subproject with all accompanying bash	Bring your own jar, plug it into existing framework with all configuration included

The new version of SparkBench features three independent levels of parallelism to enable users to dial in accurate settings for their particular simulation.

Foundations

SparkBench provides three levels of parallelism in which users can compose workloads and data generators to accomplish their benchmarking goals quickly and easily.

Workloads, Spark configuration, and other experiment structure are defined in one single config file written in [HOCON](#), a superset of JSON. They have a nested structure that starts with spark-submit configs and then goes down into workload suites and finally workloads at the bottom of the nested structure.

Workloads

The atomic unit of organization in SparkBench is the workload. Workloads are stand-alone Spark jobs that read their input data, if any, from disk, and write their output, if the user wants it, out to disk.

Some workloads are designed to exercise a particular algorithm implementation or a particu-

lar method. Others are designed to simulate Spark use cases such as multiple notebook users hitting a single Spark cluster.

Some existing categories of workloads include:

- ML workloads: Logistic Regression, K-Means, etc.
- “Exercise” workloads: designed to examine one particular portion of the Spark pipeline. A good example is SparkPi, a compute-heavy workload with very little disk IO.
- Data generators: SparkBench has the capability to generate data according to many different configurable generators. Generated data can be written to any storage addressable by Spark, including local files, HDFS, S3, etc.

Workloads can be composed with one another. They can be launched serially or in parallel.

Workload Suites

Workload suites are logical groups of workloads. Workload suites can be composed with each other for benchmarking tasks or to simulate different cluster use cases.

Workload suites control the benchmark results output and repetition of workloads. They can be composed with each other in serial or parallel fashion. The level of parallelism of the workload suite does not affect the level of parallelism for the workloads contained within each suite.

Spark-Submit Configuration

Under the hood, SparkBench converts users' configuration files into a series of spark-submit scripts. The spark-submit-config section of the configuration file allows users to change the parameters of those spark-submits.

Spark-submits, like other parts of the SparkBench configuration, can be composed serially or in parallel in order to accurately simulate different use cases. Multiple spark-submits additionally allow users to test different versions of Spark, different clusters, different configuration settings on the same cluster, and much more.

As with workloads and workload suites, spark-submits can be composed with each other and can be launched serially or in parallel. These three levels of parallelism (spark-submits, workload suites, and workloads) allow users fine-grained control over the setup of their simulation, so they can dial in the conditions to be as true to life as possible.

Example Configuration File

This is a configuration file used to benchmark performance of SQL queries against the same dataset stored in Parquet and CSV.

The first workload suite generates the data in CSV format, then picks up the CSV it just generated and rewrites it to Parquet format.

The second workload suite runs a total of four different workloads using the cross product of the two parameter lists. These four workloads are repeated ten times.

                csv", "hdfs:///tmp/csv-vs-
                parquet/kmeans-data.
                parquet"]
                query = ["select * from
                input", "select '0', '22'
                from input where '0' <
                -0.9"]
                cache = false
            }
        ]
    }
}
```

S

Key Applications

SparkBench is in active use by developers working on contributions to Spark core. These developers use the project to compare the runtimes of

standard algorithms in the latest official version of Spark against their branch with changes.

Other developers have used the custom workload plugin capability of SparkBench to create custom workloads that exercise a very specific subsystem of Spark such as the caching mechanisms in core as they relate to dynamic allocation.

SparkBench additionally provides mechanisms for developers to simulate notebook environments such as [Jupyter](#) or [Apache Zeppelin](#). By inserting a Sleep workload between workloads, SparkBench users can build up a simulation of a notebook user. It is a simple extension to copy this workload suite to simulate multiple users.

This notebook simulation technique has been used to great effect by developers in the IBM Spark Technology Center who used SparkBench to debug and benchmark changes to Spark core involving resource contention settings.

Future Work

SparkBench is under active development by IBM and contributors from all over the world. Planned future work centers around several efforts.

1. *Launching through interfaces other than spark-submit (Livy, other REST services).* The structure of SparkBench should reflect the myriad of ways that users can interface with Spark. Adding REST capability to SparkBench allows for a new variety of use cases to be covered such as Spark as a service setups and other remote architectures.
2. *Expanding selection of built-in workloads.* At the time of publication, IBM developers are working on porting many workloads from version 1.x to 2.x.
3. *Allowing tighter integration with pluggable listeners and profilers.* SparkBench sits at the level of the application. To get more detailed profiling data on specific functions and do system profiling, users can employ a variety of profilers and tracers. In the future the output of

SparkBench should be synced and packaged with the output of tracers.

4. *Increase the number of standard big data benchmarks available by default, particularly TPC-DS.* The TPC-DS dataset and associated 100 SQL queries are a key standard benchmark for SQL systems. At the time of publication, developers at IBM are in progress adding workloads for TPC-DS data generation as well as the standard queries.

Spatial Data Integration

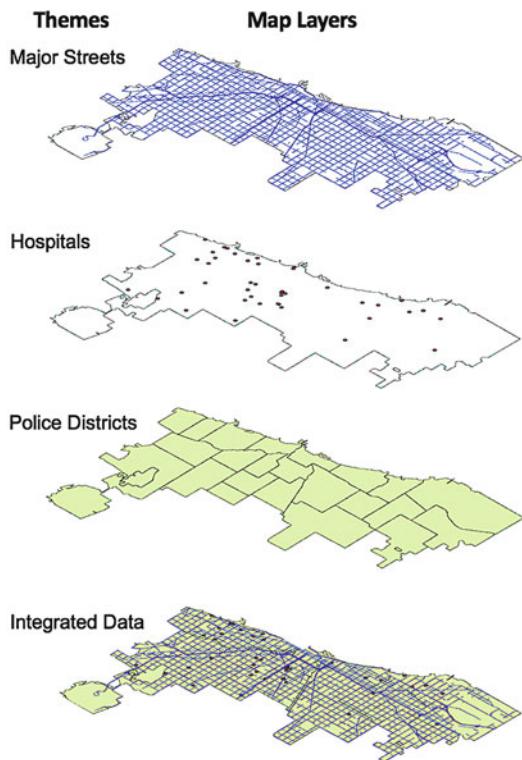

Booma Sowkarthiga Balasubramani and
Isabel F. Cruz
University of Illinois at Chicago, Chicago,
IL, USA

Synonyms

[Geospatial data integration](#); [Spatiotemporal Data Integration](#)

Definitions

Spatial data integration is a process in which different geospatial datasets, which may or may not have different spatial coverages, are made compatible with one another (Flowerdew 1991). The goal of spatial data integration is to facilitate the analysis, reasoning, querying, or visualization of the integrated spatial data. Figure 1 illustrates the integration of three layers or *themes*: major

Spatial Data Integration, Fig. 1 Spatial data integration (Chi 2017)

streets, hospitals, and police districts of the City of Chicago (Chi 2017).

Spatial data (often used synonymously with *geospatial data* and *geographical data*) refers to the information – location, shape, and relationships among geographic features – that describes the distribution of things on the surface of the Earth (DeMers 2008; Walker 1993).

Geospatial datasets that relate to physical geography, such as land and ocean boundaries, topography, weather, hydrology, natural disasters, land cover, and to human geography, such as administrative boundaries, land use, population, crime, buildings, water pipes, roads, points of interest, and many more, are freely available from a wide variety of sources (e.g., Socrata, data.gov). Many of those datasets vary both with respect to time and space. While each dataset may be important in its own right, it is often

their joint analysis that makes them critical for decision-making. Examples include finding the lakes in Maine (Egenhofer 2002), returning the towns affected by fires (Kyzirakos et al. 2014), or estimating the number of people affected by a water main break (Balasubramani et al. 2017).

Overview

Data are generated by various sources and different stakeholders, and they correspond to different locations and times. This section discusses such characteristics of spatial data that influence the techniques for spatial data integration.

Spatial and Spatiotemporal Data Types

Spatial data can be associated with (Flowerdew 1991):

Points: Sample points, selected randomly or for convenience (points in a survey, rain gauges), or points representing real objects (trees, buildings, cities).

Lines: Sample lines (paths for ecological sampling) or real phenomena (streets, rivers, geological faults).

Areas: With natural boundaries (islands, marshes) or artificial boundaries (land parcel, census tract).

Surfaces: A phenomenon defined across a region but measured only at discrete points (rainfall). Values at other points can be estimated (e.g., by interpolation).

For spatiotemporal data, we consider a single data type (Zheng 2015; Yoon and Shahabi 2008):

Trajectories: A trajectory of a moving object is a sequence of spatial points sampled at discrete instances of time. It is represented by a series of chronological points, $(p_1, t_1), (p_2, t_2), \dots, (p_n, t_n)$, where p_i is a two- or three-dimensional vector corresponding to the geospatial position observed at a time stamp t_i , where $i = 1, \dots, n$.

Spatial Data Formats

Spatial data are represented using one of the two data formats (Maffini 1987):

Vector: A coordinate-based data format that represents spatial data in the form of points, lines, and polygons. This format allows for the efficient encoding and operations to determine, for example, the eight basic topological relationships (Egenhofer 1993), namely, *disjoint*, *meet*, *overlap*, *contains*, *inside*, *covers*, *covered by*, and *equal*.

Raster: A data format that is composed of cells distributed in a regular grid, each containing an attribute value and location coordinates (Bishr 1998). This format encodes continuous data efficiently, such as in a topographic map that represents elevation using a color scale.

Conflation is the process of combining two or more sources representing the same geographic information so as to retain accurate data, minimize redundancy, and reconcile data conflicts (Longley 2005). The techniques for conflation vary based on the spatial data formats (Saalfeld 1988; Cobb et al. 1998). For example, vector-to-vector conflation involves matching vector data based on the similarities of the shapes of the vectors, geometric information, or the vector attributes. Vector-to-raster conflation exploits auxiliary spatial information (e.g., coordinates from a satellite image) and nonspatial information (e.g., the image resolution or color) and performs image processing to determine the correspondence among the datasets. Raster-to-raster conflation involves data-specific image processing techniques to extract and match various features (e.g., edges) across images (Dare and Dowman 2000).

Spatial Transformations

Spatial transformations are functions that obtain new spatial data from existing data, for example (Longley et al. 2015):

Buffering: Produces a new geometry by adding an area around the original objects (points, lines, areas).

Point-in-Polygon: Determines whether a given point lies inside or outside a given polygon.

Polygon Overlay: Outputs the polygons resulting from the intersections of two polygons.

Spatial Interpolation: Uses information from sampled points to guess the values at other points.

Density Estimation: Constructs an estimate of an unknown probability density function, based on observed data.

Heterogeneity

Differences in spatial data types and formats lead to two forms of heterogeneity that need to be resolved when integrating spatial data. Other obstacles for integrating data stem from differences in syntax, schema, or semantics (Bishr 1998). In addition, different data models, update frequency, resolution, and scale are also to be considered.

Spatial data exhibit various kinds of heterogeneity (Beck et al. 2008; Hakimpour 2003; Bishr 1998):

Syntactic Heterogeneity: Spatial data is stored in different formats (e.g., shapefile, KML). The data format dictates the tools and approaches to query, integrate, and analyze the data.

Structural or Schematic Heterogeneity: This kind of heterogeneity arises when the data model is the same (e.g., relational) but the schemas differ, including the type of an attribute (for example, °F vs. °C). Further heterogeneities occur when the same concept is in one of the table names in a schema and is a name of an attribute in another schema.

Semantic Heterogeneity: Semantic heterogeneities occur when the same entity has different names, or when different entities have the same name. For example, *Chicago* and *Windy City* represent the same entity, whereas *Square* represents a geometry with four sides of equal length or a *City Square*.

Spatial Modeling Heterogeneity: The same geographical phenomena may be modeled differently, for example, *street* as a *line* in one dataset, and as a *polygon* in another dataset.

Resolution or Granularity: There are three kinds of resolution: *spatial*, *temporal*, or *semantic*. *Spatial resolution* is the grain size or the cell size of spatial data, and represents the amount of detail that can be observed in the spatial dataset (Longley 2005). For instance, satellite imagery with a resolution of 2.4 m is more detailed than a satellite imagery with a resolution of 1.1 km. *Temporal resolution* is the time interval during which the value remains the same, for example, temperature that is published every hour, but the estimated time of arrival for a flight may be updated every five minutes. *Semantic resolution* refers to the level of specification of a real-world entity (Fonseca et al. 2002). For example, a body of water may be perceived as a lake or as a water body, depending on the application. Semantic similarity can be measured by the distance that separates two concepts in a classification hierarchy (e.g., an ontology).

Scale: Often used synonymously with resolution, scale describes the dimensions of spatial phenomena and determines its object type (Longley 2005). The details of the spatial phenomena represented in the spatial dataset heavily depends on scale. For example, the New York city is represented as a one-dimensional point on the world map, but is represented as a two-dimensional area on the city map, which is more detailed.

S

Key Research Findings

Designing spatial data integration systems is characterized by various challenges that spatial data exhibit. Quite justifiably, significant research effort has been invested over the past decades in the spatial data integration problem. This section discusses some of the most important works that focus on integrating spatial data in a seamless manner.

Spatial Entity Resolution

Entity resolution in spatial data integration refers to the process that determines whether two locations referenced by two or more different data

sources correspond to the same real-world entity (Sehgal et al. 2006). Some common approaches for entity resolution in spatial data integration are as follows:

One-Sided Nearest-Neighbor Join: This method associates data with location a in dataset A to data with location b in dataset B , if b is the closest location to a among all other locations in B (Batini and Scannapieco 2016).

Image Processing Techniques: Integration of digital maps (Doytsher et al. 2001; Saalfeld 1988) involves image processing techniques and requires complete information about the spatial entity. Satellite imagery has long been used to integrate maps.

Feature-Based Matching: These algorithms use location features, that is, attributes such as spatial coordinates, location name, and location type independently, and find mappings based on a similarity metric such as *edit distance* or *coordinate similarity*.

Feature-Based Integration: This method combines different similarity measures. For example, a feature vector consisting of the similarity metrics for spatial and nonspatial features (e.g., *edit distance* and *coordinate similarity*) is associated with each pair of locations. Final similarity is determined using is performed using machine learning techniques like logistic regression or neural networks.

Uncertainty

Uncertainty, which is the difference between an occurrence in reality and its representation in a database (Zhang et al. 2014), is omnipresent in geospatial data. Uncertainty occurs in several phases ranging from geographical abstraction, data acquisition, limited observations, different but equally valid interpretations of the geography, geo-processing techniques, and representation of the results of geographic computations to the use of the results (Devillers and Jeansoulin 2006; Zhang and Goodchild 2002). When datasets are integrated, the resulting uncertainty stems from the individual datasets as well as from the integration process itself.

Spatial Data Integration: Observations

This section highlights some details observed during spatial data integration (Goodchild et al. 1992; Cruz and Xiao 2008; Mohammadi et al. 2006; Cruz et al. 2007):

1. The set of functions that can be applied or the type of analysis that can be performed on spatial data heavily depends on the data models and probability distribution functions. For example, interpolation can be performed on point samples of mineral deposits to determine the distribution of mineral reserves for an area. However, one cannot interpolate the point samples representing occupancy in high-rise buildings to estimate the population of a city.
2. Data comes from various sources such as social media, private and public organizations, and government agencies. Each of these sources handles data using different database management techniques, formats, and scales. Even in the same organization, for example, in a city, the boundaries of the various districts (school, asphalting, sanitation, forestry) may not coincide, thus complicating correlations across different datasets.
3. The same data can be heterogeneously represented depending on the data provider, either because of the data collection method, storage and management techniques, or, sometimes, the functions used to derive the data.
4. The availability of metadata does not guarantee in itself that data will be correctly integrated. The semantics of the different datasets, the target model in the case of cross-domain data integration, the goal of the integration, and other factors are important.
5. Attribute-level metadata, which contains the data accuracy, date collected/updated, or source of a particular attribute, is usually more useful than the generic theme-based metadata, which focuses on the domain of the spatial data (e.g., agriculture, environmental) and consists of information including the spatial extent, content type, and publisher.
6. Sources with different privacy requirements further add to the data heterogeneity and to

the complexity of the data integration process. For example, data may have to be previously transformed to a coarser detail or integrated using privacy-preserving techniques. Another known risk stems from the fact that the integrated datasets may allow for a more detailed analysis than was previously possible for each dataset.

State-of-the-Art Techniques for Spatial Data Integration

Due to the complex nature of spatial data, a data integration framework cannot be generalized to all spatial data integration cases. Geostatistical techniques are specific to spatial data (Gotway and Young 2002), while others that use ontologies can be used for the integration of spatial (Fonseca et al. 2002) and nonspatial datasets (Cruz and Xiao 2005). Ontologies are knowledge representation structures that define concepts and their relationships explicitly.

Geostatistical Techniques

Geostatistical techniques for data integration aim to allow for the synthesis of data at different scales. One of the problems is the fact that spatial data is organized, subdivided, and stored based on spatial units (e.g., land parcel, grid cell of size 1 km²), which may differ across datasets.

Spatial data transformations are special cases of the *change of support problem* (COSP), where *support* includes the geometrical size and shape of a region associated with a measurement (Gotway and Young 2002). Examples of COSPs include block kriging and areal interpolation. For example, block kriging applies to the case where point values are observed but the nature of the process is associated with an area, whereas areal interpolation applies to the case where area values are observed for a set of source polygons (e.g., school districts) but need to be converted to a set of target polygons (e.g., census tracts).

Ontology-Based Approaches

To integrate datasets that exhibit different spatial (or temporal) resolutions and are different in terms of schema (structure that represents the organization of data) and semantics, an ontology

can act as a mediator between the two datasets so as to establish relationships among the attributes of the datasets (Tran et al. 2015). For example, an urban spatial ontology can be used to establish relationships such as Chicago is *inside* Illinois. It is also possible to use an ontology for each dataset and establish correspondences between the ontologies, using rules defined by the domain experts (Mena et al. 2000). Also, there are different types of ontologies with respect to their expressiveness.

A set of mappings, which defines the correspondences among the concepts in the ontologies, are established to describe topological relations (such as *disjoint*, *meet*, or *overlap*). For resources with rich quantitative spatial information, the focus is on obtaining mappings between spatially colocated regions. The similarity between two geometric shapes is then obtained using the Hausdorff distance, which is defined as the maximum distance of a set to the nearest point in the other set (Rote 1991).

However, two concepts may be matched even if there are other pairs that are better matched. Structural methods (Cruz and Sunna 2008; Melnik et al. 2002) consider the structure around each of the two concepts being matched, that is, the concepts that are adjacent to them. Then, the two concepts match if their adjacent concepts also match.

Examples of Application

Apart from facilitating complex geospatial data analytics, spatial data integration also enables data accessibility (i.e., data storage and retrieval) and data interoperability (i.e., compatibility with other datasets). Some applications that benefit from spatial data integration are described next:

Utility Data Integration: This application facilitates the exploration and analysis of the impact of disruptions in urban infrastructure systems. There are several frameworks that address the challenges in integrating utility data from different perspectives (Beck et al. 2007, 2008; Psyllidis et al. 2015).

Land-use Matching: This application maps two different land-use ontologies (Cruz and Xiao 2008; Cruz et al. 2007), which classify land parcels based on their usage, for example, residential, industrial, agricultural, or commercial, so that a single query can retrieve those parcels across different classifications.

Spatial Phenomena Correlation: This application computes the correlations between different spatial phenomena such as crop rotations and biodiversity (Tran et al. 2015) by integrating a land-use dataset and a biology dataset.

Environmental and Disaster Analysis: This application uses the query language SPARQL extended with geometric objects, set operations on those objects (e.g., union), and the result of spatial transformations on those objects (e.g., buffer), to ask queries that return the names of the towns that have been affected by fire and to construct new geometric objects, for example, the burnt areas in coniferous forests (Kyzirakos et al. 2014).

Future Directions for Research

Each of the challenges associated with big data – volume, variety, variability, velocity, and value – is patent in geospatial data integration. A comprehensive environment for integrating and analyzing geospatial data has several layers, each being conceptually complex when considered on its own and even more so when considering the interactions among them. Those layers include data extraction, data translation, ontology extraction, syntactic and semantic matching, spatiotemporal matching, application, visualization, and analytics, together with two crosscutting layers: machine learning and querying (Cruz et al. 2013).

Ontology-based approaches resolve structural and semantic heterogeneities. These are expressive techniques that enable cross-database queries and reasoning on the spatial, temporal, as well as the spatiotemporal relationships. However, ontologies are often not available for the domain of interest and even when available can be location

dependent. For example, an ontology of crime in Chicago may not apply to New York City. Land-use ontologies also vary across municipalities and counties (Wiegand et al. 2002) but can be created from the corresponding taxonomies. It is, however, nontrivial to incorporate the associated unstructured information in the ontology. Hence, the creation, reuse, and evolution of ontologies need to be streamlined.

In addition to the expressiveness issues, other issues pertain to the computational efficiency, for example, of record linkage (Felleji and Sunter 1969; Kelley 1984), large ontology matching (Faria et al. 2017), or geostatistical scale mapping (Gotway and Young 2002). When several of these strategies need to be applied, their optimization is necessary, possibly along with the determination of the order of execution of the various layers to improve overall efficiency.

Definitions

The growth of spatial data which plays a part in the agricultural products, sustainable development, and human society development is accumulated continuously. Not only the size and volume are immense, the structure is also convoluted with the abundant and deep of their contents. The spatial dataset is full of the information and experience collection from geomatics that relates to Remote Sensing (RS), Global Positioning System (GPS) and Geographic Information System (GIS). A wide variety of databases consist of electronic maps and planning network from their infrastructure. With the increase in the spatial data collection, the processes of gathering, management, and transmission data require the powerful techniques. The traditional methods lag of the ability of big data query. Thus, the Spatial Data Mining (SDM) becomes the suitable technique. The Knowledge Discovery from Geographical Information System database (KDG) approach can support SDM to be more developed in data mining and geomatics (Li and Cheng 1994). The discovered knowledge from spatial datasets can support a decision-making system on various areas such as urban planning

and construction, transportation, resource allocation, capital optimization, marketing, and medical treatment. Then, SDM benefits the global sustainability. However, the large volume of spatial datasets will impact definitely the execution time. Then, the computerization which is composed of a computer chip, a power of a central processing unit, and a transfer rate of communication channel will boost up an acceleration of an interactive process. Presently, the artificial intelligence (AI) and machine learning (ML) are important roles instead of the manual process. AI is in charge with the human deterministic intelligence simulation by three strategies which are symbolism, connectionism, and behaviorism. While the ML supervises on the human learning simulation which obtains the knowledge form expert systems automatically, SDM will request the AI and ML to improve the data mining capability.

Recently SDM is popular to present the discovered knowledge through the real-world application but should concern over the crisp data or uncertain data. In that case, the probability theory, spatial statistics, rule induction, clustering analysis, spatial analysis, fuzzy set, data fields, rough sets, genetic algorithms, visualization decision trees can support those issues (Ester et al. 2000).

Overview

SDM Concepts

The SDM can enhance the human ability for extracting, applying, and transforming the spatial data in the real-world application. Because the ML and AI belong to the SDM procedure, the SDM is more understandable by both mathematic and non-mathematic theories. So, the SDM is a technique to clean, sample, and convert a vast and complex spatial data.

The SDM Pyramid is a symbol of SDM Concepts which concentrates on transforming from the spatial data to information and knowledge. The process starts with the data preparation, data mining, and post-processed of data mining. If the description is more abstract,

coherent, and general, the technologies will be more deep and advanced. Piatetsky-Shapiro (1994) reviewed the concept of data, information, and knowledge pyramid (DIKP). The study proposed that the different levels of data presented the different concept element. So, it was impossible to make the association between each concept. Han et al. (2012) demonstrated the visual process of data mining by different graphics. However, their work was imperfect to present the role and difference of elements. It implied that the complexity of spatial data was difficult to depict the levels of data. It is compulsory to integrate DIKP and the process of SDM in order to clarify the concept and roles of SDM. Thus, the SDM Pyramid in Fig. 1 is presented as a result. The SDM Pyramid specifies the level of spatial data from bottom to top. Each level of data presents the different element concept. The SDM pyramid is the main solution of transferring and managing data between layers. For example, the RS images, the images data are analysed and usually take the resolution in distinct layers. The top layer is the coarsest resolution and small scale, while the bottom layer is the finest resolution and largest scale. Then, the data is indexed and well-organized can browse in the multi-source, multi-scale, and cross-resolution image. The SDM pyramid manifests the data characteristics from spatial knowledge to the spatial data in real world. The amount of spatial data directs variation to the data complexity. The more simple data is, the more spatial data quantity contains.

Spatial Data to Spatial Knowledge

The SDM applies an interdisciplinary methodology to acquire spatial knowledge effectively. Each unit of spatial numerical values, spatial data, spatial information, and spatial knowledge presents the dissimilar concepts but connects in detail.

- Spatial Numerical

The spatial numerical represents between a specific value and a measurement unit. The spa-

tial numerical is a transmission when the spatial objects are gathered, transformed, and applied by the computerized SDM.

- Spatial Data

The spatial data can represent raw data or processed data. The processed data illustrates digital and nondigital data such as numbers, words, symbols, graphics, images, video, and language which utilizes the raw data. The spatial data can be a reference in order to know spatial objects and numerical nature with various attributes.

- Spatial Concept

The spatial objects together with their implication and extension describe the spatial concept. The spatial concept may involve in the problem-solving and indicate the states of spatial objects

- Spatial Information

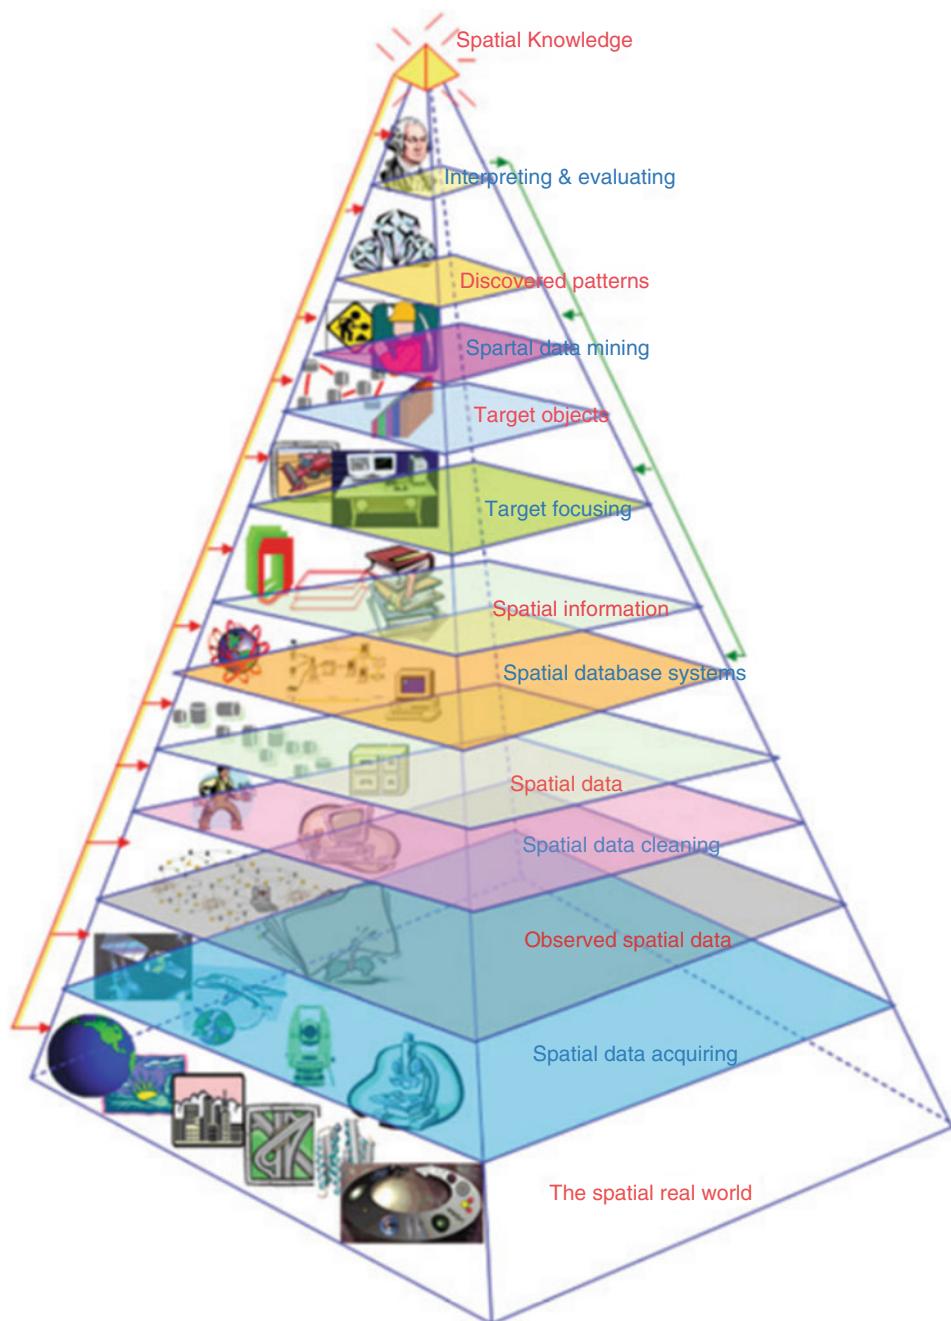

The analysis of spatial objects in the dataset can determine the spatial information. The spatial information demonstrates the meaningfulness and eliminates the possible uncertainty. It is imperative to be the decision-maker.

- Spatial Knowledge

The spatial knowledge is built from one or more parts of the spatial information. The spatial knowledge is depicted through the processes of correlation, association, classification, and clustering. Both spatial information and spatial knowledge require SDM in the data processing.

- Unified Action

The spatial data carries information to specify their properties, quantities, location, and relationship. So, the unified actions of spatial numerical values, spatial data, spatial concept, and spatial information become the spatial knowledge.

Spatial Data Mining, Fig. 1 SDM Pyramid (Li et al. 2015)

Spatial Knowledge to Discover

In an effort to discover the various spatial knowledge, SDM requires various techniques under “rule plus exception” with different views. The

miscellaneous preset rules have already qualified on the practical manipulation such as General Geometric Rule and Spatial Association Rule, Spatial Characteristics Rule and Discriminate Rule,

Spatial Clustering Rule, Classification Rule, Spatial Predictable Rule and Serial Rule and Spatial Exception or Outlier. Therefore, the spatial knowledge is extracted properly to be the Discover (Li and Du 2007).

Spatial Knowledge Representation

SDM promotes the spatial knowledge representation in order to demonstrate the knowledge. The integration of traditional expression methods can enhance the conversion of the knowledge expression method efficiently. When the knowledge extraction finishes, the knowledge measure can bound the level to depict the discovered pattern which is meaningful and interesting. A natural language, predicates logic, function model, characteristic table, semantic network, and Petri net are fundamental representations. For example, the natural language which is a general knowledge recognition of uncertainty can interpret spatial datasets based on human thinking. It is an effective tool to reorganize the thinking process. The concept is to map the object from the objective to the subjective cognition. Hence, the more the knowledge is abstract, the more the natural language is proper.

SDM Data Source

Contents and Characteristics of Spatial Data

The primitive data sources of spatial data are geographic contents. The spatial data acquisition gathers from radar, infrared, photoelectric, satellite, digital cameras and telescopes. There are three acquisition methodologies which are point acquisition, area acquisition, and mobility acquisition. The point acquisition is performed by the GPS receivers which collect the coordinates and attributes of surface points on Earth. The area acquisition targets the large areas of images which are geometrical and physical features. The mobility acquisition incorporates with GPS, RS, and GIS to observe the Earth system.

After gathering data, the main characteristics of spatial data which are size, complexity, dimension, and certainty definitely differentiate

from the common data. The location-based spatial and no-spatial data imply the implication of objects. The spatial object is a core of an object-oriented data model such as point, line, area, or complex objects in the large dataset. A point can be a single, directed, and grouped point which presents the location on the Earth surface without shape and size in the computerized system. Then the interconnection between points presents a line as rivers and roads. The line presents the spatial curve of Earth surface as linear from point-to-point or the reticulated pattern. After that, the shape and size of lines illustrate an area as the curved surface of Earth. Finally, a complex object combines more than two objects of point, line, and area.

To enhance the efficiency of the target, three main characteristics of spatial data are time, location, and theme. Due to dynamic changes, time is sensitive to collect and compute the spatial data. The gathered data should be affirmative and reliable such as weather forecast. Next, the location determines the location relationship. The topology and relationship are demonstrated by position, azimuth, shape, and size of a spatial object. Then, the theme is an extraordinary characteristic which defines the land endurance, pH value, land cover, and population density. Some developed technology such as RS is necessary to request more thematic data acquisition. The spatial data is compulsory to utilize carefully because their characteristics impact the occurrence of spatial data fusion easily. However, the spatial data uncertainty is ubiquitous during the implementation. To maintain the consistency and the integration of spatial data for bringing out spatial objects, all techniques are required to solve those issues.

Spatial Data Model

A common use of spatial data models are hierarchical model, network model, relational model, and object-oriented model. Both hierarchical and network models address the relationship between objects which consider the path of data, storage, and accessibility. The hierarchical model of 1 or more than 1 root node(s) and leaf node(s) can store and access the hierarchical database

efficiently although users' interaction are inconvenient. The network model relationship is the connection between arbitrary records with others. Then, the occurrence of multiple relationships is possible to depict as an undirected graph even if it is the irregular structure. The relational model composes of row as an entity record and column as an entity attribute. When the model concerns the relationship between two connected dimensional tables with conditions, the unique and foreign keywords require. The unique keyword is a single or composited attribute for indicating the entity, while the foreign keyword is the relationship between entities. If relational model contains the Boolean logic and arithmetic rules, the Structured Query Language (SQL) has to manage the data. The Object-Oriented model has been highly valued in GIS application since late 1980s and early 1990s. The spatial objects relationship is expressed by the generalization, union, and aggregation. After that the model was integrated between the object-oriented and database techniques. When the complicated relationship or nested relationship exists, it is better to present as a table structure.

Spatial Databases

The spatial database is built for being a tool equipment and data manipulation. The definition, representation, and storage of spatial data diverge the common transactional data. The spatial data can be collected by the data manipulation of surveying and mapping database. The different purposes will be fulfilled with the different database. There are general database, graphic database, and image database. In addition, the digital elevation model (DEM) database is productive data arrangement. When a unified spatial index is developed, users can find the data of any domain fast. The large-scale databases are also not against the performance of data display. The spatial index allows users to access data by retrieving and transferring among different levels effortlessly.

From GGDI to Big Data

The GGDI which stands for Global Geospatial Data Infrastructure can run on the Digital

Earth. GGDI to Big data is from 1970s which published the "Information Society." The study discussed on a global information infrastructure with the telecommunication infrastructure. After 10 years, the "Centralized Land Information Database" introduced a more complex network of distributed land information. The data resource management was adopted from a common approach to a computer based. Then in 1990s, the Spatial Data Infrastructure (SDI) was originated to support and accelerate the geographic data exchange standards. The local interests, demands, and constraints of country or organization are effected by the developed GGDI.

Presently, developers who usually apply the new technology for supporting their work, study and life, the digital contents are invented to present in form of internet of things and cloud computing. Thus, the big data seems to be an essential source for the digital content applications. The simulation of digital earth becomes popular in many countries. Most of the services utilize the technology of RS, GIS, ML, AL, and Internet of thing. The applications on network mapping, Web 2.0, and mobile sensors on vehicles impact significantly to the users' experience. Therefore, the spatial information system is obvious different from a traditional information system. The new geo-information systems are professional to serve the data and publish to all users. Hence, the new geo-information era improves the whole system of the geospatial information industry to prosperity. Soon the geo-information benefits for all aspects and leads to smart city definitely.

Key Research Findings

Bottleneck of SDM

Because of complex spatial entities, geographic location of features, boundaries, and relationship, SDM is capable to identify. However, the bottleneck of SDM is attentive. Some researches were

achieved with those goals but some difficulties need to be solved.

- Excessive Spatial Data

The geo-graphical information is imperative to accomplish the application development. The data source comes from RS, digital techniques, networks, multimedia, and images. So, the spatial database expands and grows rapidly. With the issues of immense dataset, the traditional implementation cannot manipulate with tons of spatial data such as the enumeration method of data analysis. Therefore, the data mining (DM) was introduced and capable to improve.

- High-Dimensional Spatial Data

The spatial data grows in both horizontal and vertical attributes, but the GIS information is still inadequate to illustrate the spatial data with high-dimension structure. The discovered knowledge can resolve the challenged. For example how to accelerate for searching and query the target data or how to decline the number of dimensional data.

- Polluted Spatial Data

The spatial entities may contain both useful and polluted data. The organized spatial data should concern about position accuracy, attribute accuracy, consistency, lineage, and integrity. The polluted spatial data is in a form of incompleteness, dynamic changes, noise, redundancy, and sparsity. They can cause a low-quality standard of data accuracy.

- Uncertain Spatial Data

The uncertain spatial data in SDM is impossible to avoid because of the approximate sample data and abstract mathematical models. Due to the crisp set, probability theory, GIS model, the sensitivity analysis for SDM can normalize to be a certain data. However, a related special entity of

every single attribute can be emphasized instead of spatial data uncertainty.

- Mining Differences

The SDM utilization succeeds in understanding and gathering the different cognitive hierarchy of spatial dataset. The different mining on different aspects will return the different results from the results of discovered knowledge despite the same database. In addition, the making use of SDM can present a hierarchical decision-maker's awareness among those differences.

- Problems to Represent the Discovered Knowledge

The natural language is the best way to illustrate the conceptual knowledge which is a kind of the discovered knowledge. An exclusion of data uncertainty in SDM process will return incomplete knowledge and be full of errors although the adequate techniques are provided.

Methods and Techniques in SDM

The variety of methods and techniques impact directly the discovered knowledge in SDM. Each method supports the different characteristics based on the context. The SDM also concerns the evolution of human thinking network and optimal solution processes.

S

Crisp Set Theory

The Crisp Set Theory was introduced by Cantor in nineteenth century based on the modern mathematics. The theory approaches on probability, evidence theory, spatial statistics, spatial analysis, and data field. The probability which was conducted by Arthurs in 1965 works properly in the stochastic probabilities with randomness spatial data. Actually, the probability is unlike from the likelihood. The big probability does not present the high likelihood and vice versa.

Then, the evidence theory is known as Dempster-Shafer theory or significance theory. When the evidence exists, the hypothesis

evaluates a minimum of the belief function. Hence, the hypothesis cannot be denied because the plausibility function measures the maximum degree. However, the evidence is null by the unsupported interval. The evidence theory can also be an identification to probability theory. It implies that the evidence theory is the extension of the probability theory. The evidence theory is divided into two parts by the SDM technique which are the certainty measures confidence and the uncertainty measures likelihood. So, the framework of evidence data mining (EDM) concentrates on mass functions and mass operators to discover the knowledge.

Moreover, the spatial clustering presents the concept of similarity. The cluster determines the dataset to maximize the similarity and minimize the dissimilarity between clusters. The data is clustered by the object characteristics through spatial raw data. Only the basic object attributes can figure directly the meaningful clusters in a spatial dataset. Then, the data point in a multi-dimensional feature space can also cluster for the pattern recognition.

Extended Set Theory

SDM is capable on the similarity of human thinking on certainty and uncertainty. The crisp set examines the certainty, while the extended crisp set considers the uncertainty. To classify which group elements belong to, the crisp set bounds the binary logic of 0 and 1 as the full membership or no membership. However, the indeterminate boundaries are not accurate with the crisp set methods. Hence, SDM enhances the crisp set theory on uncertainty by using fuzzy set, rough set, and cloud model.

The fuzzy set is the fuzziness on a fuzzy membership. A close interval as [0, 1] of the partial membership defines an uncertainty probability. Two main fuzzy techniques are the fuzzy comprehensive evaluation and fuzzy clustering analysis. The fuzzy set is more proper to classify the spatial heterogeneous distribution of geographical uncertainty. The more fuzziness is created, the more difficult and complex system is. The approximation of the elements is close to 1 means the more possible belong to the target class.

Next, a rough set focuses on an incompleteness of the lower and upper approximations in SDM. An incompleteness-based reasoning method fulfills a decision-making by the characteristic of certainty and uncertainty data. The rough set favors on the partial membership with a set of an open interval and two different terminals as {0, (0, 1), 1}. The difference between lower approximation and upper approximation sets is the indeterminate boundary whether the sufficient information of objects can classify the class belongs to. The more information of the equivalent class is classified, the more accurate objects description is.

Finally, the cloud model requires the partial membership with the random close intervals. The data distributes stochastically in the space as random [0, 1]. The randomness integrates with the fuzziness in order to conduct a model of mutual information between qualitative concepts and quantitative data.

Bionic Method

The Bionic method is the representative of Artificial Neural Network (ANN) and genetic algorithm. The neural network simulates a human brain as the networked patterns by a self-adaptive nonlinear dynamic system. The ANN contains many neurons which are connected with the immense and sophisticated junctions. The classification, clustering, and prediction GIS data of SDM with the complicate system and connected plentiful of neurons are successful by ANN. The ANN implements more precisely than the symbolic classification. The numerous neurons processing seems as a network that creates the non-linear function of a complex system. The information processing of neuron network involves with three layers which are input, middle, and output. The three layers operate depending on the dynamic response from the network status to the external data input. If between input and output layers have multiple hidden layers of units, ANN turns to be a deep neural network with the given method of deep learning. ANNs can reduce the noise disturbance in pattern recognition. So, the network is efficient on the high fault tolerance and robustness. If ANN is the nonlinear system

with many input variables, their convergence, stability, local minimum, and parameter adjustments of the network will be affected.

Others Related

- Rule Induction

The rule induction focuses on searching generic rule from the massive empirical data. The induction relates the basic statistical facts and instance of a big data while the deduction involves with axioms or basis reasoning on acknowledge knowledge (Clark and Niblet 1987). A concept tree and the rule induction which are the high-level patterns manipulate on uncovering the patterns among the spatial dataset.

- Decision Tree

The decision tree evolves the classification or decision set as a tree under certain spatial features. A test function on the tree structure of SDM generates the training object sets. Every created branch sets contain lower-nodes and sub-branches which generate iteratively. The leaf nodes are possible to be positive and negative examples.

- Visualization Techniques

In SDM, the spatial data and knowledge are better to explore and present visually. The form of visualization is worth than the words. The abstract patterns, relations, and tendencies of spatial data can be converted into the visualization by the computerized mechanism. The final results of visualization can be clarified by charts, maps, animations, graphics, images, trees, histograms, table, multimedia, and data cubes.

SDM Software

The SDM software implements the functions for discovering the spatial knowledge. The spatial data is truly existent the immense volume in the database. The implementation techniques are made use to instruct the computer understand

what is knowledge to find and how to find the spatial knowledge. The SDM software has to manipulate with the data mining system. The decision-making system is supported by the extraction of high level information. The Knowledge Discovery and data mining are invented as a technique to reveal the strategic information hidden.

Not all tools can support the knowledge discovery and data mining, the proper tool will be selected based on the data characteristics. As a feature classification scheme, was purposed and studied by Goebel and Gruenwald (1999). The researchers extracted the features of 43 different tools based on 3 groups that are general characteristics, database connectivity, and data mining characteristics. The results showed that first 2 groups describe the ability of each tool supports what kind of data. Then the third group showed that rule induction, decision trees, and statistical methods are the standard data mining techniques while the fuzzy and rough sets or genetic algorithms started developing on the knowledge discovery software.

The software can interact with the database and data warehouse. After that, the distributed and heterogeneous data are needed to operate from offline-based to online-based (cloud computing). The technology of Google or Baidu have to accelerate the services for end-users which support the location-based, positioning, recommendation and manufacturing. The application started with toolkit that is ready-to-use software. Their functions provide the variety of data mining algorithms such as IBM Intelligent Miner, SPSS Clementine, SAS Enterprise Miner.

The SDM software for the spatial data mainly focuses on the GIS data and RS images. Li et al. (2016) studied and implemented the GIS-DBMiner for GIS data and the RSImageMiner for imagery data. The GISDBMiner supports the common structured data which is stored in the database. Users start by sending the knowledge discovery command and the signals to spatial DBMS which enable to access the spatial database. Then, the algorithm performs and returns the discovered knowledge as the output. For the RSImageMiner is powerful of

the data management and data mining on image features such as shape, color, texture and pattern. The RSImageMiner manipulates the RS imagery data which working on the mining process to discover the feature knowledge. Then, continue with the knowledge-based image classification, retrieval and object recognition (Li et al 2015).

Examples of Application

The methods and techniques in SDM are powerful to increase the quality of the discovered knowledge. As the mathematical foundation of those algorithms, the classification, clustering, and prediction on the spatial data mining are interesting. Koperski (1999) reviewed a two-step decision classification by first spatial predicates extraction with the relief algorithm of ML. Both spatial (which refers to the data of geographic location, size and shape objects on the planet) and non-spatial (which refers to a creation of text, image, multi-media data for linking with the spatial data to specific the location) (Diwakar 2013) predicate the integrated with knowledge of classification decision. Then, the regional classification rules with a fuzzy decision tree in an object-oriented spatial database are examined (Marsala and Bigolin 1998). Moreover, the rough set applications also apply the various fields of approximate reasoning, ML, AI, pattern recognition, and knowledge discovery. The further improvement of rough set can be continued with the studying of the field of geospatial information sciences such as geo rough space.

The developed SDM applications focus on the behavioral data in the system due to the continuous growth in volume of the spatial data. The Internet-based geographic information (Goodchild 2007) and location-based sensing services are important to update the spatial information. The spatial data is employed in the electrical maps, planning networks, land use construction, and protection on farmland. Hence, the making use of GPS, GIS, remote sensing, radar, infrared computerized tomography imaging, etc. can be the merging techniques to rise up the application performance.

Future Directions for Research

From the SDM concepts and techniques mentioned above, there are previous researches that studied and applied the spatial data on geographical information to solve problems of resources changes (Berger 2001), environment changes (Mannion 1995), and land-use allocation effect (Carsjens and Van Der Knaap 2002). Hence, the possible future directions for research can adjust to an agriculture aspect. The trend of agricultural product is advertent and proposed. Since the main occupation in the agricultural countries works on the cultivation which can crop yearly. The mass volume of agricultural products is continuous growth. Then, the economic trend of each country and the world in both short and long-term can be driven by those farm produce. The product's popularity is the major impact for forecasting the demand and supply in the real market. If the quantity of agricultural product can be predictable, it definitely benefits to various clients. In term of investor, they can consider on the investment. While in term of government, they can determine the policy direction to support the agriculturists.

Definitions

Digital modeling of real-world networks (e.g., road networks, river network) to accurately represent geographic information is done using spatial graphs. Spatial graphs can represent n-ary relationships to model complex relations in the network. They differ from existing geographical models that can only represent binary relationships. Spatial graph is formally defined using the concepts of Xnodes and Xedges and Xgraphs in the following paragraph.

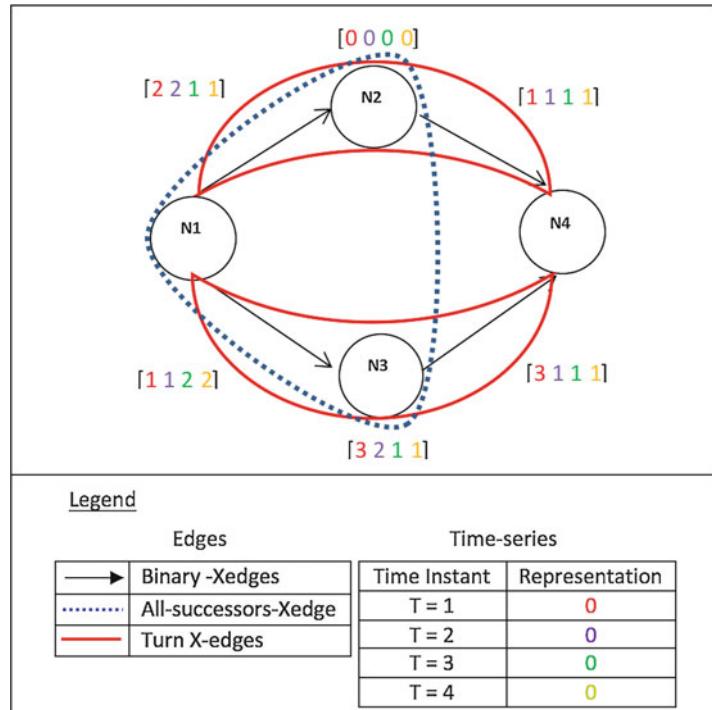

Xnode represents a real-world network feature (e.g., road intersection) that can have scalar or structured values (e.g., an array of scalars).

Xedge is a tree of Xnodes that can have scalar or structural values. Further, Xedge can be classified based on the type of network features being modeled (e.g., turn-Xedges) as shown in Fig. 1.

Xgraph can be defined as a set of Xnodes and a set of Xedges. **Spatial graph** is an ensemble of Xgraphs, which can represent n-ary relationships or discontinuity in a real-world network. Spatial graphs differ from hypergraphs because it consists of Xedge that can have a tree structure, whereas hypergraphs do not adhere to any specific structure.

Spatial graph big data is defined as a dataset with the following properties: (a) it describes the attributes of an Xgraph including attributes of its Xnodes, Xedges, and other substructures and (b) its volume, velocity, or variety exceeds the capacity of current data platforms. Examples include the longitudinal traffic volume associated with transportation networks such as road maps, as well as routes of airlines, buses, trains, ships, etc. as detailed in section “[Examples of Application](#)” on applications.

Figure 1 depicts a spatial graph big data with four nodes representing road intersections, namely, N1, N2, N3, and N4. The graph has seven Xedges including four binary Xedges ($N1 \rightarrow N2$), ($N2 \rightarrow N4$), ($N1 \rightarrow N3$), and ($N3 \rightarrow N4$) representing road segments connecting adjacent road intersections. The graph has an all-successor Xedge ($N1 \rightarrow (N2, N3)$) to represent the group of binary edges ($N1 \rightarrow N2$) and ($N1 \rightarrow N3$) from Xnode N1 to its children Xnodes N2 and

Spatial Graph Big Data,**Fig. 1** Example of spatial graph big data

N3. It also has two turn-Xedges ($N1 \rightarrow N2 \rightarrow N4$) representing a right turn and ($N1 \rightarrow N3 \rightarrow N4$) representing a left turn. The time series associated with the turn-Xedges represent turn delays. In this example, the right turn (i.e., $N1 \rightarrow N2 \rightarrow N4$) has no wait. However, the left turn has a wait of 3 for start-time 1, 2 for start-time 2, 1 for start-time 3, and no wait for start-time 4. Note that, in the figure, there are seven Xedges but six time series, because all-successor Xedges do not have a time series associated with it. For brevity “spatial graph” term is used in place of “spatial graph big data” in the following text.

Overview

City development aims to connect existing resources to ensure a productive environment for prospective citizens. Historically, the urban development has been driven by the stability of the major roadways that form the backbone of the urban infrastructure (Strano et al. 2012). In modern times, urban dwellers and goods are increasingly connected by multiple networks sup-

porting different means of transportation. The road networks have been augmented by rail networks (intercity, intracity), airport networks, and the port networks found located in cities near major rivers or navigable water bodies. These networks heavily influence many aspects of modern society, and they are implicated in many modern problems such as disease spread, congestion, and urban sprawl (Barthélemy 2011). Therefore, it is important to know how to model and analyze these types of transportation networks. In this regard, technology plays an important role to model the networks and understand their utilization.

Technological advancements, especially in the field of satellite systems, the Internet, and smartphones have had a major impact on the use and modeling of urban networks. GPS (Masumoto 1993) one of the Global Navigation Satellite System (GNSS) technologies (Lechner and Baumann 2000), is now used extensively for navigation on road networks. Further, Internet accessibility to smartphone users has been made possible by the advancement in electronics. Furthermore, when monitored at regular intervals, the location data from these devices allows us to digitally map

various movement activities (e.g., travel routes) to their physical locations, using map-matching techniques (Jensen and Tradišauskas 2009) for every user to perform different types of analysis (e.g., generating historical profiles of driver behavior).

Proliferation of technologies and the location data they generate is growing exponentially. In 2015, there were already around 2.6 billion smartphone subscriptions globally, and this number will continue to rise in the future especially in developing countries where the market is still maturing (Lunden 2015). In addition, commercial vehicles are using more sophisticated GPS devices that can monitor a variety of engine parameters (e.g., fuel usage, speed, etc.) in addition to location. Therefore, it is necessary to build technologies which can accurately and effectively model location-based data that are ever-growing size, variety, and update rate. In a big data paradigm, these issues correspond to the standard three Vs, i.e., volume, velocity, and variety (Zikopoulos and Eaton 2011). New database management systems are required to effectively harness these datasets.

In general, database applications are modeled using a three-step design process beginning with a conceptual data model (e.g., entity-relationship model), a logical data model (e.g., relational schema), and finally a physical design (e.g., R-Tree). To handle spatial features, the entity-relationship (ER) models were modified to pictogram-enhanced ER (PEER) to improve the geographical representation of the data in the model. The relational schema was modified by incorporating appropriate data types from SQL3 onward and translating the spatial relationship into spatial integrity constraints (Shekhar et al. 2004). Spatial graphs represent the physical modeling phase for modeling spatial network data, where, traditional graphs were modified to be-

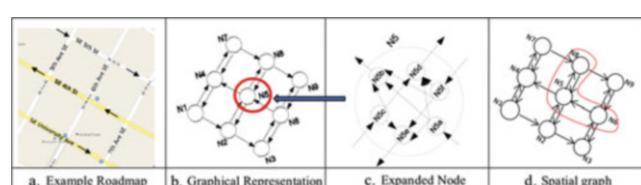

come a spatial graph to represent complex network properties with scalar or structural values.

To illustrate the limitations of simple graphs while modeling turns, consider the example road map as shown in Fig. 2a. Figure 2b shows a graphical representation of the road map where every node represents a road intersection and every directed edge represents a left or right lane of the road segment. In the original graph, the right turn at node N5 can be modeled as $N_6 \rightarrow N_5 \rightarrow N_8$, which requires the use of three nodes and two edges (3N, 2E). Consider, Fig. 2c, where the node N5 is expanded to six sub-nodes to model the turns at the intersection. Now the turn can be represented using $N_{5a} \rightarrow N_{5e}$, i.e., with just two sub-nodes and one edge, and no information is required from the other intersections. It is useful to be able to model turns at an intersection independent of other intersections. Finally, consider Fig. 2d that shows spatial graphs of segments and turns as turn-Xedges to represent the road map. The red-colored Xedge represents the turn; thus, with spatial graph, the turns can be modeled using a single Xedge.

Spatial graphs have been extensively studied in three main areas, namely, data modeling, database storage, and data mining algorithms. The research in spatial graph modeling is motivated to develop simple and effective representations of the data. For example, network size can grow rapidly as new nodes are added, and a simple model should easily accommodate and adapt to the changes. The spatial graph research in data storage is motivated to provide efficient graph-based operations (e.g., node retrieval, edge retrieval). The operations require data related to the same route; therefore, techniques (Evans et al. 2010) that store data on routes together helps to reduce the number of data page access. The research in the area of data mining uses spatial models to solve problems such as finding shortest

Spatial Graph Big Data,

Fig. 2 Modeling turns
(Shekhar et al. 2012) [Best in Color]

cost (e.g., shortest travel time) to different destinations or route planning to maximize traffic flow or crowd movement toward a destination (George et al. 2007). Section “Research Areas” describes each of these domains in further detail. Readers interested in example applications or future directions may consult section “Examples of Application” or section “Future Directions of Research” of this entry, respectively.

Research Areas

Modeling Spatial Graphs

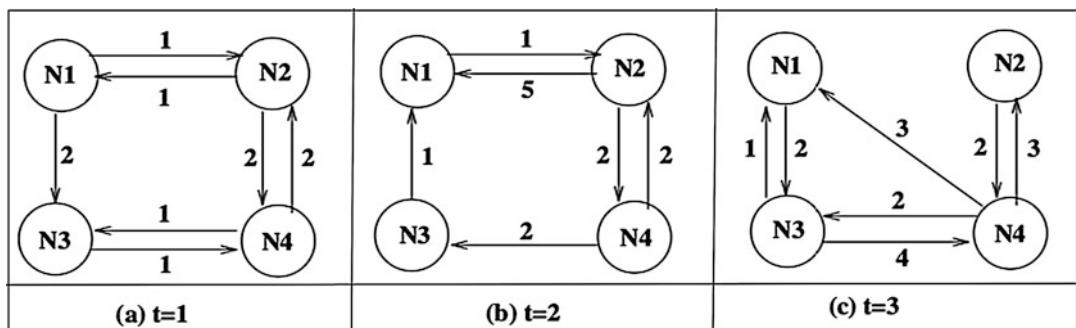

Spatial graphs typically represent transportation networks that can be viewed from one of two frames of reference, Eulerian or Lagrangian (Batchelor 2000). In the Eulerian frame of reference, traffic is observed as it travels past specific locations in the space over a period of time. It is similar to sitting on the side of a highway and watching the traffic pass a fixed location. In the Lagrangian frame of reference, the observer follows an individual moving object as it moves through space and time. This can be visualized as sitting in a car and driving down a highway. The following text discusses three spatial graph models: the snapshot and the time-aggregated graph (TAG) models, which use the Eulerian frame of reference, and the time-expanded graph (TEG) model, which uses the Lagrangian frame of reference (George et al. 2007).

1. Snapshot Model

A snapshot model represents a spatial graph with temporal attributes using a finite set of nodes and a finite set of edges connecting the nodes. Temporal attributes are represented by discrete time steps, each represented by a snapshot as shown in Fig. 9. The figure shows three time steps, $t = 1$ to $t = 3$, and shows the effect of temporal change on an edge, indicating travel time. For example, at time $t = 1$, edge N2-N1 has a value of 1. In the next time step, $t = 2$, the edge value increases to 5, indicating an increased travel cost for the edge.

2. Time-Expanded Graphs

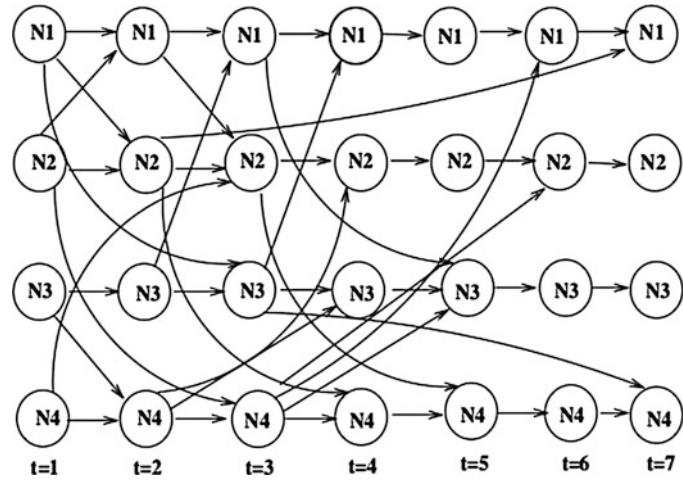

A time-expanded graph (TEG) (Köhler et al. 2002) model replicates each node along the time series such that a time-varying attribute (e.g., travel time) is represented between replicated nodes. Figure 4 shows the TEG corresponding to the spatial graph displayed earlier (Fig. 3). From the figure, observe that for edge N1-N2, weight of 1 is represented by an edge from N1 at $t = 1$ to N2 at $t = 2$. Further, the recurrence of similar edge across time between N1 and N2 at $t = 2$ mimics the invariance of edge weight over this time period. It is also interesting to see that N2 at $t = 1$ has an edge to N1 at $t = 2$ and that N2 at $t = 2$ has an edge to N1 at $t = 7$. This is because the edge weight for N2-N1 changes from 1 at $t = 1$ to 5 at $t = 2$ (Fig. 4).

Spatial Graph Big Data, Fig. 3 Snapshot model (George et al. 2007)

Spatial Graph Big Data,

Fig. 4 Time-expanded graph (George et al. 2007)

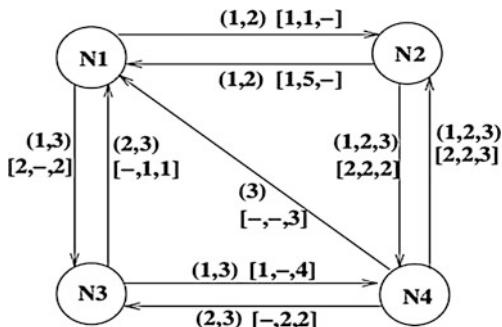

3. Time-Aggregated Graphs

A time-aggregated graph (TAG) stores a spatial graph with temporal attributes as the tuple $\{N, E, \text{Map}(N, TS_N), \text{Map}(E, TS_E), W\}$, where N is a set of nodes, E is a set of edges (E), $\text{Map}(N, TS_N)$ is the mappings from nodes to the time series associated with the nodes, $\text{Map}(E, TS_E)$ is the mappings from edges to the time series associated with the edges, and W is the time-dependent weights (e.g., travel time). Figure 5 shows the corresponding TAG for the networks as shown in Figs. 3 and 4. Observe that that node N1 has two time series associated with it for edge N1-N2 (1, 2) and N1-N3 (1, 3). Then, observe that the time-dependent weights for these edges are $[1, 1, -]$ and $[2, -, 2]$, respectively. The “-” symbol represents the time $t = 3$ when the edge N1-N2 does not exist.

Storage of Spatial Graphs

Large-scale spatial graphs with temporal attribute have hundreds of thousands of nodes and millions of time steps, amounting to terabytes of data. It is appropriate therefore to focus on secondary techniques for the storing of time-attributed spatial graphs for database systems. Figure 6 shows the process of storing a spatial graph. These methods make use of data files consisting of data pages and an indexing method. These methods employ an indexing method to output a data file containing the spatial graphs partitioned across

Spatial Graph Big Data, Fig. 5 Time-aggregated graph (George et al. 2007)

a set of data pages. Incorporating temporal data into a spatial graph poses significant challenges to their storage and analysis of disk I/O. Network topology and temporal access patterns add further constraints to the accessibility of data records.

One solution is to physically store topologically related nodes in the same data page, reducing the cost of data-page retrieval. Further, as the storage size decreases, the I/O cost is reduced due to a fewer number of pages containing the same data. The following texts describe three methods for storing spatial graphs: snapshot partitioning, longitudinal partitioning, and non-orthogonal partitioning. First, however, it is necessary to explain the concept of orthogonal storage vs. non-orthogonal storage, also known as synchronous time grouping vs. asynchronous time grouping.

Spatial Graph Big Data, Fig. 6 Process of storing spatiotemporal networks (STN)

Synchronous vs. Asynchronous Time Grouping

Synchronous time grouping is the clustering of data within a set time series, whereby some numbers of nodes and edges are stored within a set time interval. Each page is a snapshot, and longitudinal scheme represents a continuous time interval, either one time step or the entire time series. An example is storage of A1, B1, C1, and D1 in the same data page for snapshot partitioning as shown in Fig. 7a and storage of A1, A2, A3, and A4 in the same data page for longitudinal partitioning as shown in Fig. 7b. Asynchronous time data grouping allows storing data for disjoint time intervals. Thus, data from different time intervals are grouped and stored on the same data page. This model is known as sub-node model. It is useful for queries that retrieve the traversal times beginning at each time instant where temporal data is mostly not accessible orthogonally. An example is storage of A1, B2, C3, and D4 in the same data page as shown in Fig. 7c for Lagrangian-connectivity partitioning.

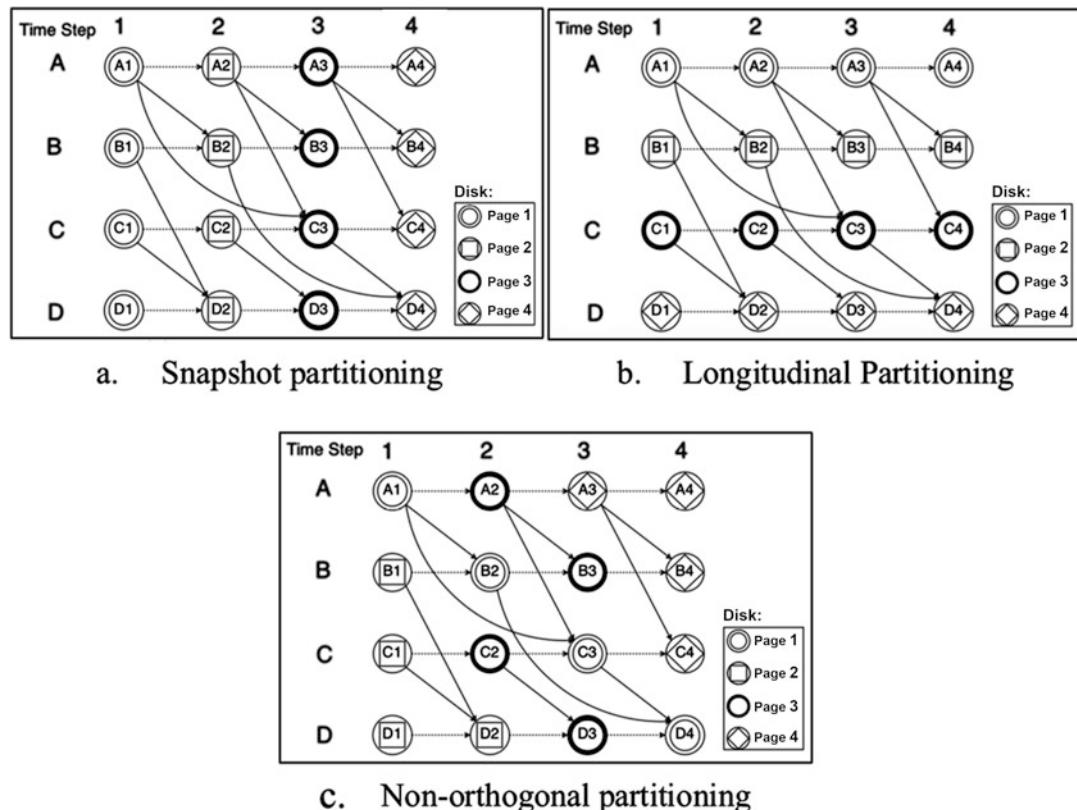

1. Snapshot Partitioning

Snapshot partitioning stores the data in pages using quad tree-based geometrical structures (e.g., R-Trees, R+-Trees, etc.). Figure 7a shows an example of snapshot partitioning, where a spatial graph with temporal attributes is represented as a snapshot model partitioned across the disk pages. As can be seen, the model preserves the graph state for a given time instant (say time $t = 1$). Further, the graph states are strictly partitioned based on time; thus, when traversing through the graph across time,

multiple-disk access needs to take place. For example, if a car's route has to be evaluated from A to D via C starting from time $t = 1$, it will require an access to edge AC at $t = 1$ stored in data page 1 and then access to edge CD at $t = 3$ stored in data page 3. Thus, the evaluation requires access to two data pages.

2. Longitudinal Partitioning

Longitudinal partitioning stores spatial graphs with temporal attributes based on the storage structure of the adjacency-list main memory. Figure 7b shows the longitudinal storage. As can be seen, each node is stored with its attribute information and all outgoing edges with their attribute information as an adjacency list. This orthogonal storage solution suffers from the increasing disk I/O to evaluate routes in large spatiotemporal networks. The example network has a short time series compared to its graph size, allowing multiple node records (with adjacency list) to fit inside a data page. However, if the time-series length was larger, then all the nodes may need multiple pages for storage. This is due to the long time series being stored with each node, resulting in only a small number of storable nodes on each data page. Consider the evaluation of the route ACD using longitudinal partitioning. First it requires accessing the traversal time attribute of edge AC at $t = 1$, stored on data page 1. Then, it requires accessing edge CD at $t = 3$, stored on data page 3, to complete the evaluation. Thus, for longitudinal partitioning, the evaluation requires two data pages.

Spatial Graph Big Data, Fig. 7 Spatial graph storage techniques (Evans et al. 2010)

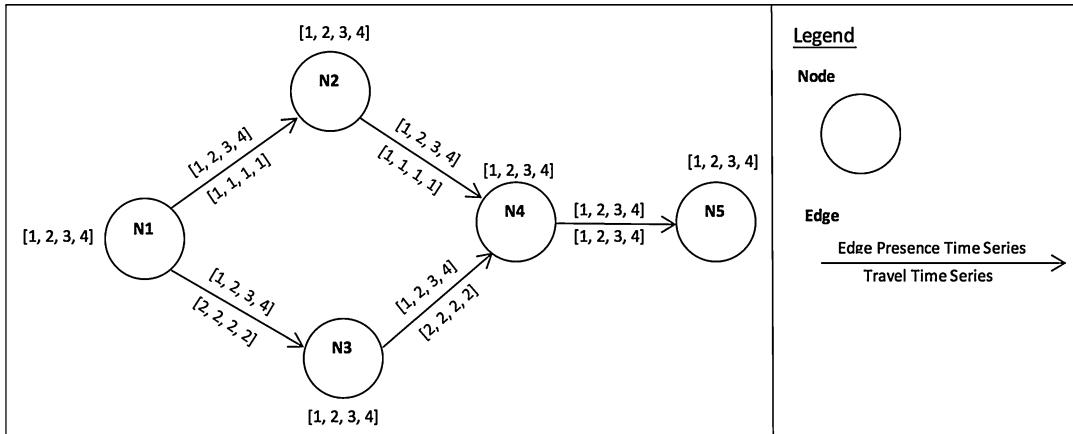

3. Lagrangian-Connectivity Partitioning

Lagrangian-connectivity partitioning (LCP) uses time-expanded graphs (TEG) to store spatial graphs with temporal attributes. Each partition stores the non-orthogonal patterns of route evaluation operations along with a novel data record based on sub-nodes. By representing a spatiotemporal network as a modified time-expanded graph, focusing on the Lagrangian connections between nodes (movement edges), a min-cut graph partitioning algorithm creates partitions clustering nodes by minimizing the cuts of these movement edges. This allows the algorithm to collocate connected temporal nodes together on data pages, stored as sub-node records as shown in Fig. 7c. This further reduces the I/O cost for the operations (described earlier). This can be seen by looking again at the evaluation of route ACD. Traversing from node

A1 to C3 and then C3 to D4 requires only one data page as all relevant sub-node records are on the same data page.

Data Mining Algorithms on Spatial Graphs

Spatial graphs with temporal attributes are used in emergency traffic planning and route-finding services. These applications require routes with the smallest duration for a given start time (useful for known events) and the route with the smallest duration that can occur at any of the start time. Developing efficient algorithms for finding such routes in a time-varying spatial network is challenging because these journeys do not always display a greedy property or optimal substructure, making techniques like dynamic programming inapplicable. The following text will outline algorithms for finding a route with the smallest duration for a given start time followed by an algorithm that finds routes with the smallest duration that can occur at any of the start times.

Spatial Graph Big Data, Fig. 8 Example spatial graph with temporal attributes

Spatial Graph Big Data, Table 1 Trace of the SP-TAG algorithm (George et al. 2007)

1. Shortest Path Computation for Time-Aggregated Graphs (SP-TAG)

The SP-TAG algorithm (George et al. 2007) uses the time-aggregated graphs to represent spatial networks, where each node (road intersection) has a node presence time series and each edge (road segment) has an edge presence time series annotated with travel time. The algorithm keeps track of the earliest time a node can be reached and updates the values as optimal values are found. The algorithm assigns t_{start} to the first node and puts the node in a priority queue (Cormen 2009). The steps are repeated until the priority queue is empty. At each step, the lowest-cost node is extracted from the queue. Then, the values for all its adjacent nodes are updated, and the extracted node is marked as closed. For each update, the minimum between the previous value and the new value of *current time + traversal time* is chosen. Then, the adjacent node is added to the queue. The time complexity of the SP-TAG algorithm is $O(m(\log T + \log n))$, where T is the number of nodes and m is the number of edges in the time-aggregated graph.

Figure 8 shows an example spatial graph having nodes with node presence time series and edges with edge presence time series, travel time series. Table 1 shows the SP-TAG algorithm trace on this graph, which shows the computation of

Iteration	N1	N2	N3	N4	N5
1	1 (closed)	∞	∞	∞	∞
2	1	2 (closed)	3	∞	∞
3	1	2	3 (closed)	3	∞
4	1	2	3	3 (closed)	6
5	1	2	3	3	6 (closed)

the shortest path from N1 to N5. Each row represents an iteration of the algorithm that updates the values to newly found optimal values. For example, at iteration 2, node N2 is closed, and the N4 gets updated as shown in iteration 3.

2. Best Start Time Shortest Path (BEST) Algorithm

The BEST algorithm uses time-aggregated graphs to represent the network, where every node has a node presence time series and every edge has an edge presence time series and travel time series. In the output, each node has a time series, with the i th entry representing the current, least travel time to the destination node for the start time t_i . The algorithm uses an iterative label correcting approach (Ahuja et al. 1993), and each

entry in a node time series is modified according to the following condition:

$$C_u[t] = \min\{C_u[t], \sigma_{uv}(t) + C[t + \sigma_{uv}(t)]\},$$

where $uv \in E$,

$C_u[t]$ – Travel time from $u \in N$ to the destination for the start time t .

$\sigma_{uv}(t)$ – Travel time of the edge uv at time t .

The algorithm maintains a list of all nodes that change its cost according to the condition and terminates when there is no further improvement indicated by an empty list. The algorithm uses two-Q-based implementation (Pallottino 1984). The computational complexity of the BEST algorithm is $O(n^2mT)$, where n is the number of nodes, m is the number of edges, and T is the length of the time series.

Figure 9 shows an example with a figurative trace. At each step, the distance list from destination gets updated to show the shortest distance for all the time instants. Further, the parent pointer list gets updated to show the corresponding parent. Table 2 shows the trace for the algorithm showing shortest distance from N4 (destination) to all the nodes for each of the time instance. Further, the table shows the queue state. Note that in Fig. 9 edge presence time series and node presence time series are omitted because all the edges and nodes are present at all times.

Examples of Application

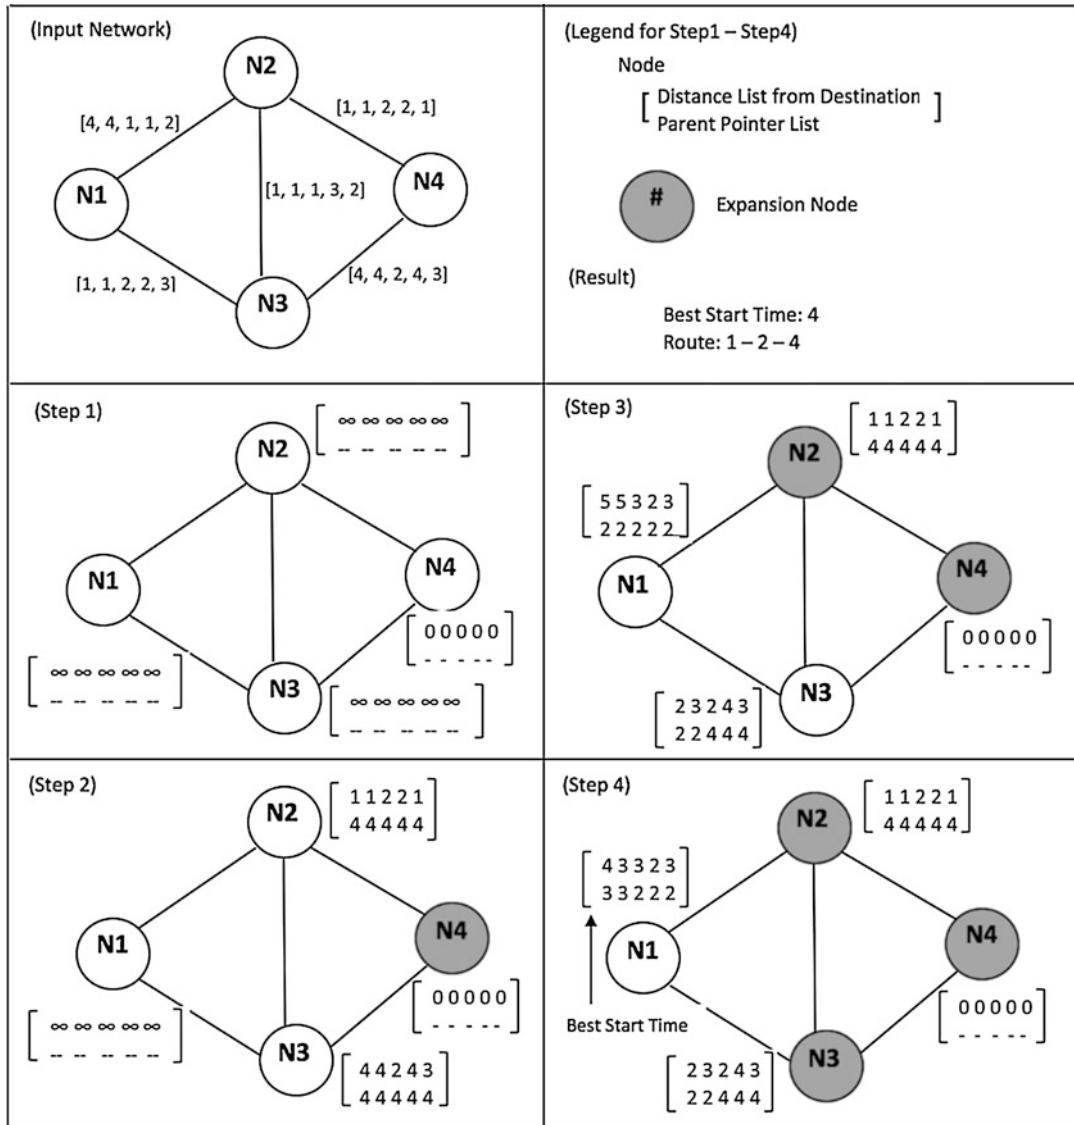

This section elaborates on three existing applications that rely on spatial graphs. Two of the applications show the use of different frames of reference (described in section “[Modeling Spatial Graphs](#)”) to the real-world applications. Section “[Historical Speed Profiles for Roadways](#)” describes the use of vehicle trajectory from a Eulerian frame of reference, and section “[GPS Trace Data for Improving Fuel Efficiency](#)” describes the use of vehicle trajectory from a Lagrangian frame of reference. Section “[Evacuation Route Planning](#)” discusses an important societal problem that talks about the use of spatial graphs in disaster management.

Historical Speed Profiles for Roadways

Traditionally, digital road maps have consisted of center lines and topologies of the road networks. These maps are used by navigation devices and web VTEQ, probe vehicles, and highway sensors to compile travel time information across road segments for all times of the day and week at fine temporal resolution (seconds or minutes). The profiles have data for every 5 min, which can then be applied to the road segment, building up an accurate picture of speeds based on historical data. An example distribution is shown in Fig. 10 (Shekhar et al. 2012). Such temporally detailed (TD) road maps contain much more speed information than traditional road maps. While traditional road maps have only one scalar value of speed for a given road segment (e.g., EID 1), TD road maps may potentially list speed/travel time for a road segment (e.g., EID 1) for thousands of time points (Fig. 10a) in a typical week. This allows a commuter to compare alternate start times in addition to alternate routes. It may even allow comparison of (different) start time and route combinations to select distinct preferred routes and distinct start times. For example, route ranking may differ across rush hour and non-rush hour and in general across different start times. However, TD road maps are big, and their size may exceed 10^{13} items per year for the 100 million road segments in the USA when associated with per-minute values for speed or travel time. Thus, industry is using speed profiles that are a lossy compression based on the idea of a typical day of a week, as illustrated in Fig. 10b, where each road segment and day of the week pair is associated with a time series of speed values for each hour of the day.

GPS Trace Data for Improving Fuel Efficiency

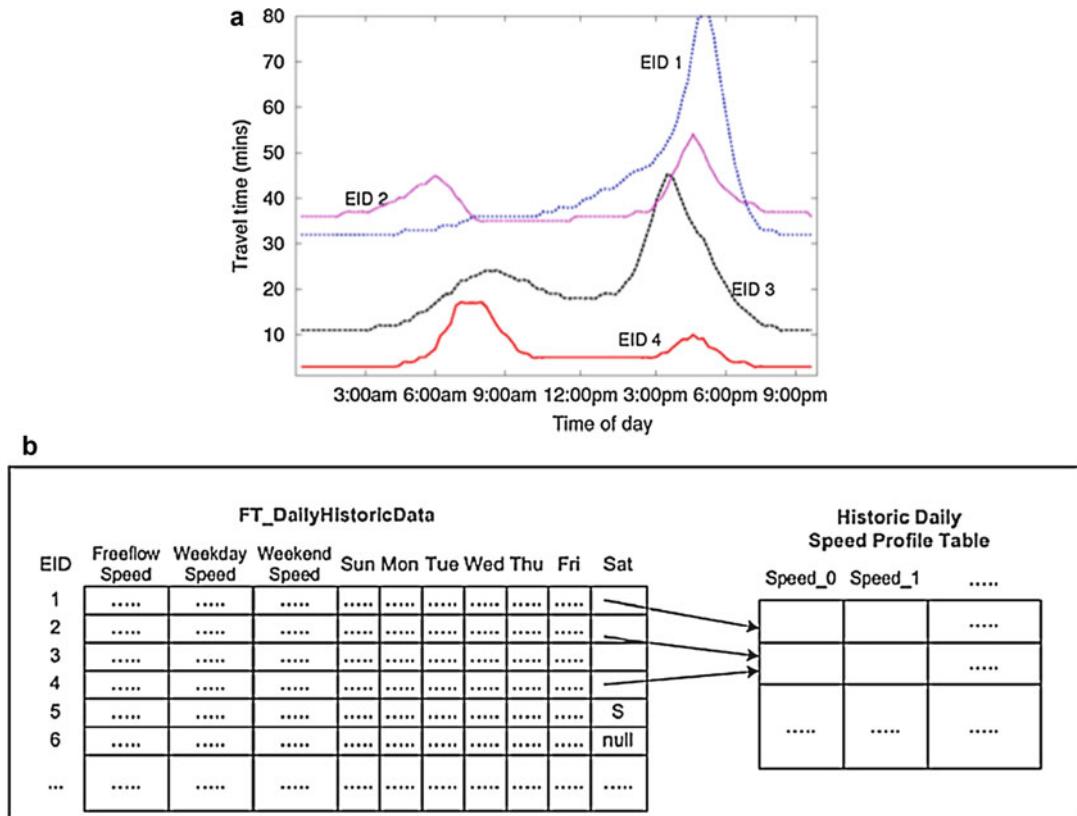

GPS trajectories are available for a large collection of vehicles due to rapid proliferation of cell phones, in-vehicle navigation devices, and other GPS data-logging devices such as those distributed by insurance companies. According to Shekhar et al. (2012), GPS traces allow indirect estimation of fuel efficiency and GHG emissions via estimation of vehicle speed, idling, and con-

Spatial Graph Big Data, Fig. 9 Trace of the BEST algorithm (George et al. 2007)

Spatial Graph Big Data, Table 2 Trace of the BEST algorithm (George et al. 2007)

Iteration	N1	N2	N3	N4	Queue
1	$\infty \dots \infty$	$\infty \dots \infty$	$\infty \dots \infty$	[0, 0, 0, 0, 0]	N1
2	$\infty \dots \infty$	[1, 1, 2, 2, 1]	[4, 4, 2, 4, 3]	[0, 0, 0, 0, 0]	N2, N3
3	$\infty \dots \infty$	[1, 1, 2, 2, 1]	[2, 3, 2, 4, 3]	[0, 0, 0, 0, 0]	N3
4	[4, 3, 3, 2, 3]	[1, 1, 2, 2, 1]	[2, 3, 2, 4, 3]	[0, 0, 0, 0, 0]	N1
5	[4, 3, 3, 2, 3]	[1, 1, 2, 2, 1]	[2, 3, 2, 4, 3]	[0, 0, 0, 0, 0]	-

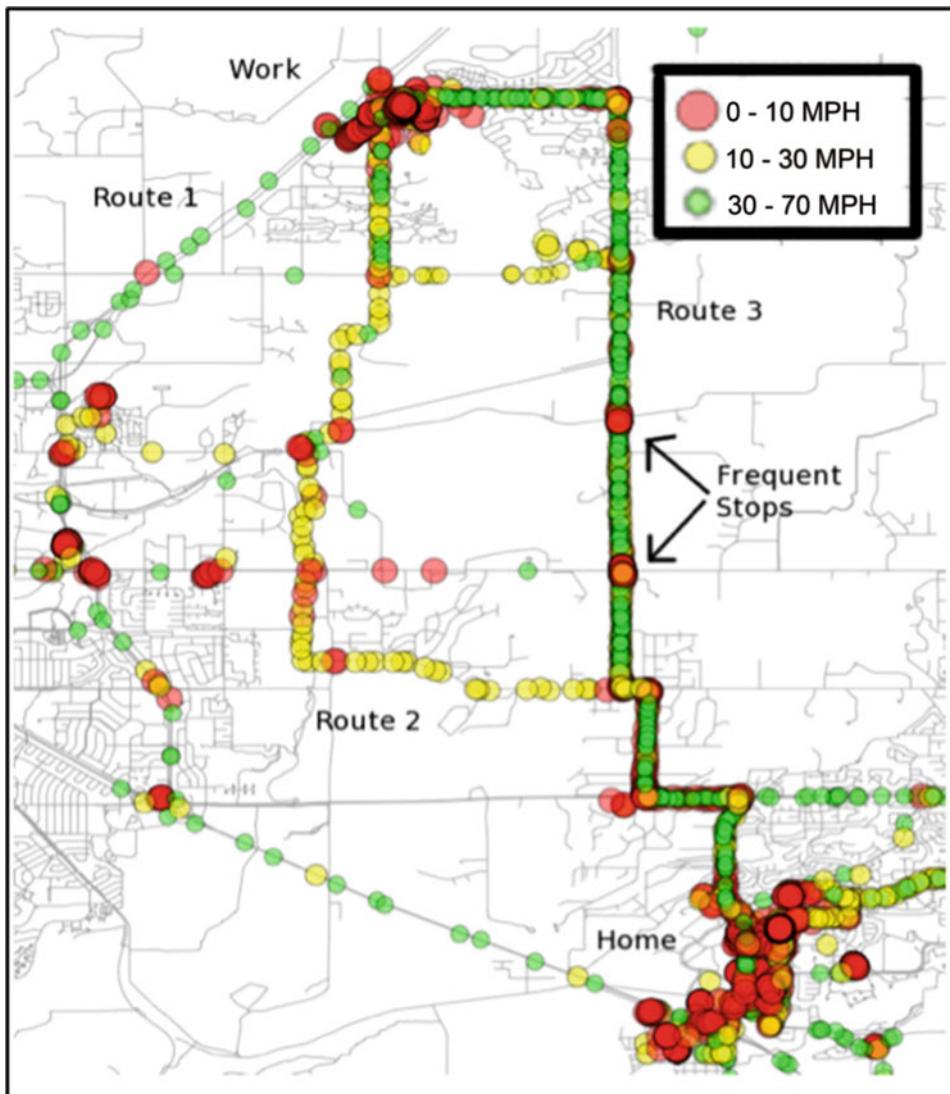

Spatial Graph Big Data, Fig. 10 Spatial big data on historical speed profiles (Shekhar et al. 2012)

gestion. They also make it possible to provide personalized route suggestions to users to reduce fuel consumption and GHG emissions. For example, Fig. 11 shows 3 months of GPS trace data from a commuter with each point representing a GPS record taken at 1 min intervals, 24 h a day, 7 days a week. As can be seen, three alternative commute routes are identified between home and work from this dataset. These routes can be compared for engine idling which are represented by darker (red) circles. Assuming the availability of a model to estimate fuel consumption from speed profiles, one may even rank alternative routes for fuel efficiency. Again, a key hurdle is the dataset size, which can reach 10^{13} items per year given constant minute-resolution measurements for all 100 million US vehicles.

Evacuation Route Planning

Large public gatherings require effective management to preserve public safety. One of the key responsibilities of a civil administration is the capability to manage adverse conditions (e.g., terrorist acts, accidents) that may require finding efficient routes to evacuate all or a portion of a population. The evacuation route planning problem (Yang et al. 2012) finds routes that minimize evacuation time given a transportation network, a population, and a set of observations. To be effective and timely, evacuation planning methods need to adhere to network capacity constraints and provide reasonable computation time. Evacuation route planning involves (taking) a big data perspective due to the size of transportation networks (order

Spatial Graph Big Data, Fig. 11 A commuter's GPS tracks over 3 months reveal preferred routes (Shekhar et al. 2012)

of 10^3 nodes and 10^6 edges), the large number of evacuees (order of 10^6), as well as the capacity constraints for every node and edge.

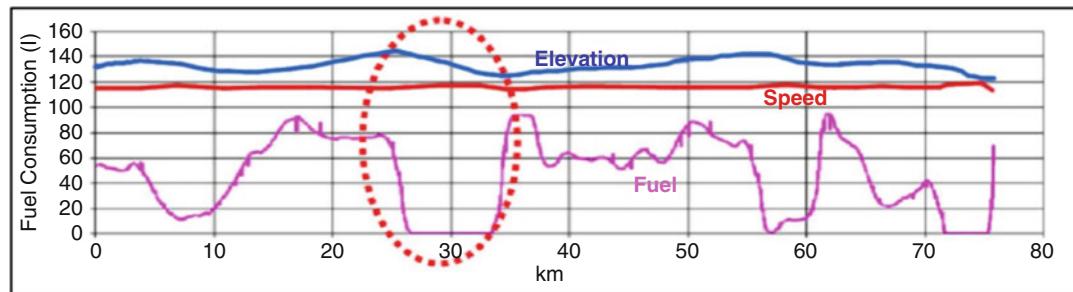

Future Directions of Research

The section describes two future directions of research related to spatial graphs. The first is driven by the increased use of sensors that can measure every aspect of vehicles including its

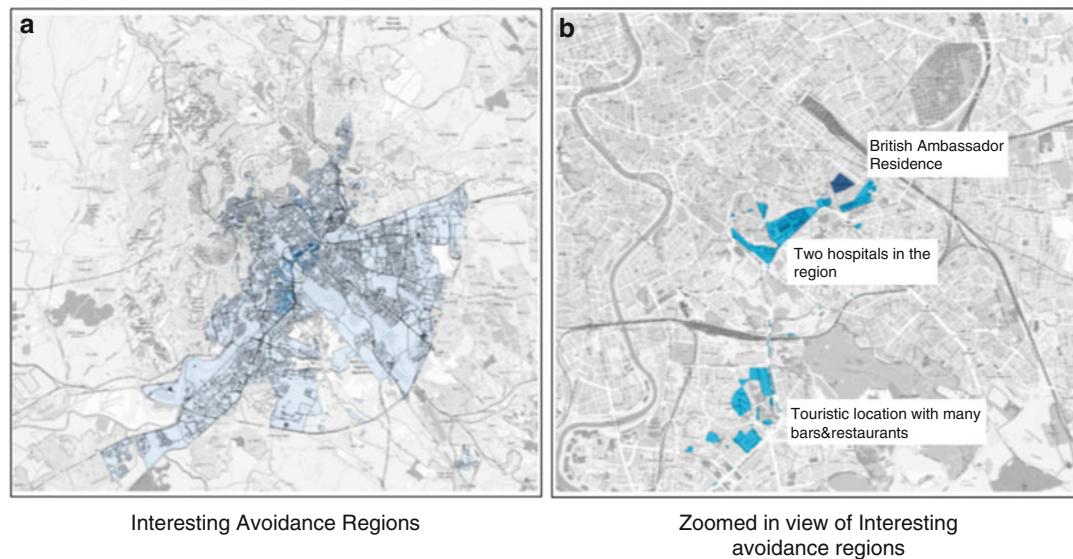

surroundings. This would potentially allow to make variety of profiles for a vehicle. The second is driven by the need to identify city areas that are affected due to multiple reasons (e.g., natural calamities, adverse neighborhood) based on trajectory data.

Time Annotated Engine Measurement Spatial Data

Engine measurement datasets may be used to study the impacts of the environment (e.g., ele-

Spatial Graph Big Data, Fig. 12 Engine measurement data improve understanding of fuel consumption (Capps et al. 2008)

Spatial Graph Big Data, Fig. 13 Case study on identification (Eftelioglu et al. 2018)

vation changes, weather), vehicles (e.g., weight, engine size, energy source), traffic management systems (e.g., traffic light timing policies), and driver behaviors (e.g., gentle acceleration or braking) on fuel savings and greenhouse gas emissions. Fuel efficiency can be estimated from fuel levels and distance traveled as well as engine idling from engine RPM. These attributes may be compared with geographic contexts such as (e.g., elevation changes) to improve understanding of fuel efficiency and greenhouse gas emission.

For example, Fig. 12 shows heavy truck fuel consumption as a function of elevation from a study (Capps et al. 2008) at Oak Ridge National Laboratory. Notice how drastically fuel consumption changes drastically with elevation

slope changes. Commercial fleet owners have studied such datasets to fine-tune routes to reduce unnecessary idling. It is tantalizing to explore the potential of these datasets to help consumers gain similar fuel savings and reductions in greenhouse gas emission. However, these datasets can grow big. Measurements of 10 engine variables, once a minute, over the 100 million US vehicles in existence, may have 10^{14} data items per year.

Distressed Area Identification

Distressed area identification uses GPS trajectories on a road network to identify distressed areas or the regions that are usually avoided by the commuters. This emerging area is important to applications such as sociology, city/transporta-

tion planning, and crime mitigation, where it can help domain users to understand the driver behavior under varying adverse conditions (e.g., rush hour, congestion, dangerous neighborhoods, etc.).

For example, Fig. 13 shows results from a recent case study (Eftelioglu et al. 2018) on a real dataset consisting of 1312 vehicle GPS trajectories in Italy over a period of 3 years. The study used the input trajectory data and road network data to output interesting avoidance regions as shown in Fig. 13a. The zoomed-in view (Fig. 13b) shows that drivers avoid areas with increased security measures (e.g., important government buildings) or increased congestion (e.g., hospitals or tourist locations).

GeoSocial data; Spatial data

Definitions

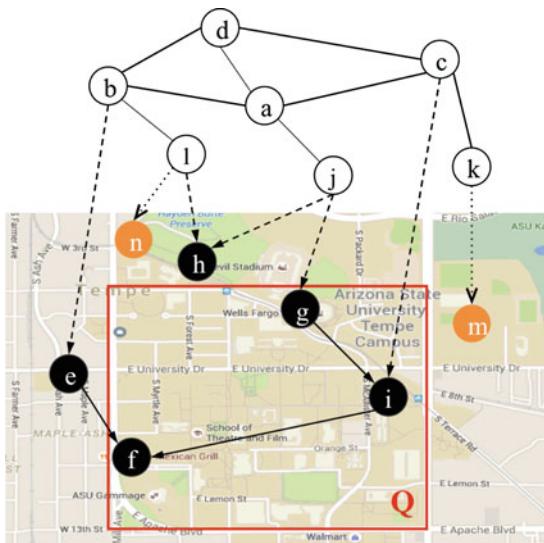

In the past decade, social networking services, e.g., Facebook and Twitter, managed to unprecedentedly connect hundreds of millions of people all over the world. Users register to online social networks in order to keep in touch with their friends and family, learn about their news, get recommendations from them, and engage in online social events. Thanks to the widespread use of mobile and wearable devices, popular social networks, e.g., Facebook, prompt users to add spatial attributes to social entities, e.g., check-ins, posts, and geo-tagged photos. Such spatial attributes are already being tied to social networking data to form what we call, *Spatio-Social Data*. Spatio-Social data brings both the physical space, social relationships, user interactions, and social media content into effect together, which led to the rise of many interesting applications. For instance, users in a location-based social networking service (e.g., Foursquare and Facebook Places) are associated with a geo-location and might alert friends when visiting a place (e.g., restaurant, bar) by checking in on their mobile phones.

Overview

Figure 1 gives an example of how Spatio-Social data looks like. The figure depicts a social graph in which there exist three types of entities: (i) *person* (e.g., Alice, Bob, Carol, Dan, etc.) with a name and age attributes, (ii) *place* (e.g., restaurants) with a name and a spatial location attributes, and (iii) *content* (e.g., tweet) with id, social media content (e.g., Tweet text), and location attributes. The graph consists of four types of social connections: (i) *friend of* that represents the social relationship between persons, e.g., Alice is a friend of Dan; (ii) *visited* that represents the users' visits to places, e.g., Dan visited Pita Jungle restaurant in Tempe AZ; (iii) *posted* that represents the relationship between people and social media content, e.g., Mat posted a tweet within the ASU stadium area; (iv) *rated* that represents the users' interactions with the physical space, e.g., Kate gave a five-star rating to Sushi 101.

Spatio-Social Graph

In a GeoSocial graph, a user may issue the following query: “Find Restaurants in Phoenix that are visited by Alice’s Friends.” In addition, such data can be utilized to process GeoSocial analytic tasks, e.g., “Report restaurants in Phoenix that are visited by teenagers ($13 < \text{age} < 18$).” We call such queries that search the social graph with both social and spatial predicates, *GeoSocial Graph Search (G^2S) queries*. We can formally define a GeoSocial Graph Search G^2S query as a regular path query with geospatial predicates performed on the social graph. A G^2S query takes as input a sequence of social graph predicates as well as a spatial predicate. The social predicate is applied to traditional social graph entities and/or connections with nonspatial attributes, e.g., person, whereas the spatial predicate is performed on social entities that possess spatial attributes, e.g., restaurants. G^2S then returns a set of social graph paths that match the social predicates as well as satisfy the spatial predicate. Existing graph database systems, e.g., Neo4j, allow users to define spatial properties on graph elements. MongoDB is utilized by Armenatzoglou et al. (2013)

- a: {name: Alice, age: 19}
 b: {name: Dan, age: 20}
 c: {name: Carol, age: 35}
 d: {name: Bob, age: 25}
 j: {place: Kate, age: 18, ...}
 k: {place: Mat, age: 23, ...}
 l: {place: Katharine, age: 21, ...}
- e: {place: Pita Jungle, location:<x1,y1>}
 f: {place: Chipotle, location:<x2,y2>}
 g: {place: Sushi 101,...}
 h: {place: Subway,...}
 i: {place: McDonald's,...}
- m: {id: 1, tweet: "Nice Weather", location:<x10,y10>}
 n: {id: 2, tweet: "Good Game", location:<x10,y10>}

Spatio-social Data, Fig. 1 GeoSocial graph data

to manage both social and geographic data. Each user in the GeoSocial graph is assigned a spatial location. A Range Friends query searches for friends within a given distance from the user. The Nearest Friend query searches the nearest friend of a user.

Geo-tagged Social Media

Social media content is rich in content, e.g., text, video, hyperlinks, photos, and spatial location. Existing work studied keyword search on streaming social media data (Busch et al. 2012; Wu et al. 2013; Yao et al. 2012). Other newly emerging applications on GeoSocial media include event detection (Abdelhaq et al. 2013; Li et al. 2012; Marcus et al. 2011; Watanabe et al. 2011), news extraction (Sankaranarayanan et al. 2009), and analysis (Tweet Tracker 2013). Bao et al. (2012) propose a GeoSocial news feed, which ranks the news feed based on both the social and geospatial proximity of each post to the user.

User Check-In Data

Myriad Web applications produce *location-based ratings* that embed user and/or item locations. For example, applications like Foursquare and Yelp allow users to “check in” at spatial destinations

(e.g., restaurants) and rate their visit and thus are capable of associating both user and item locations with ratings. Existing recommendation techniques assume ratings are represented by the (*user*, *rating*, *item*) triple and thus are ill-equipped to produce location-aware recommendations.

Recent systems produce *three* main types of location-based user interactions (Sarwat et al. 2014; Levandoski et al. 2012a): (1) Spatial ratings for nonspatial items, represented as a four-tuple (*user*, *ulocation*, *rating*, *item*), where *ulocation* represents a user location. Items are nonspatial in nature (e.g., movies) and thus do not have an associated location. As an example, traditional e-commerce applications (e.g., Netflix) may use a user’s home address as *ulocation*, while mobile applications may associate the location where the user rated the item as the *ulocation*. (2) Nonspatial ratings for spatial items, represented as a four-tuple (*user*, *rating*, *item*, *ilocation*), where *ilocation* represents an item location. Examples of applications that produce such ratings are e-commerce applications that gather user opinions on venues/destinations (e.g., restaurant review websites), but do not collect user locations.

Key Research Findings

Spatio-Social Graph Queries

Basic approaches that answer GeoSocial Graph Search (G^2S) queries fall into two main categories, listed as follows:

- (1) *Social-Then-Spatial (SoSpa)* approach This approach leverages the query processor of an existing graph data management system (Kylola et al. 2012; Prabhakaran et al. 2012; Sarwat et al. 2012, 2013b; Shao et al. 2013). It first traverses the social graph to find matching paths (Chen and Chen 2008; Fan et al. 2011; Jin et al. 2010). When a spatial entity is encountered during the social graph traversal, SoSpa tests these entities against the spatial predicate. Finally, SoSpa returns only paths that satisfy both the social path predicates and the spatial range predicate.
- (2) *Spatial-Then-Social (SpaSo)* approach This approach runs in two sequential phases:
 - (a) Spatial filtering: This phase employs a state-of-the-art spatial database management system that harnesses a spatial index, e.g., R-tree, to first retrieve the social graph entities that satisfy the spatial predicate.
 - (b) Social filtering: This phase traverses the social graph to only return social graph paths that match the social predicates and contains only the spatial entities retrieved in the spatial filtering phase. Even though both approaches correctly answer G^2S queries, nonetheless they may lead to performance penalties by traversing unnecessary graph paths that incur extra I/O and CPU overhead which increases the overall latency of G^2S queries (Sarwat and Sun 2017).

Spatio-Social Media Queries

Existing systems provide scalable indexing mechanisms that allow users to interactively explore spatio-textual data at scale. Various spatial and spatio-textual indexing techniques are explored in the literature (Budak et al. 2014; Magdy et al. 2014; Skovsgaard et al. 2014) to

support spatial queries on geo-tagged social media. Novel systems extend those techniques to reduce the indexing latency and increase the digestion rate. Existing research work addresses the problem of tuning the in-memory part of the spatio-textual index to minimize the overall index storage and maintenance overhead. Initial studies show that space-partitioning spatial indexes achieve better performance in processing real-time social media, e.g., spatial grid index or spatial quad tree. On the contrary to data-partitioning spatial indexes, e.g., R-tree, cell boundaries in space-partitioning indexes do not change with the incoming data. Instead, each cell covers a specific area of the space and holds whatever data it contains. Recent research work also studies the problem of real-time geo-tagged social media content insertion in the spatio-textual, spatio-visual index by employing lazy batch updates so that the amortized insertion cost per social media content is minimized. A large body of work investigates compression techniques to minimize the memory footprint of geo-tagged social media to efficiently utilize main memory and storage resources. Such systems investigate storing only necessary information in main memory, e.g., recent tweets or local top frequent keywords, and get rid of any other information so that incoming spatial exploration queries can fetch its answers in main memory and avoid hitting the relatively slower secondary storage.

S

Spatio-Social Recommendation

Existing spatial database systems allow users to look up spatial data that matches exactly the designated query and hence do not leverage the user interaction with the physical space. Recommendation (Sarwat et al. 2017; Levandoski et al. 2012b; Herlocker et al. 2004; Koutrika et al. 2009) is the process of suggesting useful data to the user based on a large pool of historical user interaction data (e.g., a user rating a venue on Yelp). To take into account the user interaction with the physical space, existing approaches extend spatial data structures with user interaction data to support spatial data recommendation. The straightforward approach constructs a spatial

index, e.g., R-tree, on all spatial data objects and calculates the similarity between different items and data points. When the user asks for a set of spatial objects in a certain boundary region, the system first searches for all the points lying within the region. It is not feasible to go through all the data point outcomes from the search. For this purpose, the system filters huge data ignoring all those points that may not interest him based on his previous interactions with the system. Then, only the items with top-k recommendation scores are displayed to the user. The performance can be further optimized to give faster recommendations by augmenting existing spatial indexes to filter spatial data using both their spatial attributes and their recommendation scores.

The system produces recommendations by employing an adaptive hierarchical grid structure to partition data ratings by their *user location* attribute into spatial regions of varying sizes at different hierarchies. For a querying user located in a region R , we apply an existing collaborative filtering technique that utilizes only the ratings located in R . Existing systems can dynamically balance scalability and recommendation locality. In this case, the system produces recommendations by using *travel penalty*, a technique that penalizes recommendation candidates the further they are in travel distance to a querying user (Sarwat et al. 2013a). The challenge here is to avoid computing the travel distance (Hjaltason and Samet 1999) for all spatial items to produce the list of k recommendations, as this will greatly consume system resources. Existing systems address this challenge by employing an efficient query processing framework capable of terminating early.

Future Direction for Research

Spatio-Social data is rich in semantics. The graph model can carry structure information, spatial information, textual information, and user data at the same time. Such data is inherently heterogeneous; hence there is always room for novel applications that combine a variety of Spatio-Social

aspects. Another direction of future research is to explore the appropriate approach to analyze and explore Spatio-Social data using visual map interfaces. The challenge is that Spatio-Social data is growing at a staggering rate. In that case, an interesting area of research will be to extend de facto distributed computing systems and streaming engines to support fast and scalable processing of Spatio-Social data.

Spatiotemporal Data Integration

► Spatial Data Integration

Spatiotemporal Data: Trajectories

Xiaofang Zhou and Lei Li

School of Information Technology and Electrical Engineering, University of Queensland, Brisbane, QLD, Australia

Synonyms

Moving objects; Routes; Spatiotemporal representation; Traces

Definitions

Let $p(l, t)$ be a *spatiotemporal point* with location l at time t . A *trajectory* is defined as $\tau = < p_1, p_2 \dots p_n >$ where $p_i.t \leq p_j.t$ if $i < j$. That is, a trajectory is a sequence of spatiotemporal points ordered by time.

Location l can be represented as a longitude and latitude pair in geographical space or a road segment ID and distance offset in a road network. A trajectory without temporal information is often called *route* or *path*, and a collection of

trajectories of an object is called its *trace*. The trajectory with a specific origin and destination pair (OD pair) is also called a *trip*.

Overview

A trajectory records how an object moved in a space. Such information is easier than ever to acquire with the prevalence of location-capturing devices such as GPS nowadays. Therefore, large volumes of trajectory data are being accumulated from various sources every day, for animals, human, vehicles, and natural phenomena (Zheng 2015). Animal trajectory data can be obtained by attaching tracking devices to animals, for environment protection and animal behavior studies. *Movebank* has collected animal movement data from thousands of studies at millions of locations. Human trajectories are collected from travelers, cyclists, and joggers, due to the recent popularity of electronic fitness tracking devices and mobile devices. Transport-related trajectory data, which by far are the most voluminous, most interesting, and most useful type of trajectory data, are generated by GPS devices and fixed-location data-capturing devices from vehicles, airplanes, and ships. Taxi service providers like *Uber* and *DiDi* create terabytes of trajectory data every single day. Natural phenomena trajectory data are also collected for scientific studies. *NOAA Air Resources Laboratory* (Draxler and Rolph 2003) stores a massive amount of meteorology trajectories that can be used to better understand the causes and impacts of natural disasters and to protect the natural environment.

The works on trajectory data can be categorized into several topics (Zheng and Zhou 2011). The first one is *trajectory preprocessing*, including noise removal to improve data quality, map matching that aligns points to road segments for road network-constrained moving objects (such as cars), data compression, and trip segmentation that prepares data for further uses like clustering and classification. The second one is related to *trajectory data management*, which aims at answering retrieval queries efficiently by building indexes and developing query algorithms. The

third one is *trajectory mining*, which involves finding the patterns among the trajectories, classifying them into different categories, detecting outliers, and reducing the uncertainty between two consecutive points. Finally, based on all the previous steps, trajectory data can be used to solve problems ranging from more conventional applications such as traffic condition prediction and route planning to the more recent applications such as fuel and pollution emission minimization in a city.

Key Research Findings

Trajectory Preprocessing

Essentially, the raw trajectory is an array of (l, t) data, which can be noisy, too dense, or too coarse in terms of sampling rates and cannot be directly used for a variety of applications. Therefore, like any other types of raw data, preprocessing is needed before actual uses.

Noise Removal

Due to the accuracy of the devices, the data collected are not always accurate. Some of the data points obviously drift off the course. The simplest approach is using the mean or median value of a sliding window to filter out the noise point. However, it fails when there are multiple consecutive noise points. More practical approaches apply outlier detection methods, like computing the travel speeds of the points and removing those that surpass the threshold (Yuan et al. 2013).

Map Matching

If there exists an underlying road network that confines object movement (e.g., for cars), it is always beneficial to attach the GPS points to the corresponding roads. Based on the time when the matching is executed, it can be categorized into *real-time mode* and *post-processing mode*. The real-time map matching is widely applied in real-time turn-by-turn navigation systems. It requires fast computation and can only use the previous few points (i.e., no future points can be used), while it cannot guarantee the continuity on the path during the trip. The post-processing map

matching can utilize the entire trajectory, so it is more accurate but time-consuming.

The techniques used in map-matching methods can be divided into four groups. The first one mainly considers the geometry distance between GPS point/trajectory segment and the candidate map points/map edges that could be possibly aligned on. The second group also considers topology of a map such as connectivity and contiguity of roads. The third group further improves the accuracy by using probability-based methods like the *Hidden Markov Model* and *Kalman Filter*. More advanced approaches combine the existing methods with additional information like Wi-Fi, Bluetooth, and cellular fingerprint on mobile phones, driver behaviors, and other semantic information about the road network, the objects, and other related information.

Compression

The amount of trajectory data increases at an increasing pace, leading to gigantic storage overhead as well as computation and communication costs. However, not many applications need the trajectory data to be that precise, so compression is necessary in many cases.

A simple approach to reduce the size is to remove some points if they do not affect the precision dramatically. In this way, the new and more compact trajectory is an approximation of the original one. Another approach takes advantages of the road network if applicable. Data size can be reduced significantly after using consecutive matched road segments to represent points because normally there are multiple GPS points along the same road segment. Further compression can be achieved with the help of frequent sequential pattern mining and Huffman Coding (Song et al. 2014), or using other string compression methods like *Burrows-Wheeler Transform*, because a series of roads can be viewed as a string with each road representing a character in the alphabet (Koide et al. 2017).

Segmentation

In many high-level applications where trajectory data are used (such as traffic and traveler behavior analytics), shorter trajectory segments

make more sense than the original long trajectory. This is not only because shorter trajectories can better support similarity-based analysis but also improve computation efficiency (many trajectory similarity measures are of quadratic complexity). Further, segmentation based on OD pairs can also bring semantic information to trajectories. Trajectory segmentation (or trip segmentation) is the process that breaks a long trajectory into a series of short trajectories.

The segmentation processing has three main categories. Firstly, the trajectory can be segmented based on time interval. It is like resampling the original trajectory on a lower sampling rate. Secondly, it can be segmented based on the shape (Lee et al. 2007), which involves finding the turning points. Finally, semantic meaning of the points (like walk segment, driving segment, and segments between taxi waiting time) can also serve as segmentation points.

Trajectory Management

Querying and processing directly on a large volume of trajectories are actually very time-consuming. Therefore, how to organize and index the trajectory data to support trajectory query answering efficiently becomes a research topic, which is called trajectory management (Deng et al. 2011).

Trajectory Query

Based on the type of query entity (i.e., points, regions, and trajectories), trajectory queries can be classified into three types. *P-Query* asks for points which satisfy a given spatiotemporal relationship to specified trajectory segment(s) (e.g., top-k nearest neighbors) or reversely. Similarly, *R-Query* asks for regions, and *T-Query* asks for trajectories. An example of a spatiotemporal relationship is “within 500 m of a gas station between 9:00pm and 9:30pm.”

Trajectory Index

Compared with other general data types, trajectory data has unique characteristics like continuous long time span. Meanwhile, queries on trajectory also often ask for information

in a continuous time window. Based on these characteristics, three types of indexes are proposed.

The first type augments the existing multi-dimensional index with a temporal dimension, like *3D R-Tree*. The second type further breaks the temporal dimension down to multi-version structures, such as *HR⁺-Tree* and *MV3R-Tree* (Tao and Papadias 2001). The third type focuses on dividing the spatial dimension into grids and then building a separate temporal index on each grid. This category includes *SETI* and *MTSB-Tree*.

Trajectory Similarity

Like any other data types, a similarity (or distance) measurement is needed to compare between trajectories.

The simplest scenario is the distance from a point to a trajectory, which is measured by the distance to the nearest point in the trajectory. As for the distance between a set of nodes and a trajectory, the closer matched pair of points is assigned with larger weights using the sum of distance, while those faraway pairs are given much lower value typically in an exponential way.

The similarity between two trajectories is usually measured by some kind of aggregation of distances between trajectory points (Wang et al. 2013). Along this line, several typical similarity functions for different applications include *Closest Pair Distance*, *Sum-of-Pairs Distance*, *Dynamic Time Warping*, *Longest Common Subsequence*, *Edit Distance with Real Penalty*, and *Edit Distance on Real Sequences*. It is worth noting that some of those similarity functions were originally proposed for time series data. But as trajectories can be regarded as a special kind of time series in a multidimensional space, these similarity functions can also be applied to trajectory data.

Trajectory Uncertainty

Because trajectory data is always a sample of the object's actual movement trace, the uncertainty exists between any two points in a trajectory especially when the sampling rate is low (Zheng

et al. 2012). On one hand, some works aim to reduce the uncertainty of the trajectory. On the other hand, other works try to add more uncertainties for privacy protection reasons.

The first group of researches focuses on providing conservative bounds for the positions of uncertain objects between two points, which is achieved by employing geometric cylinders or beads. Independent probability density functions can be used to model the uncertain positions (Cheng et al. 2004).

The other group of approaches aim at providing the most k likely routes between sample points with the help of a set of uncertain trajectories, because these trajectories that share similar routes can often supplement each other to make themselves more complete (Su et al. 2013).

Contrary to the previous attempts, techniques are developed to work on preventing user privacy leaking by blurring the published trajectory while preserving the utility of the data.

Trajectory Mining

Trajectory Pattern Mining

Trajectory pattern mining aims at discovering trajectory groups based on their proximity in either a spatial or a spatiotemporal sense. There are four main categories of patterns that can be discovered from a single trajectory or a group of trajectories.

The first one is the *moving together pattern*, which discovers a group of objects that move together for a certain time period. A *flock* is a group of objects that travel together within a disk of some user-specified size for at least k consecutive timestamps. Apparently, the fixed disk shape with a fixed size can be too strict and rigid to use in practice, so *convoy* is proposed by finding patterns based on density. In this way, patterns of any shape and size can be discovered. However, both flocks and convoys are strict on period, so *swarm* (Li et al. 2010a) is proposed to further generalize the cluster with objects lasting for at least k timestamps. To cope with stream data, *traveling companion* uses a data structure (called traveling buddy) to continuously find convoy-/swarm-like patterns from trajectories and can work online.

By allowing the membership of a group to evolve gradually, *gathering* (Zheng et al. 2014) can be used to detect events and incidents.

The second one is *trajectory clustering*. Unlike general clustering tasks that use feature vectors to represent objects, it is hard to generate a uniform feature vector because different trajectories contain different and complex properties, such as length, shape, sampling rate, number of points, and their orders. A number of works have been done using the trajectory similarity. Although some of them work on the entire trajectory, it is rare for two objects traveling together for the entire journey. So more practical approaches partition trajectories into segments before clustering. If the trajectories are matched to map, the trajectory clustering task can be done by applying graph clustering algorithms.

The third one is *mining sequential patterns from trajectories*. A *sequential pattern* means a certain number of moving objects travel a common sequence of locations in a similar time interval and the locations of the sequence do not have to be consecutive. A general solution is using trajectory clustering first and then reforming trajectories with cluster IDs. In this way, existing sequential pattern mining algorithms like *PrefixSpan* can be used. If the trajectory can be matched on map, the resulting sequence of road IDs can use *Suffix Tree* to find the frequent patterns (Song et al. 2014).

The last one is *mining periodical patterns from trajectories*. Some object movements have periodical patterns over the long history. For example, people go to work in the morning and go back home at night. Animals migrate from one place to another at different time of the year. A straightforward approach is to use general frequent pattern mining methods. However, real-life periodic behaviors are complicated and involve multiple interleaving periods, partial time span, and spatiotemporal noises and outliers. Therefore, a more advanced two-stage method is proposed (Li et al. 2010b). In the first stage, it mines all the frequent visiting places by density-based clustering algorithms. The temporal data corresponding to entering and leaving these places can be used to find the period values. In the second stage,

larger periodic patterns are created by applying hierarchical clustering algorithms on the partial movement sequences.

Trajectory Classification

Trajectory classification helps divide trajectories into different statuses. For example, taxi trajectories can be *occupied*, *non-occupied*, and *parking*. A cell phone user can be *stationary*, *walking*, and *driving* or even *driving*, *biking*, *commuting by bus*, and *walking*. In general, the classification has three steps. First of all, trajectories are divided into segments in preprocessing stage. After that, features of each segment are extracted. Finally, existing sequence inference models (such as *Dynamic Bayesian Network*, *Hidden Markov Model*, and *Conditional Random Field*) can be used.

Outliers Detection

Outliers of trajectory data can be points significantly different from others spatially or temporally and can also be observations that do not follow the expected patterns or constraints. One general approach is to leverage standard frequent pattern mining methods. If the trajectory cannot fall into any cluster, it might be an outlier (Lee et al. 2007).

Examples of Application

Trajectory data can be found in many applications; here we just list a few as examples.

Travel Recommendation. It aims to find interesting locations and travel sequences from trajectories generated by many people. (Zheng and Xie 2011) identifies staying points from users' trajectories and clusters these points into locations of interest. After that, it can identify the top-k most interesting locations and travel experts in a city and do the recommendations based on their data. Moreover, it can recommend trajectories themselves, because historical traveling experiences can also reveal valuable information on how other people usually choose routes between locations.

Traffic Condition Estimation. The trajectories of vehicles on the road can reflect the traffic condition (Yang et al. 2013). It needs a series of

processing to generate a speed profile from trajectories: map matching, speed generation, missing value estimation, and compression. The result not only can be used for finding the fastest path from one place to another at different departure time but also can help find the congestion of road network and provide decision support for urban planning.

Map Inference. Normally, vehicle trajectories can always be matched to some roads on a map. However, when a new road is developed and the map has not been updated, or if there is even no map for the current region, map matching will fail. Map inference works under this scenario to infer new maps or update existing maps based on trajectories.

Diagnosing Traffic Anomalies. Such examples can be that a taxi driver takes a malicious detour, that an unexpected road change occurs, or that people travel a wrong path. They can all be discovered by trajectory outlier detection using trajectory clustering.

Future Movement Prediction. Periodic trajectory pattern mining can be used to predict the next direction or destination of the current moving objects, like a group of animals or a commuter. The prediction can further help compress the trajectory data itself.

User Similarity Estimation. There are many aspects of similarity between users, like connections from social network, point of interest, check-in history, and any other logs, that can be obtained. Besides them, trajectory data, which reveals the life patterns of the users by trajectory classification and clustering, can also help improve the accuracy of similarity comparison.

Sport Tactic Analysis. For many team games like soccer, basketball, hockey, and rugby, the players' movements are essentially trajectories. By analyzing the video data from different cameras, the trajectory of each player can be reconstructed and are used in tactic analysis by many professional clubs nowadays. Some of them even hire a data analyst as a coaching staff.

Airspace Monitoring and Aircraft Guiding. A large volume of aircraft trajectory data is managed by an air traffic controller. They use

these trajectories to monitor the “health” of the airspace, which is implemented by trajectory clustering and outlier detection.

Scientific Study. Meteorologists use trajectory of SO_2 and NO_x in an isentropic and constant level to analyze the contributions of acidic deposition. Zoologists use the trajectory of animals to study their movement patterns. Biologists use proteomic trajectories to study mouse retina development.

Future Directions for Research

As summarized above, there exists a rich body of research on all aspects of trajectories, from data capturing, cleaning, compression, and indexing to processing. We have witnessed an accelerating trend of research activities from both academic and industry on this topic. There are three main drivers in today's big data landscape, which will also drive the research in trajectory data management, processing, and analytics in the foreseeable future.

First, it is about volume. Not only the volume of trajectory data now can reach TB level daily for some large navigation or taxi-/car-sharing companies, but also the number of queries has increased dramatically. What is the best way to process map matching for one billion points every day? How can we reduce the processing costs if we have 10,000 shortest path queries in the same region? This is a scenario that exists already, as when a user opens a map-based app and inputs a location, it issues a shortest path query. For every problem we solved before, it is the time to revisit them, to see how they can become scalable using new computing platforms and how better algorithms can be designed to support batch query processing (for a very large number of streaming queries on streaming data).

Second, it is about semantics. After all, trajectory data are low-level data which can be noisy and with a high level of redundancy (among consecutive points of one moving object, among the history data of one moving object over a long period, and among objects with similar moving patterns). There is a dilemma between justifying

the high costs of storing all data available and the fear that some data which we only find useful in the future for some purposes we do not know yet might be lost if we do not store them. Clearly, a new way of thinking is needed to manage trajectory data based on a semantic hierarchy, from raw data, calibrated data, events detected, summarization of data for a basic set of requirements, patterns discovered, and general statistics. Data can be gradually reduced over time and eventually removed. In such a way, trajectory data can be at the center for data integration and data analytics, as location and time are two ubiquitous dimensions for most information useful to us. Trajectory will no longer be considered as specialized data with limited applications; rather, it is an enabler data asset underpinning the future of a data-rich society.

Third, trajectory data can reveal so much about a person. With so much location and movement data about a person captured and accessed so easily, security and privacy become an extremely serious issue for trajectory data. Simple facts about one visiting or not visiting a place can be highly sensitive. This problem can become much more significant when the trajectories are used with other data sources including social network data. Some research has already started on this topic, but much more is needed urgently.

University, Aalborg, Denmark

Synonyms

Geo-textual data; Spatial and textual data

Definitions

With the proliferation of GPS-equipped mobile devices, notably smartphones, massive volumes of geo-located, or geo-tagged, text content are becoming available. For example, Foursquare hosts over 105 million locations around the world with over 12 billion check-ins (<https://foursquare.com/about> accessed January 2018), where each location is associated with both a geographical location and text content and similarly each check-in

is also associated with a location and text. Facebook also supports location check-ins. We refer to such data as *geo-textual*, or *spatio-textual*, data. Other examples of such data include points of interest (POIs) with descriptive text, geo-tagged microblog posts (e.g., tweets), geo-tagged photos with text tags (e.g., as found at Flickr and Instagram), geo-tagged news, and geo-tagged web pages. Spatio-textual data can be divided into (i) streaming spatio-textual data that arrives at a high rate, exemplified by geo-tagged tweets, and (ii) static spatio-textual data that is relatively stable, exemplified by collections of POIs.

Overview

Massive volumes of spatio-textual data are available from many sources. Furthermore, as new spatio-textual data is being generated, the volumes will continue to grow at rapid pace as mobile devices continue to proliferate. Additionally, spatio-textual data often comes with rich context information, such as temporal information. With this development as the backdrop, many research problems and solutions have been proposed for managing, analyzing, and mining spatio-textual data. We proceed to cover three representative types of research problems.

Spatial keyword queries To support the querying or search of spatio-textual data, many types of spatial keyword queries have been proposed. In general terms, a spatial keyword query takes a location and keywords and arguments and finds the spatio-textual objects that best match the location and keywords. For example, a user may want to find a nearby place whose textual description is relevant to “fine arts.” A number of index structures and query processing algorithms (Zhou et al., 2005; Hariharan et al., 2007; Felipe et al., 2008; Cong et al., 2009, 2012; Wu et al., 2012a,b; Rocha-Junior et al., 2011; Khodaei et al., 2010; Vaid and Jones, 2005; Zhang et al., 2013a,b; Chen et al., 2006; Christoforaki et al., 2011) have been developed for efficiently processing different kinds of spatial keyword queries.

Querying spatio-textual streams Spatio-textual data may arrive at a high rate (e.g., geotagged tweets, photos, or check-ins) and can then be modeled as data streams. In such streaming settings, continuous queries are of particular interest as users may want to be notified when interesting spatio-textual objects arrive. Several solutions (Chen et al., 2013, 2015; Li et al., 2013; Wang et al., 2015; Hu et al., 2015) for continuously querying spatio-textual streams have been proposed. For example, a user may want to be notified when tweets arrive that contain the term “flu” and are posted from within 5 km of the user’s home.

Exploring spatio-textual data When users do not have clear ideas about what to query or search for, it is beneficial to provide functionality that enables users to search, navigate, and discover new facts from spatio-textual data. Several proposals exist on exploring spatio-textual data (Feng et al., 2016; Skovsgaard et al., 2014; Zhao et al., 2016). For example, when a user is exploring a region on a map, the user can be shown the top- k most frequent terms in the region, and the result can be updated interactively when the user slides over the map.

Key Research Findings

Spatial keyword queries Consider a set \mathcal{D} of spatio-textual objects. An object $p \in \mathcal{D}$ is a two-tuple: $\langle \lambda, \psi \rangle$, where λ encodes a geo-location and ψ is a text value. Many types of spatial keyword queries on spatio-textual data exist that target different applications. The most standard spatial keyword queries generalize fundamental queries from spatial databases and information retrieval. In spatial databases, the arguably most fundamental queries are range and k nearest neighbor queries. In information retrieval, queries may be Boolean keyword expressions, returning results that satisfy the Boolean expressions, or ranking-based, returning the k objects that are most similar to query keywords according to

some text similarity function. Basic spatial keyword queries return a set or ranked list of objects from \mathcal{D} .

Four types of basic queries are covered below. Let ρ be a spatial region, λ be a point location, τ be a Boolean keyword expression, ψ be a set of keywords, and k be the number of objects to return. (1) A *Boolean range query* $q = \langle \rho, \tau \rangle$ returns all objects in \mathcal{D} that are located in region ρ and that satisfy the Boolean expression τ . An example is “Retrieve all objects whose text description contains the keywords *vegetarian*, *pizza*, and *latte* and whose location is within 1 km of the query location.” (2) A *Boolean kNN query* $q = \langle \lambda, \tau, k \rangle$ returns up to k objects from \mathcal{D} , each of which satisfies the Boolean expression τ , ranked in increasing spatial distance from λ . An example is “Retrieve the k objects nearest to the query location such that each object’s text description contains the keywords *vegetarian*, *pizza*, and *latte*.” (3) A *top- k range query* $q = \langle \rho, \psi, k \rangle$ returns up to k objects from \mathcal{D} that are located in the query region ρ , now ranked according to their text relevance to the set of keywords ψ . Here, an example is “Retrieve up to k objects whose locations are within 1 km of the query location, and that have the highest ranking scores, measured by the relevance of their text descriptions to the query keywords *vegetarian*, *pizza*, and *latte*.” (4) A *top- k kNN query* $q = \langle \lambda, \psi, k \rangle$ retrieves k objects from \mathcal{D} , ranked according to a function that takes into consideration both spatial proximity and text relevance. This functionality is exemplified by the query “Retrieve the k objects with the highest ranking scores according to a function that combines their distance to the query location (a point) and the relevance of their text description to the query keywords *vegetarian*, *pizza*, and *latte*.”

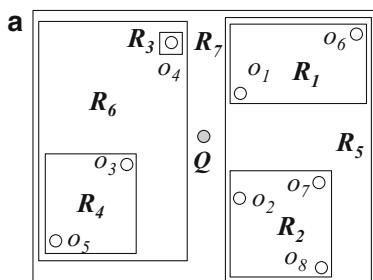

Index structures and algorithms have been developed to enable efficient processing of spatial keyword queries. Existing spatial keyword indexing techniques often combine a spatial index and a text index so that both textual and spatial information can be utilized to prune the search space when processing spatial keyword queries. The existing indices can be categorized according

to the spatial index they utilize: (i) R-tree-based indices (Zhou et al., 2005; Hariharan et al., 2007; Felipe et al., 2008; Cong et al., 2009; Wu et al., 2012a,b; Rocha-Junior et al., 2011), (ii) grid- or quad-tree-based indices (Khodaei et al., 2010; Vaid and Jones, 2005; Cong et al., 2012; Zhang et al., 2013a,b), and (iii) space-filling curve-based indices (Chen et al., 2006; Christoforaki et al., 2011).

The grid-based indices combine a spatial grid index and an inverted index for handling spatio-textual data, with two obvious ways of combining the two types of indices being the spatial primary index and the text primary index (Vaid and Jones, 2005). In the spatial primary index, spatio-textual objects are first organized by a grid index based on their spatial information. Then, for each grid cell, an inverted file is built for the objects that fall in the cell. In contrast, the text primary index extends the inverted index with the spatial information. Specifically, in the text primary index, each word is associated with a postings list, in which postings, each representing id of an object containing the word, are organized by a grid cell based on their locations. Each posting in a postings list contains the id of an object that contains the word of the postings list, and the postings are organized in a grid according to the locations of their objects. Using the example set of spatio-textual objects shown in Fig. 1a, b, the structure of the text primary index is exemplified in Fig. 2. The two index struc-

tures are proposed for tackling the problem of retrieving web documents relevant to a keyword query within a prespecified spatial region, i.e., the Boolean range query. For example, using the spatial primary index, at query time a set of cells that intersects with the query region is retrieved first. Then, the objects in these cells whose documents satisfy the query keywords are returned as the result. There exists no method to extend the two indices to efficiently handle the other three types of basic queries. A straightforward extension would not work better than using only an inverted file.

The R-tree-based geo-textual indices typically combine the R-tree index and the inverted index. The IR-tree (Cong et al., 2009) is a representative structure in this category. The index augments each node of the R-tree with a summary of the text content of the objects under the node. Specifically, each node contains a pointer to an inverted file that summarizes the text content of the objects in the subtree rooted at the node. The inverted file for a node contains (1) a vocabulary of all distinct terms in the text descriptions of the objects in the node's subtree and (2) each term t that is associated with a postings list, which is a sequence of pairs $\langle c, wt_{cp,t} \rangle$. Here, if the node is a non-leaf node, c is a child node of the node, and $wt_{c,t}$ is the number of times term t occurs in the object in the subtree that contains t the most times. If the node is a leaf node, c is an object in the node, and $wt_{c,t}$ is the frequency of

Spatio-textual objects and their bounding rectangles

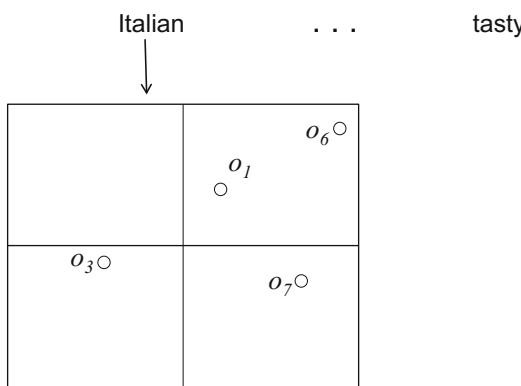

b	object	terms and term frequencies
o_1	(Italian, 2)(restaurant, 2)(pasta, 1)	
o_2	(coffee, 3)(restaurant, 3)(tasty, 1)	
o_3	(Italian, 1)(pizza, 1)(tasty, 1)	
o_4	(restaurant, 1)(pizza, 1)(tasty, 1)	
o_5	(coffee, 4)(restaurant, 3)	
o_6	(Italian, 4)(restaurant, 4)	
o_7	(Italian, 1)(coffee, 1)(restaurant, 4)(pasta, 1)	
o_8	(coffee, 3)(restaurant, 3)(tasty, 1)	

Text information of objects in (a)

Spatio-textual Data, Fig. 1 Example. (a) Spatio-textual objects and their bounding rectangles. (b) Text information of objects in (a)

term t in the object. The structure of an IR-tree is illustrated in Fig. 3.

The IR-tree supports all the four types of basic queries. We proceed to use the Boolean range query and top- k k NN query to illustrate how the IR-tree can be used to handle the basic queries. The high-level algorithm for using the IR-tree to handle the Boolean range query starts at the root node of an IR-tree and checks each entry in the node. If an entry overlaps the query

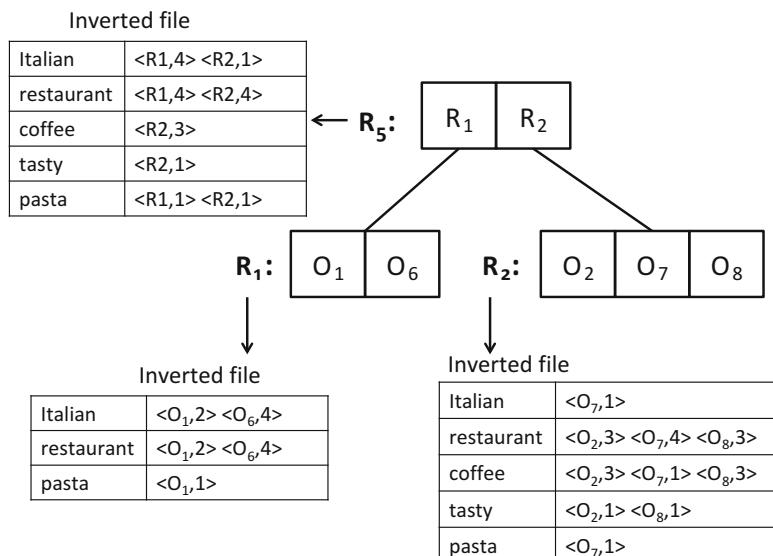

Spatio-textual Data, Fig. 2 Grid structure for keyword *Italian*

region and satisfies the keyword expression, the algorithm will check the entry's child node. The checking is done recursively over the IR-tree. When a leaf node is reached, the spatio-textual objects in the leaf nodes are checked, and objects satisfying both the spatial condition and the Boolean keyword condition are returned as results. Note that each non-leaf node contains summary information on both the spatial location and the terms of the objects in the node's subtree. For example, in node R_5 in Fig. 3 tells which terms the inverted file associated with the node will tell what keywords are contained in the objects in the node's subtree. If a query targets objects containing the term “rice,” the inverted file tells that there is no need to search R_5 's subtree.

The key idea of employing the IR-tree to compute the top- k k NN query is that each tree node on the summary information for each entry can be used to estimate a good upper bound on the relevance score, considering both spatial proximity and keyword relevance, to the query. This makes it possible to extend the best-first traversal algorithm, a standard algorithm for efficiently computing spatial k NN queries using the R-tree, to compute the top- k k NN query. The algorithm

**Spatio-textual Data,
Fig. 3** IR-tree and its inverted files

starts at the root and maintains a priority queue to keep track of the nodes and objects that have yet to be visited, for which the estimated upper bounds for each node, or the spatio-textual relevance score for each object, are used as the keys of nodes or objects, respectively. When deciding which node to visit next, the algorithm picks the node with the best key value from the set of nodes that have yet to be visited. The algorithm stops when the upper bounds of the remaining nodes are smaller than the currently k best results. The benefit of using the IR-tree for computing spatial keyword queries is that both spatial and textual information can be used in a combined fashion to prune the search space during query processing.

There also exist spatio-textual indices that combine a space-filling curve, e.g., the Z-order curve, and the inverted file. A typical example is the SFC-QUAD index (Christoforaki et al., 2011), which extends the inverted file with spatial information using space-filling curve. Specifically, the docIDs in each inverted list are assigned and ordered based on their spatial positions along a Z-order curve. SFC-QUAD is designed for *Boolean range query*. When processing a query with a given spatial region, a set of object ID ranges that fall in the query region are found. Then, these ranges are merged into a smaller number of ranges for reducing random disk I/O costs. Subsequently, the corresponding parts of the inverted lists of the query keywords within the ID ranges are retrieved, and then existing techniques for checking the Boolean expression of query keywords can be employed on the retrieved inverted lists. There exists no method to extend this type of index to efficiently handle the other three types of basic queries.

Beyond the basic spatio-textual queries, many other types of spatio-textual queries exist that are designed for different types of user needs. For example, the *m-closest keywords* (*mCK*) query (Zhang et al., 2009, 2010; Guo et al., 2015) retrieves a set of objects whose text content together contains a set of m query keywords and such that the maximum distance between any two objects is minimized. Another example is the *collective keyword* query (Cao et al., 2011, 2015; Long

et al., 2013), which takes a location λ and a set of keywords ψ as arguments. Its search space is all subsets of the set of objects \mathcal{D} , and it returns a set of objects such that (i) the textual descriptions of these objects collectively cover ψ , (ii) the result objects are all close to λ , and (iii) the result objects are close to each other. These problems of retrieving a group of objects satisfying keyword covering condition while minimizing the distance within the group or between the group and query are NP-hard, and heuristic and approximation solutions are developed to answer these queries efficiently.

Querying streaming spatio-textual data On streaming spatio-textual data, the four kinds of spatial keyword queries can be posed as snapshot queries. Furthermore, subscription queries on streaming spatio-textual data are often of great interest. A typical type of subscription query on spatio-textual data streams is the *Boolean subscription query* (Chen et al., 2013; Li et al., 2013; Wang et al., 2015), in which both spatial and keyword conditions serve as Boolean filters. For example, a user may want to subscribe to tweets that are posted within 500 m of the user's office and that contain the terms "sales" and "clothing," to receive such tweets continuously.

Other kinds of subscription queries also exist. Specifically, top- k subscription queries return a subscriber only the top- k results, which are ranked by considering text relevance, spatial proximity, and the freshness of the object with respect to the query. For example, a subscription query may be submitted for a POI (e.g., a hotel) over streaming geo-tagged tweets, where the location of the POI is the query location and selected keywords from the POI's text description (e.g., service, cleanliness, free Wi-Fi) can be used as the query keywords. Such a subscription query may be of interest to a management team of a POI that wants to be continuously fed with the top- k tweets, ranked based on the their relevance to the query keywords, their proximity of tweets to the query location, and their freshness.

Each user may submit multiple subscription queries, and the number of Internet users is huge. Hence, the number of subscription queries may

be large. Thus focus has been on developing efficient solutions to handle large numbers of spatial keyword subscription queries over spatio-textual streams (Chen et al., 2013; Li et al., 2013; Mahmood et al., 2015; Wang et al., 2015; Chen et al., 2015).

The high-level idea of existing solutions is to group queries such that the queries in one group can be processed together over the spatio-textual data stream, rather than being processed individually, which is much more computationally expensive. Intuitively, similar queries should be grouped together so that good filtering conditions for a group can be designed to check whether a new spatio-textual object can be a result for some queries in the group. In addition to being able to efficiently process a large number of subscription queries over spatio-textual data streams where spatio-textual objects arrive at a high rate, such solutions must be capable of efficiently handling the arrival of new subscriptions and the discontinuation of existing subscriptions. The existing solutions also involve index structures to organize subscription queries for efficient query processing.

Exploring spatio-textual data There exist at least two types of research for exploring spatio-textual data. First, the region search problem aims to identify a region of a user-specified shape and size that maximizes or minimizes some aggregate score of the objects inside it (e.g., the sum of relevance of objects to a query), for user exploration. For certain aggregation scores like SUM, algorithms (Imai and Asano, 1983; Nandy and Bhattacharya, 1995; Choi et al., 2012) with complexity $O(n \log n)$ have been proposed, where n is the number of objects in \mathcal{D} . For more general aggregation function, such as submodular monotone score function, a solution with the worst-case complexity $O(n^2)$ exists (Feng et al., 2016). To improve the efficiency, an approximate algorithm is proposed to select a set T of spatial points from the space for representing spatial objects in \mathcal{D} . The selected points together preserve some properties of \mathcal{D} such that the result region found on the set of points T can be an approx-

imation of the result on \mathcal{D} with performance guarantees (Feng et al., 2016).

Second, rather than finding a region that satisfies a user's needs, the problem of region exploration aims to explore and discover properties of user-specified regions. Given a user-specified region, one study (Skovsgaard et al., 2014) considers the problem of retrieving the top- k frequent words over the geo-textual data stream for the region. A new indexing technique is proposed for counting frequent items in static-sized summaries to allow the summaries to grow and shrink dynamically to adapt to changes in the incoming data. At query time, relevant summaries are merged to provide answers of the top- k frequent words with correctness guarantees.

Another example study of region exploration (Zhao et al., 2016) aims to efficiently discover topics in the spatio-textual data in a user-specified query region. Instead of learning a topic model for each query region, which is time-consuming, a two-phase approach to the exploratory topic mining task is advanced: (1) Indexing and Pre-Computation To support efficient online learning, the geographical space is partitioned into cells, and a grid-based index is constructed to organize the spatio-textual data. Then, by considering the memory constraint and accuracy guarantee of the online topic learning algorithm in the second phase, some cells are selected for learning latent Dirichlet allocation (LDA) models. (2) Online Topic Learning For a given query region, the pretrained topic models on the cells that overlap with the query region are combined as approximate topics for the spatio-textual data in the query region.

S

Examples of Application

Querying, mining, and exploring spatio-textual data have many applications. The basic types of spatial keyword queries are being supported in many online services that host large amounts of spatio-textual data, such as geo-tagged web pages, points of interest, geo-tagged tweets, and check-in. Other types of spatial keyword queries are designed to serve users for scenarios that

the basic queries are not sufficient. For example, consider a query with keywords “hotel, sports shop, and beach.” Perhaps no nearby single place is a good match for all the keywords. Instead, a group of places that are close to each other and are close to the query location may together meet the user’s needs better than any single object. Furthermore, it is expected that more applications will arise as more and more spatio-textual data is being generated in huge amount.

Querying streaming spatio-textual data is also very useful. For example, one application can be annotation of POIs with up-to-date geospatial social updates, such as geo-tagged tweets, as a manager of a POI may be interested in up-to-date tweets whose locations are close to the POI and whose text is relevant to the description of the POI. As another example, Groupon customers register their locations and keywords describing their interests. Then Groupon pushes Groupon messages to those customers that are near the messages and that have keywords that are relevant to the text of the messages.

Exploration of spatio-textual data is a desirable function as the amount of spatio-textual data continues to grow. The region research functionality can be used to find most influential regions for exploration, e.g., finding the best location for a billboard to influence as many consumers as possible to adopt a product, where the consumers may belong to a social network. Another example application of the region search is to find a region with most dense or diverse collection of services and attractions. One application of region exploration is to see what is happening in a region of interest.

Future Directions for Research

First, apart from spatial proximity and text relevance, many factors such as the quality of a spatio-textual object, click-throughs, and diversity can be considered in the ranking of spatial keyword query results. It is natural to consider whether these factors are useful for the ranking of query results and how important they are in ranking results. Reliable evaluation of ranking

functions for spatio-textual data is essential to answer these questions. However, the utility of a result is dependent on the individual user. It is thus challenging to establish a reliable ground truth for the results of ranking queries.

Second, personalized location recommendation (Liu et al., 2017) aims to understand users’ topical interests and mobility preferences from the users’ historical data. Existing work on spatial keyword queries does not consider personalization, while personalized location recommendation does not consider spatial keyword search. It is of interest to attempt to bridge this gap, thus enabling personalized search on spatio-textual data.

Third, it is an open problem to effectively and efficiently support continuous queries on spatio-textual streams. For example, instead of receiving individual tweets from a stream, users may want to be notified in real time of relevant trending events or even of causal relationships among events. Furthermore, high-velocity spatio-textual data streams call for distributed systems to support querying and data analytics.

Storage Failure

► Data Longevity and Compatibility

Storage Hierarchies for Big Data

Dirk Duellmann

Information Technology Department, CERN,
Geneva, Switzerland

Motivation

Big data applications usually have to rely on a combination of storage media to achieve an economic balance between the capabilities of different media types and application needs.

Applications requirements vary significantly in data lifetime, number of concurrent data producers/consumers, fraction of active to passive data volume, sharing between parallel processing units, and the relative balance between CPU and IO requirements.

Storage media properties vary by several orders in price per capacity, latency for sequential and random access patterns, aggregate and single stream bandwidth, power requirements, endurance, and reliability. Several methods exist to further adapt these capabilities by combining several storage devices of the same type, but

larger and economically efficient setups are constructed by combining several different storage technologies.

In addition, larger storage deployments typically provide services to more than one application and hence aim to achieve an economic compromise between total cost of ownership and functional capabilities matching the ensemble of their applications.

Tiered Storage and HSM Systems

The above trade-off has since the mainframe days led to storage systems covering several layers in the traditional memory hierarchy (see Fig. 1) and integrate multiple technologies (e.g., disk and tape, disks of different capabilities) into tiered storage systems.

In addition to combining technology capabilities, these systems usually provide an abstraction for accessing data independent of the storage media and mechanisms allowing to move data between the different media.

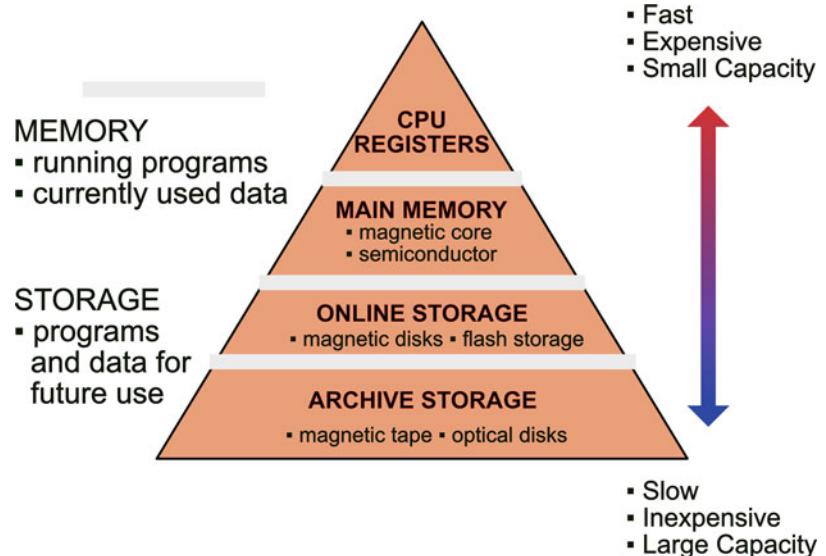

Hierarchical storage management (HSM) systems extend the above abstraction and automatize the data movement between different media or quality of service based on the measured or predicted access patterns.

The resulting storage systems facilitate also the use of different storage technologies over the life cycle of larger data sets. Since they reduce the operator effort for data movements, they can diminish the risk of data loss due to human manipulation errors. Typical examples of HSM systems for data life cycle management are archive and backup systems, which manage access to one or more consistent data snapshots across different storage technologies.

Additional end-user benefits are a single consistent system interface and a stable abstraction from a, potentially evolving, back-end implementation of the storage system. This abstraction is particularly important in large shared storage installations, which usually need to operate without downtime and hence require the replacement of faulty components and storage media to take place with minimal impact on normal operation.

Automated data migration between storage technologies can conceptually take place at different data granularity – from small groups of data blocks within a user file to large groups of files that span multiple tape volumes. The dominating implementation choice though are systems that consider complete, individual data files as management granularity.

Storage Hierarchies for Big Data, Fig. 1 Memory and storage hierarchy

Hybrid Disk Drives and Multitiered File Systems

Conceptually similar, but at small volume scale, also hybrid disk drives implement a tiered storage system. These devices combine the fast random access characteristic of NAND-flash with the more economical storage capacity of magnetic disks in a single unit. Based on the measured access patterns, the device dynamically replicates often used data blocks in its small flash cache area, which can greatly improve application performance without adverse effects on volume cost or total unit capacity. These hybrid devices are most useful in deployments with space or connectivity constraints (e.g., laptops and small or embedded servers).

In contexts free of the above constraints, a similar hybrid combination can be constructed via multitier file systems such as FusionDrive (Apple Core Storage) or Hybrid Storage Pools in ZFS (Bonwick and Moore, 2003; Gregg, 2009) that combine the fast access of NAND-flash with the large capacity of magnetic disks.

Challenges for Hierarchical Storage Systems

HSM systems can greatly improve resource utilization in particular in environments with stable, organized workflows and established prioritization between concurrent applications.

In more complex environments, with many concurrent interdependent applications and many users with differing or conflicting priorities, HSM system can show visible limitations. In these cases both storage system operation and user experience become complex and less predictable – up to the point that the HSM automation benefits are out-weighted by additional human effort to stabilize operation (by manually partitioning the resources and throttling concurrent user activity) and artificial storage operations by the user side to “trick” the system into the desired behavior.

A further challenge in large-scale deployments can arise from a mismatch between the granularity of HSM data movements (e.g., individual files) and the conceptual entities of a user workflow (e.g., larger groups of files in a typical big data application). This granularity mismatch

leads to difficulties let HSM data migrations appear as complete, atomic operations in the problem space of the user. A HSM with a purely file-based interface can only incomplete information of the user intention to access (or abandon) a larger group of files. The system may hence fail to properly predict the resource and time requirements to complete the intended operation or to predict the interference with data movements on behalf of other users/applications in a shared storage system.

Storage Hierarchies in Practical Applications

Tiered storage and hierarchical storage systems are today used in a variety of environments and are one of the key mechanisms to construct large-scale, cost-efficient storage systems that can adapt to changing access patterns over the lifetime of larger data set deployments. Data-intensive sciences such as high-energy physics, astrophysics, astronomy, and life sciences have constructed massive scientific data repositories (Bird et al., 2005; Pace, 2014) of several hundreds of petabytes by combining robotic tape archives, distributed disk clusters, and fast solid-state storage. The availability of reliable, high-bandwidth networks enabled to build large, distributed data repositories that enable collaborative scientific discovery and result sharing across dispersed communities. In data-intensive sciences, resource efficiency is of particular importance since computing budget constraints for storage media could limit the achievable statistical precision and hence relevance of a study.

On the commercial side during the last decade, large data amounts from legacy sources and databases and an increasing volume of environmental or commercial sensors have become the basis for many analytical applications. Hadoop with HDFS as location-aware storage environment for parallel processing and S3 as archive storage with disk or tape as back-end have become increasingly popular. Recently also, the large available amount of directly

addressable memory has allowed to move previously big data analytical problems entirely into memory or nonvolatile solid-state storage to avoid the latency of magnetic media access and TCP networking round trips for much of their execution. In this context Apache Spark (Zaharia et al., 2010) plays an important role in combining parallel data selection on a large disk-based repository with large distributed in-memory caches in the same run-time environment.

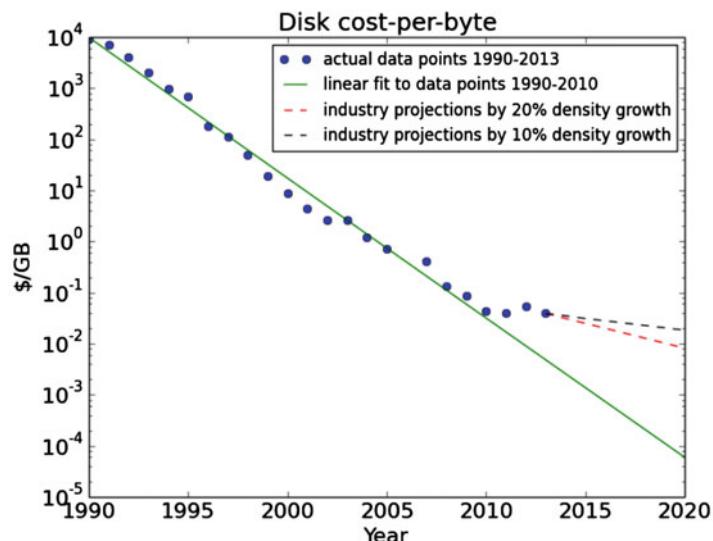

Expected Technology and Market Changes

The established role of storage hierarchies in big data applications is expected to continue also in the future, when several new technologies will become available and market changes will shift the price balance between the available media types. On the magnetic disk side, one can since several years observe a slowdown of the areal media density evolution (see Fig. 2 from Kryder rate Walter, 2005; Gupta et al., 2014; Mellor, 2014; Klein, 2017) as the R&D effort increases to productize new magnetic recording techniques like shingled magnetic recording (Feldman and Gibson, 2013) (SMR), microwave-assisted magnetic recording (Zhu et al., 2007) (MAMR), and

heat-assisted magnetic recording (Kryder et al., 2008) (HAMR).

Recording technologies such as SMR further imply a shifted balance between update and read performance, which will limit scalability in some use cases, unless combined with fast memory- or flash-based cache. Another influence on the media price balance may arise from the increasing consolidation of magnetic disk deployments to only a few, larger cloud providers, who are seeking increased influence on the design of magnetic disk units (Brewer et al., 2016). For the small number of vendors in the disk market, it will likely become more important to suit large computer center deployments than to maintain compatibility with the traditional form factor of previous desktop computer generations. The home and mobile markets are already largely based on devices with NAND-flash storage, which will see increasing competition from direct accessible persistent memory with higher durability and reduced write amplification (Intel 2015; <https://arstechnica.com/information-technology/2017/03/intels-first-optane-ssd-375gb-that-you-can-also-use-as-ram/>). This storage technology, if their advertised price point and functional capabilities are confirmed, would allow to further extend the problem space reachable by in-memory processing. Together with DRAM these new media would also enable

Storage Hierarchies for Big Data, Fig. 2 Magnetic disk price evolution

faster hybrid storage devices with NAND-flash or magnetic disks. Tape at the high volume end of the storage hierarchy has but due to very low media and power cost been remarkably successful – despite its for many applications problematic combination of high sequential rate and high access latency. Also here, visible market consolidation is influencing the continued technology evolution, and archive storage hierarchies involving tape will get increasing competition from disk- and flash-based alternatives (Gupta et al., 2014).

Conclusion

In conclusion, the use of tiered or hierarchical media combinations from several layers of the storage hierarchy will continue, and the recent fast, high-density, direct-access solid-state storage will allow to enlarge the problem size accessible to big in-memory applications. For problems that require larger volume scalability, the parallel cloud processing environments will benefit from some continued media density (and hence volume) growth but at lower Kryder rate. The performance gap between sequential read and other access methods (e.g., random access, write/update access) will continue to increase on the magnetic disk side. The benefits of integrating magnetic media with direct-access solid-state storage will therefore for many big data applications get even more important.

Storage Technologies for Big Data

Zhaojie Niu and Bingsheng He

National University of Singapore, Singapore,
Singapore

Overview

This article introduces big data storage systems. It first describes the development of storage techniques for big data. Then, it compares the different storage models and their most suitable use cases. Finally, it talks about the impact of emerging hardware on the big data storage techniques and introduces some hot research topics.

Introduction and Background

In the big data era, data are increasingly gathered from heterogeneous devices like IoT devices, sensor networks, scientific experiments, websites, and many other applications producing data in various formats. The data sets are

so voluminous and complex that traditional relational databases are inadequate to deal with them. Thus, innovative research and development of storage systems that can provide highly scalable, reliable, and efficient storage for dynamically increasing data is required. A movement to NoSQL (Not only SQL) occurs, and many NoSQL databases are proposed. They have simplicity of design, simpler “horizontal” scaling to clusters consists of thousands of servers, and more fine-grained control over availability. The data structures used by NoSQL databases are optimized for target data formats and sources, which are different from those used in relational databases, making some operations faster in NoSQL. Many NoSQL stores compromise consistency (in the context of CAP theory (Seth and Nancy, 2002)) in favor of partition tolerance, availability, and performance. These NoSQL stores also lack true ACID transaction supported by traditional relational databases, although a few databases, such as Google spanner (David et al., 2017), start to embrace the relational model.

Relational databases have been widely used efficiently for transaction processing in terms of storage and processing for many decades. The relational databases support ACID transaction that also limits their horizontal scalability. To achieve availability and better scalability, most NoSQL databases compromise consistency and do not support true ACID transaction support as traditional relational databases. The strengths and weakness for traditional relational database and NoSQL database are summarized in Table 1.

The NoSQL databases mainly consists four types of data models: key-value, column-oriented, document-oriented, and graph. These NOSQL systems are being used to handle exponentially growing data but cannot tolerate the performance degradation caused by data persistence. On the other hand, these systems face the challenges posed by the inherent difficulties in scaling DRAM and the cost of the DRAM. To address these challenges, new emerging hardware technologies like nonvolatile main memory (NVRAM) have lately received a great deal of attention in the database community. NVRAM is positioned between DRAM and secondary storage (such as SSD), both in terms of performance and cost. NVRAM can fundamentally change in-memory databases as data structures do not have to be explicitly backed up to hard drives or SSDs but can be inherently persistent in main memory (David et al., 2015; Jasmina et al., 2015; Mihnea et al., 2017; Sudarsun et al., 2016; Colaso et al., 2017). In section “[Taxonomy of Big Data Storage Technologies](#)”, we introduce these NoSQL systems based on the data model and how the emerging hardware impacts the design of the NOSQL systems.

Taxonomy of Big Data Storage Technologies

NoSQL databases mainly consist four types of data models: key-value, column-oriented,

Storage Technologies for Big Data, Table 1 Strengths and weakness for traditional relational database and NoSQL database

DB	Strength	Weakness
Traditional relational database	Support highly structured data; Efficient storage and processing in auxiliary server; ACID transaction support; Vertical scalability; Specialized data manipulation languages; Specialized data schema	Performance and processing delay bottleneck with growth of data; ACID support which hinders scalability; Limitation for schema-less and unstructured data
NoSQL database	Support heterogeneous structured data; Horizontal scalability with extendible commodity servers; High reliability; High availability	No compliance with ACID in order to achieve high scalability and high availability for most NoSQL databases

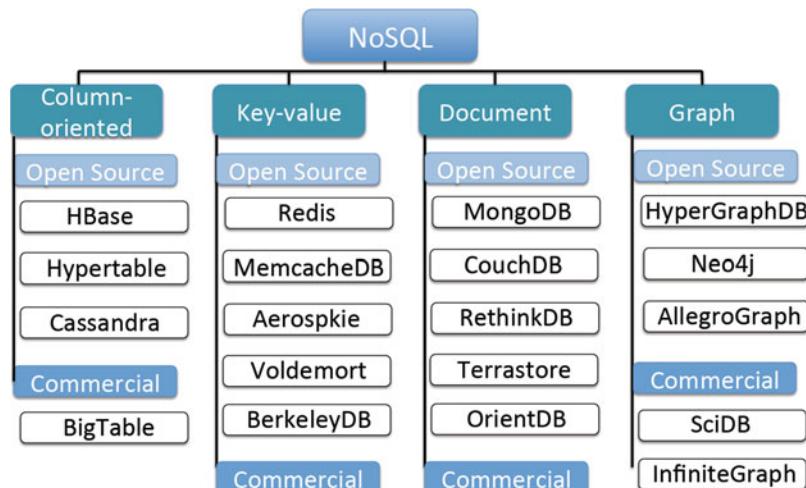

Storage Technologies for Big Data, Table 2

Performance, scalability, flexibility and complexity of different data models for NoSQL databases

Data model	Performance	Scalability	Flexibility	Complexity
Key-value	High	High	High	None
Column-oriented	High	High	Moderate	Low
Document-oriented	High	Variable	High	Low
Graph	Variable	Variable	High	High
Relational	Variable	Variable	Low	Moderate

Storage Technologies for Big Data, Fig. 1

Taxonomy of big data storage technologies based on data models

document-oriented, and graph (Michael, 2014). The performance, scalability, flexibility, and complexity for different data models are different that is shown in Table 2. We classify NoSQL databases based on the data models and introduce some representing systems for each category.

We classify the current representing big data storage system according to data models as shown in Fig. 1 and introduce them one by one in detail. We also discuss the recent development on emerging storage techniques with nonvolatile memory (NVRAM).

Key-Value Data Model

The key-value type, basically, uses a hash table in which there exist a unique key and a pointer to a particular item of data. A bucket is a logical group of keys, but they don't physically group the data. There can be identical keys in different buckets. This in-memory data structure design needs to explicitly backup in case of system crashes in DRAM which degrades the

performance. NVRAM guarantees data consistency even across power outages while it comes with new challenges as the consistency and persistence of in-memory data structures have to be guaranteed even across system crashes. Data structure and algorithms of the hash table especially on NVRAM need to be redesigned for the use in NV-persisted in-memory databases (David et al., 2015).

S

Column-Oriented Data Model

In column-oriented NoSQL database, data is stored in cells grouped in columns of data rather than as rows of data. Columns are logically grouped into column families. Column families can contain a virtually unlimited number of columns that can be created at runtime or the definition of the schema. Read and write is done using columns rather than rows. To increase the scalability and reduce the cost of using DRAM, SAP starts to explore the new column-based in-memory data structures and efficient algorithms

which are directly stored and used in NVRAM blocks (Mihnea et al., 2017).

Document-Oriented Data Model

The data which is a collection of key-value pairs is compressed as a document store quite similar to a key-value store, but the only difference is that the values stored (referred to as “documents”) provide some structure and encoding of the managed data. XML, JSON (Java Script Object Notation), and BSON (which is a binary encoding of JSON objects) are some common standard encodings. In order to provide efficient memory access for these objects, cost-effective memory placement mechanisms are proposed on NVRAM (Sudarsun et al., 2016).

Graph Data Model

In a Graph Base NoSQL database, you will not find the rigid format of SQL or the tables and columns representation; a flexible graphical representation is instead used which is perfect to address scalability concerns. Graph structures are used with edges, nodes, and properties which provide index-free adjacency. Data can be easily transformed from one model to the other using a Graph Base NoSQL database. With the increase of the scale of the graph, the capacity of scaling of DRAM is not able to satisfy the requirements of analytics over graph with trillions of connections. Explores of replacing DRAM with emerging nonvolatile memories (NVRAM) on large-scale graph analytics framework are performed. Some hybrid memory systems with NVRAM and DRAM are proposed in a cost-effective manner and the performance it can achieve is close to DRAM-only performance (Jasmina et al., 2015).

Synonyms

Stream performance evaluation

Definitions

Stream benchmarks deal with performance evaluation techniques and define related metrics for stream data processing systems.

Overview

Firstly, we discuss background information on database benchmarking, foundations, main metrics, and main features for stream data benchmarking. Then, we provide related stream benchmarks and categorize them with respect to the application area.

Historical Background

Lee et al. (1997) initiated one of the first works in the related area, MediaBench, by evaluating and synthesizing multimedia and communications systems. Abadi et al. (2003) and Motwani et al. (2003) pioneered one of the first stream data processing systems, Aurora and STREAM, respectively. The need to compare the performance characteristics of streaming systems relative to each other and to alternative (e.g., Relational Database) systems endorsed the development of Linear Road benchmark (Arasu et al., 2004).

Foundations

Stream data processing is key when the large volumes of input data have to be processed fast

to quickly adapt and react to changes. Therefore, stream data processing has gained significant attention.

The main intuition behind stream benchmarks is to define a standard to compare streaming systems, which has different characteristics, in a various use-cases. Stream benchmarks simulate an environment with different workloads and analyze the behavior of the systems to be tested. The more similar the benchmark to the real production environment, the more realistic and valuable it is.

In the high level, stream benchmark framework consists of two main components: system under test and driver. Driver is responsible for simulating the production environment w.r.t. a given use-case. System under test is actual tested streaming system which can be out-of-the-box or tuned.

Accurately representing the system under test is important when designing benchmarks. Schroeder et al. (2006) categorize benchmarks into closed, open, and partly open models. In a closed system model, the input arrivals are triggered after the completion of the previous input processing and some thinking time delay. In an open system model, on the other hand, new input arrivals and the completion of the previous input processing are independent. In a partly open system model, we specify the settings for which partly open model behaves like a closed or an open model.

Below, we categorize existing stream benchmarks in literature. Firstly, we talk about the main metrics in stream benchmarks and their definitions. Secondly, we analyze stream benchmarks which concentrate on specific features such as fault tolerance and state management. Lastly, we analyze stream benchmarks built for specific industrial use-cases.

Metrics

Main metrics for stream benchmarks are latency and throughput. Achieving high throughput while preserving low latency is the main goal for streaming systems.

Latency

Defining a standard latency metric definition for streaming systems is a challenging task. One reason is significant architectural and computational differences among stream data processing engines. Another reason is calculating latency for stateful operators in nontrivial.

Chintapalli et al. (2016a) use Redis for stateful computations as part of the system under test. The authors calculate the event-time latency by subtracting the window start time and duration time from the last updated time of a particular input record. Perera et al. (2016) propose reproducible benchmarks for Apache Spark and Flink on public clouds. The authors do not use a standard latency definition, as, in this case, the latency measurement is experiment and application specific. Lu et al. (2014) propose a new stream benchmark by separating the data generator and system under test. The authors put a mediator layer between the two components. They define latency as an average time span from the arrival of a record till the end of processing of the record. Qian et al. (2016) also adopted a similar approach. Karimov et al. (2018) develop stream benchmark framework that overcome overhead of a mediator layer. The authors show how processing-time latency might mislead when compared with event-time latency.

Throughput

Throughput is another essential metric for stream data processing systems. Similar to latency, measuring and defining a standard throughput metric for all streaming systems is nontrivial.

Chintapalli et al. (2016a) separate the data generator and system under test with an intermediate layer between them. The authors calculate the throughput by configuring the speed of data generator for a specific workload. Lopez et al. (2016a), on the other hand, rely on Kafka's sampled throughput rates. Lu et al. (2014) measure the overall system under test throughput and throughput per node. The authors define overall throughput metric by count (average count of records per second) and size (average data size in terms of bytes processed per second). Shukla and Simmhan (2016) define throughput as the rate of

output tuples emitted from the output operators in a unit time. Dayarathna and Suzumura (2013) define job throughput in two ways. First, the authors measure the time required to process a specific amount of events. Second, the authors measure the number of tuples processed in a given amount of time. The throughput computation is performed based on both time periods. Samosir et al. (2016), on the other hand, adopt the throughput metric used in batch processing systems. Karimov et al. (2018) propose maximum sustainable throughput throughout the whole experiment.

Benchmarking the energy consumption of stream data processing engines is another important aspect of stream benchmarks. Dayarathna et al. (2017) adopt Linear Road benchmark for testing the energy efficiency of S4, Storm, ActiveMQ, Esper, Kafka, and Spark Streaming. The key finding of this work is that better power consumption behaviors in the context of data stream processing systems can be achieved by setting tuple sizes to be moderate and scheduling plans to have balanced system overhead.

Features

Besides focusing on metrics computations, stream benchmarks also concentrate on specific features of stream data processing engines.

Fault Tolerance

Lopez et al. (2016a) study streaming systems' tolerance to failures by analyzing the system behavior after detecting the failure. The system behavior includes the message losses and latency/throughput change during node failure. Gradvohl et al. (2014) categorize fault tolerance behavior in stream data processing systems into replication components, upstream backup, checkpoint, and recovery and analyze the system utilization of these strategies. Mohamed et al. (2017) propose a driver which allows programmatic specification of complex fault scenarios. Chauhan et al. (2012) measure the systems' tolerance to faults by (i) measuring the

number of events handled and (ii) checking the number of events that were missed when nodes go down in cluster. Qian et al. (2016) adopt identity workload and consider only one node failure at a time. The benchmark suite collects the performance metrics in node-failure workload and compares it with non-faulty workload.

State Management

Linear Road benchmark, Arasu et al. (2004) and Jain et al. (2006), consists of continuous queries which update operator state by processing the incoming stream. Kipf et al. (2017) analyze the limitation of efficiently exposing the state to analytical queries for stream data processing systems. The authors compare main-memory databases and streaming engines and propose new methods to advance state management in streaming systems.

Key Applications

In this section we categorize stream benchmarks based on different industrial use-cases.

Data mining. Zhang et al. (2012) and Le-Phuoc et al. (2012) are the pioneers to propose SRBench and LSBench, the first benchmarks for RDF streaming and Linked Stream Data processing. The authors adopt wide range of queries including simple graph pattern matching queries and the ones with complex reasoning tasks. DellAglio et al. (2013) propose CSRBM, an extension for SRBench. The authors overcome the main shortcoming of SRBench and LSBench, which is inability to assess the correctness of query evaluation results, by analyzing the operational semantics of the particular processors. Ali et al. (2015) address another limitation of SRBench and LSBench, addressing the dynamic application requirements and data-dependent properties. The authors propose the workloads which include fluctuating streaming rates during query execution and changing the application requirements over a some time duration. Implementing, modeling, and evaluating the provisioning algorithms for stream processing applications is

another related work, in which authors propose VISIP Testbed (Hochreiner, 2017). The toolkit provides a common runtime for stream processing applications.

E-commerce. Teng et al. (2017) analyze streaming system behavior in e-commerce scenarios. The authors provide a data generator, as part of the benchmark suite, with certain user models, which adopt a certain user habits in e-commerce platforms. Tucker et al. (2008) propose NEXMark, an extension of XMark, Schmidt et al. (2001), based on online auction system. Currently, NEXMark is used as a benchmark suite in Apache Beam, Buzzwords (2017).

IoT. Shukla and Simmhan (2016) develop a benchmark suite for streaming systems for IoT applications. The authors classify 13 common IoT tasks with functional categories. Moreover, the benchmark suite provides two IoT applications being statistical summarization and predictive analytics. CityBench is the benchmark to evaluate RDF stream processing systems in IoT scenarios, Ali et al. (2015). The authors use traffic vehicles, parking, weather, pollution, cultural, and library events, with changing event rates and playback speeds as part of the data generator. Shukla et al. (2017) extend the existing stream benchmarks in IoT proposing RIoTBench. The benchmark includes 27 common IoT tasks. Moreover, the authors propose four IoT application benchmarks composed from the proposed tasks.

Network. Nazhandali et al. (2005) propose stream benchmark for sensor network systems, suitable for sensor processors. The authors propose new metrics being EPB (Energy Per Bundle) and CFP (Composition Footprint) to evaluate and compare systems under test. Lopez et al. (2016b) analyze the performance of Virtualized Network Function for real-time thread detection using stream processing. Wolf and Franklin (2000) propose telecommunication benchmark for network processors. The authors adopt four workloads for data stream processing in telecommunications scenario. Trivedi et al.

(2016) analyze yet another interesting aspect, the (ir)relevance of network bandwidth to modern streaming engines. The key finding of this paper is that current streaming engines need significant architectural improvements as they cannot benefit from high bandwidth networks.

Multi-core processors. Zhang et al. (2017) benchmark the current design of stream data processing engines on multi-core processors analyzing the possible bottlenecks of massively parallel JVM-based streaming engines.

CEP. Mendes et al. (2009) were among the pioneers to propose a benchmark for CEP systems. The authors provide series of queries to exercise factors such as window size and policy, selectivity, and event dimensionality. Mendes et al. (2013) propose BiCEP, the domain-specific benchmark suite, to evaluate different performance aspects of event processing platforms. Alevizos and Artikis (2014) adopt existing techniques to analyze widely used Esper system which employs a SQL-based language and RTEC which is a dialect of the Event Calculus.

Machine learning. Gama et al. (2009) propose a general framework for assessing predictive stream learning algorithms. Gama et al. (2013) focus on decision models and develop a benchmark suite to evaluate continuously evolving streaming and to detect and react to real-time input data. Imai et al. (2017) utilize a machine learning model to predict the maximum sustainable throughput in streaming systems.

Bottlenecks. When designing a system, it is important to detect and avoid bottlenecks. For streaming systems, Chintapalli et al. (2016b) show the Zookeeper being a main performance bottleneck for Storm. For stream benchmarks, Friedrich et al. (2017) show the limitations of existing benchmark designs and the possible biased results. Moreover, Artisans (2017) makes a disclaimer for the original implementation of Chintapalli et al. (2016a), showing an intermediate message layer, Kafka,

and external state management system, Redis, are actually being a bottleneck for Flink's overall performance.

Synonyms

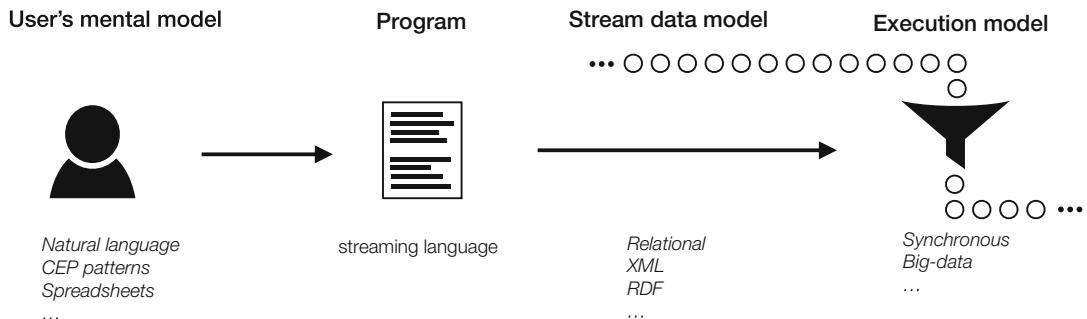

[Continuous dataflow language](#); [Streaming language](#); [Stream processing language](#)

Definitions

A *stream processing language* is a programming language for specifying streaming applications. Here, a *stream* is an unbounded sequence of data items, and a *streaming application* is a computer program that continuously consumes input streams and produces output streams. This article surveys recent streaming languages designed around the user's mental model, the stream data model, or the execution model, as illustrated in Fig. 1. In addition to specific languages, this article also discusses *abstractions* for stream processing, which are high-level language constructs that make it easy to express common stream processing tasks.

Overview

Continuous data streams arise from many directions, including sensors, communications, and commerce. Stream processing helps when low-latency responses are of the essence or when streams are too big to store for offline analysis. Programmers can of course write streaming applications in a general-purpose language without resorting to a dedicated domain-specific language (DSL) for streaming. However, using a streaming language makes code easier to read, write, understand, reason about, modularize, and optimize. Indeed, a suitable streaming language can help developers conceive of a solution to their streaming problems.

Stream Processing Languages and Abstractions, Fig. 1 Stream processing languages

This article provides definitions, surveys concepts, and offers pointers for more in-depth study of recent streaming languages. The interested reader may also want to refer to earlier papers for historic perspective: the 1997 survey by Stephens focuses on streaming languages (Stephens, 1997), the 2002 survey by Babcock et al. focuses on approximate streaming algorithms (Babcock et al., 2002), and the 2004 survey by Johnston et al. addresses dataflow languages, where streaming is a special case of dataflow (Johnston et al., 2004).

The central abstractions of stream processing are streams, operators, and stream graphs. A *stream* is an unbounded sequence of data items, for example, position readings from a delivery truck. A streaming *operator* is a stream transformer that transforms input streams to output streams. From the perspective of a streaming application, an operator can also have zero input streams (*source*) or zero output streams (*sink*). Finally, a *stream graph* is a directed graph whose nodes are operators and whose edges are streams. Some literature assumes that the shape of stream graphs is restricted, e.g., acyclic, but this article makes no such assumption. While only some streaming languages make the stream graph explicit, others use it as an intermediate representation. For example, the query plan generated from streaming SQL dialects is a stream graph.

The field of streaming languages is diverse and fast-moving. To understand where that diversity comes from, it is instructional to classify streaming languages by their *raison d'être*. Some streaming languages are based on the attitude

that since streams are data in motion, data is most central, and the language should be built around a data model (relational, XML, RDF). Other streaming languages focus on the execution model for processing the dataflows efficiently, by enforcing timing constraints or exploiting distributed hardware (synchronous, big-data). A third class of streaming languages focus more on enabling the end user to develop streaming applications in high-level or familiar abstractions (complex events, spreadsheets, or even natural language). Section “[Findings](#)” surveys languages in each of these classes, and section “[Examples](#)” gives concrete examples for two languages.

Findings

This section gives an overview of the field of stream processing languages by surveying eight prominent approaches. Each approach is exemplified by one concrete language. The approaches are grouped along the lines of the previous section into approaches driven by the data model, by the execution model, or by the target user.

Data-Model Driven Streaming Languages

The success of the **relational** data model for database systems has inspired streaming dialects of the SQL database language. These dialects benefit from developers' familiarity with SQL and from its relational algebra underpinnings. A prominent example is the CQL language, which complements standard relational operators with operators to transform streams into relations and

vice versa (Arasu et al., 2006). CQL lends itself to strong static typing, cf. Figure 10 of Soulé et al. (2016). Efforts toward standardizing streaming SQL focused on clarifying semantic corner cases (Jain et al., 2008).

The success of **XML** as a universal exchange format for events and messages has inspired XML-based streaming languages. These languages take advantage of a rich ecosystem of XML tools and standards and of the fact that XML documents are self-describing. The languages come in different flavors, from view maintenance over XML updates in NiagaraCQ (Chen et al., 2000) to languages that process streams where each data item is a (part of an) XML document (Diao et al., 2002; Mendell et al., 2012).

The Resource Description Framework (**RDF**) is a versatile data format for integration and reasoning, based on triples of the form `(subject, predicate, object)`. A popular language for querying static RDF knowledge bases is SPARQL (Prud'hommeaux and Seaborne, 2008), and C-SPARQL (Barbieri et al., 2009) extends SPARQL for continuous queries, just like CQL extends SQL. A stream is a sequence of timestamped triples, but a query can also return a graph by emitting multiple triples with the same timestamp.

Execution-Model Driven Streaming Languages

Dataflow **synchronous** languages (Benveniste et al., 2003) were introduced in the late 1980s as domain-specific languages for the design of embedded control systems. A dataflow synchronous program executes in a succession of discrete steps, and each step is assumed to be instantaneous (the synchronous hypothesis). A programmer writes high-level specifications in the form of stream functions specifying variable values at each step or instant. Section “[Synchronous Dataflow in Lustre](#)” illustrates this approach with the language Lustre (Caspi et al., 1987).

Streaming **big data** is motivated by the “4 Vs”: a lot of data (volume) streams quickly (velocity) into the system, which must deal with diverse data and functionality (variety) and with uncertainty (veracity). Languages for big-data

streaming let users specify an explicit stream graph that can be easily distributed with minimal synchronization and are extensible by operators in widely adopted general-purpose languages. Section “[Big-Data Streaming in SPL](#)” elaborates on this for the concrete example of SPL (Hirzel et al., 2017).

Target-User Driven Streaming Languages

Complex event processing, or **CEP**, lets users compose events hierarchically to span the gap between low-level and high-level concepts. There are various pattern languages for CEP that compile to finite automata. Recognizing this, the MATCH-RECOGNIZE SQL extension proposal simply adopts familiar regular expressions as the CEP pattern language (Zemke et al., 2007). While the SQL basis focuses on a relational model, regular expressions can also be used for CEP in big-data streaming (Hirzel, 2012).

Since there are many more **spreadsheet** users than software developers, a spreadsheet-based streaming language could reach more target users. Furthermore, spreadsheets are reactive: changes trigger updates to dependent formulas. ActiveSheets hooks up some spreadsheet cells to input or output streams, with normal spreadsheet formulas in between (Vaziri et al., 2014). When the two-dimensional spreadsheet data model is too limiting, it can be augmented with windows and partitioning (Hirzel et al., 2016).

A streaming language based on **natural language** might reach the maximum number of target users. However, since natural language is ambiguous, a controlled natural language (CNL) is a better choice (Kuhn, 2014). For instance, the language for META is a CNL for specifying event-condition-action rules, temporal predicates, and data types (Arnold et al., 2016). The data model includes events and entities with nested concepts and can be shown to be equivalent to the nested relational model (Shinnar et al., 2015).

Examples

This section gives details and concrete code examples for two out of the eight approaches for languages surveyed in the previous section:

the synchronous dataflow approach exemplified by Lustre (Caspi et al., 1987) and the big-data streaming approach exemplified by SPL (Hirzel et al., 2017).

When it comes to implementing streaming languages, there is a spectrum from basic to sophisticated techniques. At the basic end of the spectrum are configuration files in some existing markup format such as XML. The streaming engine interprets the configuration file to construct and then execute a stream graph. An intermediate point is a domain-specific embedded language (EDSL or sometimes DSEL) (Hudak, 1998). As the name implies, an EDSL is a domain-specific language (DSL) that is embedded in some host language, typically a general-purpose language (GPL). The line between simple libraries and EDSLs is blurred, but in general, EDSLs encourage a more idiomatic programming style. Recently, EDSLs have gained popularity as several GPLs have added features that make them more suitable for hosting EDSLs. At the sophisticated end of the spectrum are full-fledged, stand-alone DSLs with their own syntax, compiler, and other tools. While stand-alone streaming DSLs are not embedded in a GPL, they often interface with a GPL, e.g., for user-defined operators.

For clarity of exposition, the following examples use stand-alone streaming languages. Stand-alone languages are the norm for synchronous dataflow, because self-contained code is easier to reason about. On the other hand, for big-data streaming, EDSLs that specify an explicit stream graph are popular, because they are easier to implement. But as the example below illustrates, once implemented, stand-alone languages also have advantages for big-data streaming.

Synchronous Dataflow in Lustre

Synchronous dataflow languages were introduced to ease the design and certification of embedded systems by providing a well-defined mathematical framework that combines a logical notion of time and deterministic concurrency. It is then possible to formally reason about the system, simulate it, prove safety properties, and generate embedded code. The synchronous dataflow language Lustre is the backbone of the industrial lan-

guage and compiler Scade (Colaco et al., 2017) routinely used to program embedded controllers in many critical applications.

In Lustre a program is a set of equations defining streams of values. Time proceeds by discrete logical steps, and at each step, the program computes the value of each stream depending on its inputs and possibly previously computed values. Consider the example of Fig. 2 adapted from Bourke et al. (2017). The function *counter* takes three input streams, two integer streams *init* and *incr*, and one boolean stream *reset*. It returns the cumulative sum of the values of *incr* initialized with *init* and similarly reset when *reset* is *true* (Line 5). The variable *pn* (Line 4) stores the value of the counter *n* at the previous step using the initialization operator (\rightarrow) and the non-initialized delay **pre**.

A stream is not necessarily defined at each step. The clock of a stream is a boolean sequence giving the instants where it is defined. Streams with different clocks can be combined via sampling (**when**) or stuttering (**current**). For instance, the *tracker* function of Fig. 2 tracks the number of times the speed of a vehicle exceeds the speed limit. The **when** operator samples a stream according to a boolean condition. The function *counter* is thus only activated when *x* is *true* (Line 12). The **current** operator completes a stream with the last defined value when it is not present (Line 13). The value of *t* is thus sustained when *x* is *false*. The execution of such a program can be represented as a timeline, called a chronogram (illustrated in Fig. 2), showing the sequence of values taken by its streams at each step.

Specific compilation techniques for synchronous languages exist to generate efficient and reliable code for embedded controllers. Compilers produce imperative code that can be executed in a control loop triggered by external events or on a periodic signal (e.g., every millisecond). The link between logical and real time is left to the designer of the system.

Since the seminal dataflow languages Lustre (Caspi et al., 1987) and Signal (Le Guernic et al., 1991), multiple extensions of the dataflow synchronous model were proposed. Lucid Synchrone (Pouzet, 2006) combines the dataflow

```

1 node counter (init, incr: int; reset: bool) returns (n: int);
2 var pn: int;
3 let
4   pn = init -> pre n;
5   n = if reset then init else pn + incr;
6 tel
7
8 node tracker (speed, limit: int) returns (t: int);
9 var x: bool; cpt: int when x;
10 let
11   x = (speed > limit);
12   cpt = counter(0, 1, false) when x;
13   t = current(cpt);
14 tel

```

speed	28	29	32	30	44	53	58	48	33	28	29	...
limit	30	30	30	30	55	55	55	30	30	30	30	...
<i>x</i>	F	F	T	F	F	F	T	T	T	F	F	...
<i>cpt</i>				1			2	3	4			...
<i>t</i>	0	0	1	1	1	1	2	3	4	4	4	...

Stream Processing Languages and Abstractions, Fig. 2 Lustre code example with a possible execution

synchronous approach with functional features à la ML, the n-synchronous model (Mandel et al., 2010) relaxes the synchronous hypothesis by allowing communication with bounded buffers, and Zélus (Bourke and Pouzet, 2013) is a Lustre-like language extended with ordinary differential equations to define continuous-time dynamics.

Recent efforts focus on the compilation, verification, and test of dataflow synchronous programs. New techniques have been proposed to compile Lustre programs for many-core systems (Rihani et al., 2016) or improve the computation of the worst-case execution time (WCET) of the compiled code (Bon enfant et al., 2017; Forget et al., 2017). Kind2 (Champion et al., 2016) is a verification tool based on SMT solvers to model-check Lustre programs, and the Vélus compiler (Bourke et al., 2017) tackles the problem of verifying the compiler itself using a proof assistant. Lutin (Raymond and Jahier, 2013) (and its industrial counterpart, the Argosim Stimulus tool Argosim, 2015) is a DSL to design non-deterministic test scenarios for Lustre programs.

Big-Data Streaming in SPL

Big-data streaming languages are designed to handle high-throughput streams while at the same time being expressive enough to handle diverse data formats and streaming operators. A popular

way to address the requirement of high throughput is to make it easy to execute the streaming application not just on a single core or even a single computer, but on a cluster of computers. And a popular way to address the requirement of high expressiveness is to make it easy for programmers to define new streaming operators, possibly using a different programming language than the stream processing language they use for composing operators into a graph.

SPL is a big-data streaming language designed for distribution and extensibility (Hirzel et al., 2017). It was invented in 2009 and is being actively used in industry (IBM, 2008). An SPL program is an explicit stream graph of streams and operators. Unlike dataflow synchronous languages, and like other big-data streaming languages, SPL uses only minimal synchronization: an operator can fire whenever there is data available on any of its input ports, following semantics formalized in the Brooklet calculus (Soulé et al., 2010). Since synchronization across different cores and computers is hard to do efficiently, reducing synchronization simplifies distribution, giving the runtime system more flexibility for which operators to co-locate in the same core or computer. There is no assumption of simultaneity between different operator firings. When downstream operators cannot keep up with the data

```

1 stream<float64 len, rstring caller> Calls = CallsSource() { }
2
3 stream<float64 len, int32 num, rstring who> CallStats = Aggregate(Calls) {
4   window Calls: sliding, time(24.0 * 60.0 * 60.0), time(60.0);
5   output CallStats: len = Max(Calls.len),
6                     num = MaxCount(Calls.len),
7                     who = ArgMax(Calls.len, Calls.caller);
8 }
```

Stream Processing Languages and Abstractions, Fig. 3 SPL code example

rate, they implicitly throttle upstream operators via back-pressure.

Figure 3 shows an example SPL program. Line 1 defines a stream *Calls* as the output of invoking an operator *CallsSource*. In SPL, streams carry tuples that are strongly and statically typed and whose fields can hold simple numbers or strings as in the example but can also hold nested lists and tuples. The *CallsSource* operator has no further configuration (empty curly braces); for this example, assume it is user-defined elsewhere. Programmers can define their own operators either in SPL or in other languages such as C++ or Java. Lines 3–8 define a stream *CallStats* by invoking an operator *Aggregate*. The code configures the operator with an input stream *Calls*, with a **window** clause for a 24-h sliding window with 1-minute granularity, and with an **output** clause. While many operators support these and other clauses, they can also contain code restricted to the operator at hand. The *Aggregate* operator in SPL’s standard library supports intrinsic functions for *Max*, *MaxCount*, and various other aggregations. Programmers can extend SPL with new operators that, like *Aggregate*, support various configurations and operator-specific intrinsic functions.

SPL was influenced by earlier big-data streaming systems such as Borealis (Abadi et al., 2005) and TelegraphCQ (Chandrasekaran et al., 2003), generalizing them to be less dependent on relational data and more extensible. Various other streaming systems after SPL, such as Storm (Toshniwal et al., 2014) and Spark Streaming (Zaharia et al., 2013), also target big-data streaming. Like SPL, they use explicit stream graphs as their core abstraction, but unlike SPL, they use embedded (not stand-alone) domain-specific languages.

While the examples of Lustre and SPL draw a stark contrast between synchronous dataflow and big-data streaming, there are also commonalities. For instance, the StreamIt language is synchronous, but like big-data streaming languages, it uses an explicit stream graph as its core abstraction (Thies et al., 2002). And Soulé et al. show how to reduce the dependence of StreamIt on synchrony (Soulé et al., 2013).

Future Directions for Research

The landscape of streaming languages is far from consolidating on any dominant approach. New languages keep coming out to address a variety of open issues. One active area of research is the interaction between streams (data in motion) and state (data at rest). While CQL gave a conceptually clean answer (Arasu et al., 2006), people are debating alternative approaches, such as the Lambda architecture (Marz, 2011) and the Kappa architecture (Kreps, 2014). Another active area of research is how to handle uncertainty, such as out-of-order data, missing fields, erroneous sensor readings, approximate algorithms, or faults. On this front, streaming languages have not yet reached the clarity of databases with their ACID properties. When it comes to implementation strategies, there has been a recent surge in embedded domain-specific languages. But while EDSLs have fewer tooling needs and are less intimidating for users familiar with their host language, they are less self-contained and offer less static optimization and error-checking than stand-alone languages. We hope this article inspires innovation in streaming languages that are well-informed by those that came before.

Synonyms

Continuous query optimization; Stream processing optimization

Definitions

Stream query optimization is the process of modifying a stream processing query, often by changing its graph topology and/or operators, with the aim of achieving better performance (such as higher throughput, lower latency, or reduced resource usage), while preserving the semantics of the original query.

Overview

A stream query optimization modifies a stream query to make it faster. Users want stream queries to be fast for several reasons. They want to grasp opportunities or avert risks observable on the input streams before it is too late. They want any views derived from the input streams to be up-to-date and not stale. And they want their system to keep up with the rate of input streams without falling behind, which would require shedding load or saving data to disk for later processing.

Knowing about stream query optimizations helps developers at all layers. Application developers who know about stream query optimizations can get the most out of the optimizations built into their streaming platform and can supplement them by hand-optimizing their application where necessary. Streaming platform developers can use knowledge about

stream query optimizations to make their platform faster by implementing additional optimizations or by generalizing their existing optimizations to apply in more situations. Finally, researchers who invent new optimizations need to know the state-of-the-art optimizations to channel their efforts into the most innovative and impactful direction.

The rest of this section introduces some basic concepts and gives a high-level overview and categorization of the most common stream query optimizations.

An optimization should be both safe and profitable. An optimization is *safe* if it can be applied to a stream query without changing what it computes, as determined by the user's requirements. An optimization is *profitable* if it makes the stream query faster, as measured by metrics that matter to the user, such as throughput, latency, or resource efficiency. There is a substantial literature on different stream query optimizations, with different safety and profitability characteristics. This entry lists the most common optimizations along with short descriptions. More in-depth descriptions can be found in our survey paper and tutorial on stream processing optimizations (Hirzel et al., 2014; Schneider et al., 2013).

Stream query optimizations are best understood with respect to stream graphs. A *stream graph* is a directed graph whose edges are streams and whose nodes are operators. Root and leaf nodes are called sources and sinks, respectively.

This entry uses terminology that makes only few assumptions so as not to unnecessarily restrict its scope. For instance, this entry does not assume restrictions on the shape of the stream graph: unless specified otherwise, it does not assume that stream graphs are acyclic, or are single-source-single-sink, or are trees. A *stream* is an ordered sequence of data items, which are values that can range from simple numbers to flat tuples to more elaborate structured data that may be deeply nested and have variable size. Streams are conceptually infinite, in the sense that as the streaming computation unfolds over time, the sequence of data items is unbounded in length. *Operators* are primarily stream transformers but can also have state and side effects beyond the output streams they produce. Indeed, sources and sinks are operators that typically have the side effect of continuously consuming input from and producing output to the external world outside of the stream graph.

Figure 1 lists the most popular stream query optimizations. Each optimization has a symbol (e.g., **B**), a name (e.g., Batching), and two annotations indicating its effect on the graph and the semantics. The optimizations to the left (shown in orange and red) leave the stream graph unchanged. This means the graph still contains the same nodes and edges, and any changes are limited to the behavior of individual operators. The optimizations on the right (shown in blue and green) change the stream graph. The optimizations on the top (shown in orange and blue)

Stream Query Optimization, Fig. 1 Overview of stream query optimizations discussed in this entry

keep the semantics stable. This means that as long as their safety preconditions are satisfied, the observable behavior of the stream query is the same before and after applying the optimization. These optimizations are safe in the sense discussed above. The extreme case is batching and fusion at the very top, which are not only safe, but have safety preconditions that are trivial to satisfy. Only the three optimizations at the very

bottom have unstable semantics: load shedding, which always changes the semantics, and algorithm selection and fission, which sometimes change semantics if the algorithm is approximate or if the fission perturbs the order of data items. These forms of semantic changes are sometimes tolerable depending on application requirements.

The following section will elaborate on each of the optimizations from Fig. 1 with illustrations, definitions, and literature references.

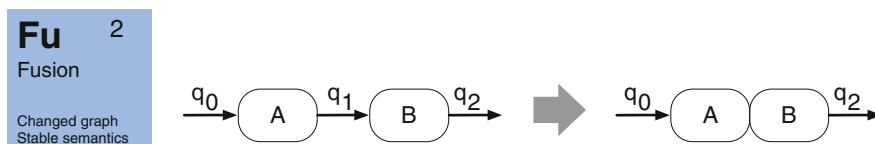

Key Research Findings

Batching Definition: Batching reduces overhead by processing multiple data items together. This optimization improves throughput by amortizing the cost of operator-firing and communication over several data items. However, this throughput gain is usually at the expense of additional latency, as an operator cannot fire until

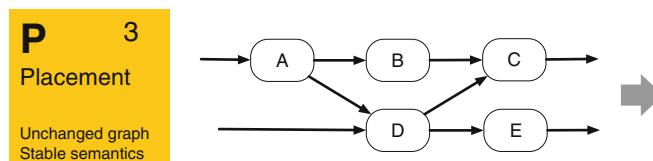

it has received a batch-size number of data items.

References: In the literature, batching is also called train scheduling (Carney et al., 2003) and execution scaling (Gordon et al., 2006). Batching can be dynamic, as in SEDA (Welsh et al., 2001), or static, as in StreamIt (Gordon et al., 2006).

Fusion Definition: Fusion combines smaller operators into a larger one, to avoid the overhead of data serialization and transport. Operators may be fused in many ways, for example, by placing the operators into the same thread or by keeping operators in separate threads that share a common address space. Fusion may come at the cost

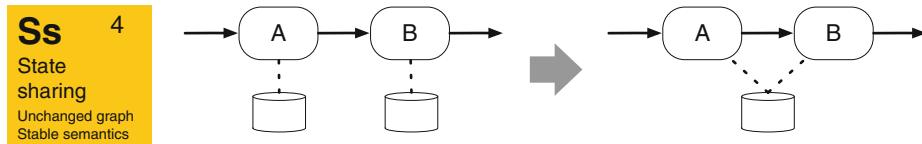

of decreased pipeline parallelism. **References:** StreamIt (Gordon et al., 2002) aggressively fuses fine-grained operators, followed by fission. In Aurora, fusion is referred to as superbox scheduling (Tatbul et al., 2003). System S uses the COLA fusion optimizer (Khandekar et al., 2009), which balances safety and profitability constraints.

Placement Definition: Placement assigns operators to hosts and cores to reduce communication costs or better utilize available resources. Frequently, these two goals are at odds. When

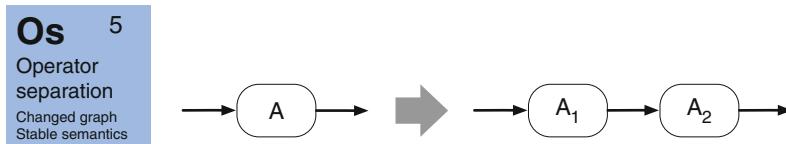

multiple operators are placed on the same host, they communicate at lower cost, but they compete for common resources, such as disk, memory, or CPU. On the other hand, when operators

are placed on different hosts, that reduces contention but incurs higher communication costs. *References:* StreamIt uses placement to optimize streaming applications deployed on multi-core machines with nonuniform memory access (Gordon et al., 2002). Pietzuch et al. use metrics gathered from network conditions to place operators in a distributed setting (Pietzuch et al., 2006). SODA incorporates job admission with the placement decisions (Wolf et al., 2008).

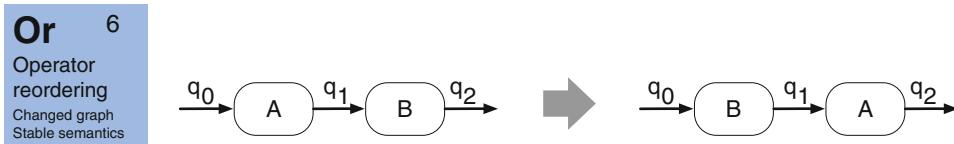

State sharing *Definition:* State sharing attempts to avoid unnecessary copies of data. While the main goal of the optimization is to reduce the memory footprint of a streaming application, it can also impact performance by reducing stalls due to cache misses or disk I/O. *References:* State sharing can be applied generally between

streaming operators, such as in the work of Brito et al. (2008). Or, it can be applied in more restricted forms, such as in CQL, which shares only window state (Arasu et al., 2006), or in the work of Sermulins et al., which shares queue state between two pipelined operators (Sermulins et al., 2005).

Operator separation *Definition:* Operator separation splits a large computation into smaller steps. In some cases, this optimization can result in reduced resource consumption. Often, this optimization is used to enable other optimizations, such as operator reordering. *References:* Using algebraic equivalences for separating operators is

a common technique in database query execution planning (Garcia-Molina et al., 2008). Yu et al. (2009) present a stream query compiler that uses explicit annotations to determine when to separate aggregate operators. Decoupled software pipelining separates general code by analyzing data dependencies from first principles (Ottoni et al., 2005).

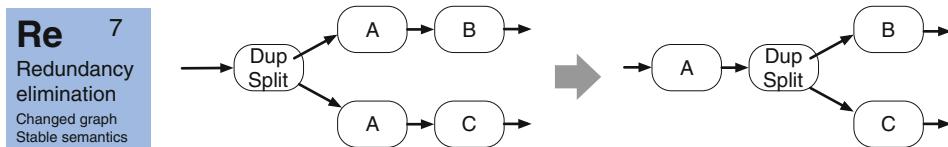

Operator reordering *Definition:* A reordering optimization moves more selective operators, which reduce the data volume, upstream. This has the benefit of reducing the data flowing into downstream computation, thus eliminating unnecessary work. However, care must be taken

to preserve the desired semantics, and operators should only be re-ordered if the operations are commutative. *References:* Reordering based on the properties of relational algebra is common in database query planning (Garcia-Molina et al., 2008). The Volcano (Graefe, 1990) system

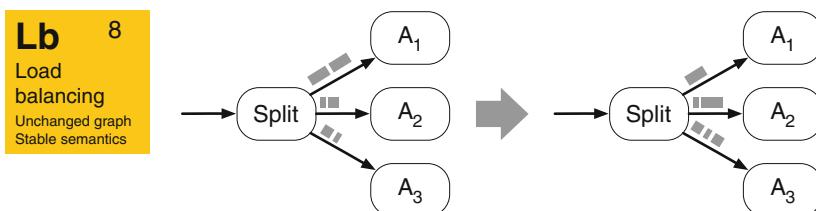

implements a particularly profitable case of reordering: swapping split and merge operators in a data-parallel pipeline to avoid choke-points.

Eddies (Avnur et al., 2000) is a dynamic technique for finding the most profitable ordering of operators with independent selectivities.

Redundancy elimination *Definition:* Redundancy elimination eliminates superfluous computations. This optimization must ensure that removing a given computation does not change the resulting output. While, in general, determining program equivalence is undecidable, in practice, streaming languages are often based on an algebra, which makes the optimization

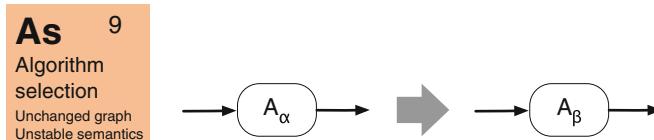

feasible. *References:* The Rete algorithm (Forgy, 1982) is a highly-influential approach to detecting and eliminating redundancies in a multi-tenant system. NiagaraCQ (Chen et al., 2000) applied similar ideas to processing streaming XML. Pietzuch et al. (2006) eliminate redundancy at application launch time.

Load balancing *Definition:* Load balancing attempts to distribute workload evenly across resources. To be effective, a load-balancing optimization must adapt to workload skew, e.g., when there are many accesses to a popular data item. *References:* River uses intelligent routing for load balancing in a cluster (Arpac-Dusseau et al., 1999). Caneill et al. use online

adaptive routing, which considers downstream communication (Caneill et al., 2016). In contrast, Amini et al. use operator placement for load balancing in a cluster (Amini et al., 2006). StreamIt also uses placement for load balancing, but targets multi-core machines (Gordon et al., 2002).

S

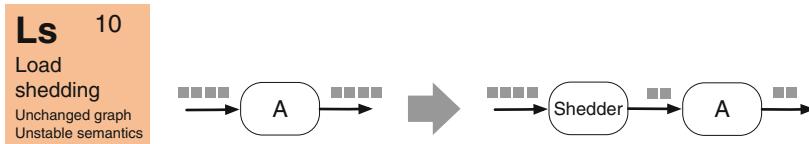

Algorithm selection *Definition:* Algorithm selection uses a different algorithm to implement an operator. There are various reasons to change the algorithm. For example, one algorithm may be more general than another. One algorithm may

optimize for different criteria. Or, one algorithm may perform better than others under different circumstances. *References:* Changing the operator algorithm for particular workloads is common in database systems (e.g., using a hash join vs.

a nested loop join Garcia-Molina et al., 2008). In streaming systems, SEDA allows an operator to pick a different algorithm to provide degraded service (Welsh et al., 2001). Borealis allows an

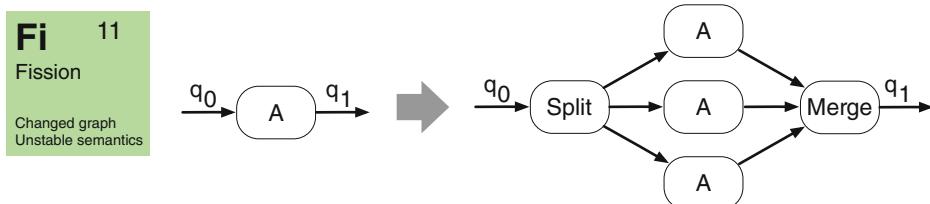

operator to switch to a different algorithm based on a control input (Abadi et al., 2005). And, SODA offers algorithm selection at the granularity of entire jobs (Wolf et al., 2008).

Load shedding Definition: Load shedding copes with high load by dropping data items to process. Load shedding may change the expected results of a computation, and therefore the semantics of the streaming application.

References: Aurora implements priority-based

load shedding (Tatbul et al., 2003). Compact Shedding Filters perform load-shedding at data-generating sensors, rather than the server, to avoid unnecessary network communication (Gedik et al., 2008).

Fission Definition: Fission, often referred to as data parallelism, attempts to process multiple data items in parallel by replicating an operator. Note that when parallelizing operators, the optimizer must respect ordering or state constraints to ensure the correctness of the computation. **References:** The StreamIt compiler applies fission to stateless operators with static selectivity (Gordon et al., 2006). Schneider et al. explored how to make fission safe in the more general case of partitioned-stateful and selective operators (Schneider et al., 2015). Finally, Brito et al. propose using transactional memory to make fission safe in the case of arbitrary operator state (Brito et al., 2008).

Fission One application that benefits a lot from fission is streaming radio astronomy, which forms evolving imaging maps of radio emission from the sky over a wide range of frequencies (Biem et al., 2010b). High-performance processing is a critical requirement in this application, due to the sheer volume of sensor data that flow in real-time from a very large array of antennas, which is typical of phased array radio telescopes (see SKA 2000). The application's flow graph is organized as a split-merge topology. An initial operator performs frequency mapping and blocking so that a subsequent operator splits the data into blocks of frequency channels. Each such block is then processed in parallel by performing indexing and convolution operations, forming a costly stateless parallel region that highly benefits from fission. Finally, the results are merged via an aggregation to form the complete imaging map.

Fusion In Biem et al. (2010a), a streaming application is presented for maintaining live traffic

Examples of Application

We illustrate the use of the three most popular optimizations, namely, fission, fusion, and batching, in the context of real-world streaming applications from the literature.

status information using GPS sensor data. The application processes floating car data originating from public transportation vehicles to extract up-to-date traffic information, such as speed and traffic flow measurements at the level of streets within a city, traffic volume measurements by region, estimates of travel times between different points, etc. The application is organized as a graph of streams and operators, where different operators perform individual tasks, such as data parsing and cleaning, snapping GPS points to roads, aggregation and statistics maintenance, prediction of travel times, etc. The operators in the flow graph of the application are grouped into processing elements, which are then distributed across machines. The operators that are assigned to the same processing element are fused inside a shared address space, in order to reduce the data transfer latency.

Batching The batching optimization is particularly useful when interacting with external systems. A common use case for such interaction is managing state. For instance, LinkedIn, which is a business- and employment-oriented social networking service, runs several streaming applications that manage state, such as user profiles and aggregate counts. These applications include email digest generation, top-k relevant category detection, and profile update standardization, among others (Noghabi et al., 2017). In these applications, the state needs to be accessed from either the local disk-based or remote state management systems. Similarly, many of these streaming applications write their output to an external system, such as a message queue. When an external interaction is to be performed on a per-tuple basis, batching is an effective optimization that can amortize the overheads and significantly improve the performance.

Future Directions for Research

In an ideal world, programmers would code their streaming applications at the most natural level of abstraction without having to worry about runtime performance, and the streaming system

would automatically execute the applications with consistently high performance. While stream query optimizations have made significant advances toward this goal, they still fall short on automation and predictability.

It is still difficult to fully automate streaming optimizations, because automatic optimizers may not find the most profitable setting. Finding the most profitable setting ahead-of-time, before executing the streaming application, is tricky because the performance model may be complicated (e.g., when multiple optimizations interact) or some information required by the performance model may be missing or hard to predict. An alternative to ahead-of-time optimization is online feedback-directed optimization, which is subject to the trade-offs inherent in the SASO properties of feedback control (stability, accuracy, settling, and no overshoot) (Hellerstein et al., 2004). Work such as that of De Matteis and Mencagli, which uses a control-theoretic approach to perform online adaptations to optimize for latency (De Matteis et al., 2016), is a promising direction.

When streaming applications fall short of their expected peak performance, programmers often optimize them by hand. This has the advantage of giving programmers more control over squeezing the last bit of performance out of their application. Unfortunately, it can also clutter their code, can make the performance brittle by over-fitting to the current workload and execution environment, and may even inhibit automated optimizations. One approach to address these issues is to decouple the optimizer hints and directives from the core application logic (Hirzel et al., 2017).

Overall, there is still much work to be done in developing more effective optimizations, more reliable performance models, and more unintrusive language features for giving optimizer hints. This entry represents a snapshot of the state of the art, and we encourage the reader to venture beyond it.

Stream Window Aggregation Semantics and Optimization

Paris Carbone¹, Asterios Katsifodimos², and Seif Haridi¹

Definitions

Sliding windows are bounded sets which evolve together with an infinite data stream of records. Each new sliding window evicts records from the previous one while introducing newly

arrived records as well. Aggregations on windows typically derive some metric such as an average or a sum of a value in each window. The main challenge of applying aggregations to sliding windows is that a naive execution can lead to a high degree of redundant computation due to a large number of common records across different windows. Special optimization techniques have been developed throughout the years to tackle redundancy and make sliding window aggregation feasible and more efficient in large data streams.

Overview

Data stream processing has evolved significantly throughout the years, both in terms of system support and in programming model primitives. Alongside adopting common data-centric operators from relational algebra and functional programming such as select, join, flatmap, reduce, etc., stream processors introduced a new set of primitives that are exclusive to the evolving nature of unbounded data. Stream windows are perhaps the most common and widely studied primitive in stream processing which is used to express computation on continuously evolving subsets out of a possibly never-ending stream. In essence, stream windows grant control on the granularity and the scope of stream aggregations.

Several early stream processing systems (e.g., TelegraphCQ (Chandrasekaran et al., 2003), STREAM (Arasu et al., 2004)) provided support for windowing through a predefined set of primitives to construct time- and count-based sliding windows. For example, periodic tumbling and sliding windows were already standardized as early as the SQL-99 standard and studied thoroughly in the Continuous Query Language (CQL) (Arasu et al., 2006) as well as the stream processing language (SPL) (Hirzel et al., 2009) among others. A *tumbling* window is a simple case of a stream window type, which is defined as a sequence of periodic consecutive sets of records in a stream with a fixed length that is termed *range*. For example, if we assume a stream of car speed events, the following simple query in CQL would discretize that stream into

windows of every 30sec interval and compute the maximum speed per window:

```
SELECT max(speed)
from CarEvents
[RANGE 30 Seconds]
```

In principle, in tumbling windows each record can only belong to a single window. As a result, the evaluation of each window can be performed trivially by grouping records by the window they belong to and executing each window aggregation independently. However, sliding windows add a challenging twist to the formula, namely, the “slide.” As an example consider the following sliding window query in SQL-99:

```
SELECT AVERAGE(speed)
FROM CarEvents
[WATTR timestamp
RANGE 7 minute
SLIDE 3 minute]
```

The *slide* represents “when” or “how often” a window has to be evaluated while including all records defined in its *range* in the computation of the average speed. In this sliding window example, there is an overlap of 5 min between each consecutive window, and thus, a naive execution would result into redundant operations in its great majority. Beyond periodic windows, today’s Apache open-source systems such as Flink (Carbone et al., 2015, 2017), Beam, and Apex provide support for more advanced, often user-defined, sliding window definitions such as session (Akidau et al., 2015) or content-driven windows (Bifet and Gavalda, 2007), among others.

Sliding windows have their own set of optimization techniques that aim to reduce the redundant computations caused by the intersection of events between neighboring windows. In this paper we categorize optimization techniques into *slicing*, *pre-aggregation*, and *hybrid* and analyze them throughout the rest of this chapter.

Basic Concepts

There are many interpretations of window semantics, from simple range and count event-time windows (Arasu et al., 2006) to policy-based (Hirzel

et al., 2009) and composite event-time windows with retraction for out-of-order processing (Li et al., 2008b). The SECRET model (Botan et al., 2010) aimed to subsume most of the windowing semantics proposed in academia and commercial systems. However, for the sake of brevity, a more simplified description is used here, with a heavy focus on window aggregation, based on the recent work on the Cutty aggregator (Carbone et al., 2016) and FlatFat (Tangwongsan et al., 2015).

Stream Discretization

Data streams are unbounded sequences of records which are described by a given schema T . More formally, a stream $\bar{s} \in \text{Seq}(T)$ is a sequence out of all possible sequences $\text{Seq}(T)$ over T . Windows are finite subsequences reflecting intervals of a stream \bar{s} . An interval $s[a, b]$ is simply a set of records from index a to b over a stream \bar{s} and the set of all possible intervals $\text{Str}(T) \subset \text{Seq}(T)$.

In their most general form, windows can be derived by *discretizing* an unbounded stream. A *Discretizer* transforms a stream $\bar{s} \in \text{Seq}(T)$ into a sequence $\bar{w} \in \text{Seq}(\text{Str}(T))$ of (possibly overlapping) windows. In the most system-agnostic manner, every possible discretization of a stream can be aided through a discretization function provided to a special *Discretize* or *Windowing* stream operator.

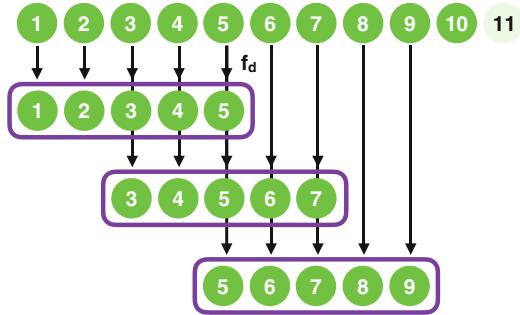

Definition 1 $\text{Discretize} : f_{\text{disc}} \times \text{Seq}(T) \rightarrow \text{Seq}(\text{Str}(T))$

Figure 1 depicts a simple example of a discretization function f_d applied on a stream of elements which forms count windows with a “range” of 5 records and a “slide” of 2 records.

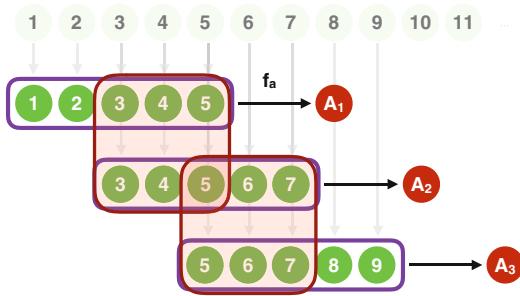

Aggregating Sliding Windows

Conceptually, in data stream programming models, an *Aggregate* operator computes an aggregation on each window derived after a stream discretization, given an aggregation function f_a .

Definition 2 $\text{Aggregate} : (f_a : \text{Str}(T) \rightarrow T') \times \text{Seq}(\text{Str}(T)) \rightarrow \text{Seq}(T')$

Stream Window Aggregation Semantics and Optimization, Fig. 1 Discretization of a count window of range 5 and slide 2

Stream Window Aggregation Semantics and Optimization, Fig. 2 Aggregation of a count window of range 5 and slide 2

Examples of f_a is a SUM or AVG, but also more complex aggregations can be executed in a window, such as building a machine learning model. Figure 2 shows how aggregates are formed on each consecutive window of a discretized stream. The main reason for optimizing the window aggregation process stems from two issues that can be observed in this example. First, a consecutive execution of the aggregation operation after discretization can be inefficient both in terms of space needed to log all elements of each window as windows can be very large in size. At the same time, the response time has to be minimized when iterating through all window contents in order to calculate an aggregate. Finally, and most importantly, as highlighted in Fig. 2, sliding windows might involve a large amount of overlapping across consecutive windows. In this example there is an overlapping of three records between every two windows.

The first problem is solved by simply pipelining discretization with aggregation and thus, effectively providing a partial evaluation of window aggregates. Partial aggregation is described in section “[Partial Window Aggregation](#)”. The overlapping problem is more complex, and its optimization techniques are further classified by window types into slicing, general pre-aggregation, and hybrid techniques, covered thoroughly in sections “[Window Slicing](#)”, “[General Pre-aggregation](#)”, and “[Cutty: A Hybrid Approach](#)”, respectively.

Partial Window Aggregation

A complete partial window aggregation scheme has been proposed in both FlatFat (Tangwongsan et al., 2015) and Cutty (Carbone et al., 2016). According to that scheme, an aggregation f_a can be decomposed into partial aggregation operations in order to pipeline the process during discretization. A window aggregation function is therefore decomposed into `lift` and `lower` and a `combine` functions as such:

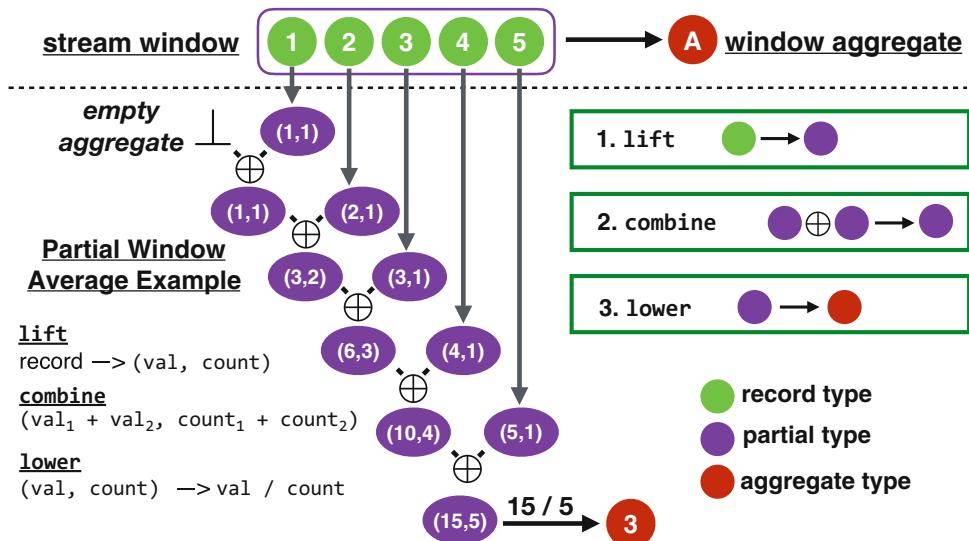

$\text{lift} : T \rightarrow A$ maps an element of a window to a partial aggregate of type A .

$\text{combine } \oplus : A \times A \rightarrow A$ combines two partial aggregates into a new partial aggregate (equivalent to a `reduce` function).

$\text{lower} : A \rightarrow T'$ maps a partial aggregate into an element in the type T' of output values.

The main and only requirement for partial aggregation is to have an *associative* `combine` function so that aggregation can be used to evaluate a full window aggregate in discrete steps (Arasu and Widom, 2004; Krishnamurthy et al., 2006; Tangwongsan et al., 2015).

An example of partial aggregation of a window is depicted in Fig. 3. The goal in this example is to partially compute the average value out of a set of records with values 1 to 5. The invariant is that only one partial aggregate is kept in memory (initially an empty aggregate). That aggregate is incrementally updated by each record that arrives in a window. To compute an average, two values have to be maintained in the aggregate type: a *sum* and a *count*. `lift` function, each record is first mapped into an aggregate type of its value

Stream Window Aggregation Semantics and Optimization, Fig. 3 Partial aggregation example for window average

and a count of 1. The `combine` function updates the partial aggregate with the new sum and count until all elements of a window have arrived. Then finally, the `lower` function transforms the aggregate into the window average, in this case this is 3.

Window Slicing

The amount of overlapping across sliding windows introduces additional space and computational complexity that partial aggregation itself cannot solve.

In the case of windows with predefined periodic characteristics such as a time or count slide, a family of optimization techniques is used to further decompose windows into nonoverlapping partial aggregates which can be shared and combined to calculate full window aggregates. This technique is typically named “slicing” or “bucketing.” The two most popular slicing techniques that have also been deployed in production stream processing systems in the past are *panes* (Li et al., 2005a) and *pairs* (Krishnamurthy et al., 2006).

Panes

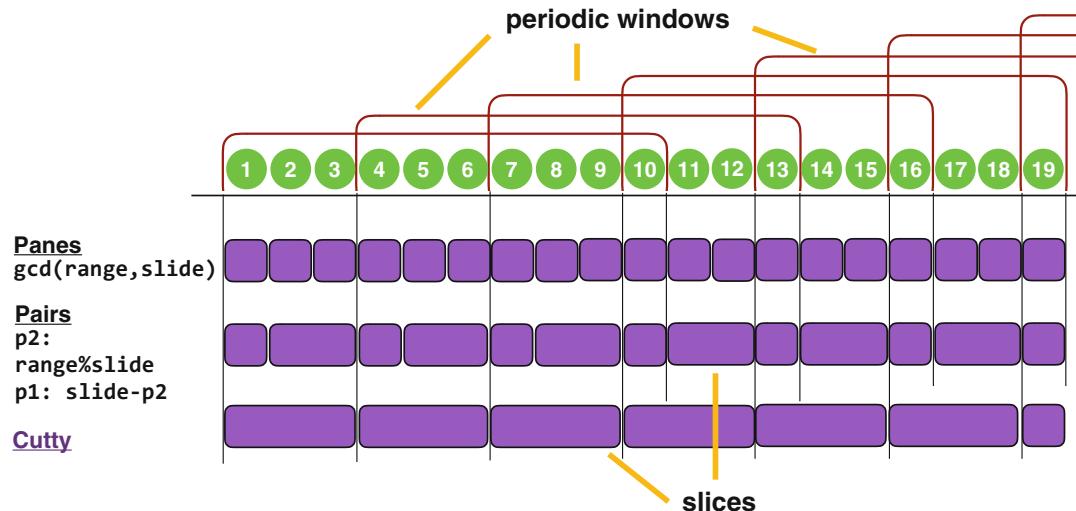

The main idea behind *Panes* is that if we have a periodic window query with a fixed slide and a

range, it is trivial to break down the aggregation process into partials with a constant size, equal to the greatest common denominator of the respective *range* and *slide*. For example, if we have a sliding window with a range of 9 min and a slide of 6 min, the stream would be sliced and pre-aggregated into buckets, each of which corresponds to 3 min of the ingested stream (greatest common denominator of 6 and 9).

Panes have been criticized (Krishnamurthy et al., 2006) for their lack of general applicability, yielding unbalanced performance that depends highly on the combination of range and slide. For example, a window of range 10 s and a slide of 3 s would break down to slices of a single second, no longer exploiting the amount of nonoverlapping segments in a stream (as depicted in Fig. 4).

Pairs

The *pairs* technique (Krishnamurthy et al., 2006) splits a stream into two alternating slices: $p_2 = \text{range} \bmod \text{slide}$ and $p_1 = \text{slide} - p_2$. This technique utilizes better nonoverlapping segments in a stream and seems to work well with most combinations of range and slide. Intuitively, pairs break slicing only when a stream window starts or ends. This is visualized in Fig. 4 where

Stream Window Aggregation Semantics and Optimization, Fig. 4 Example of different slicing techniques

it results into a lower number of slices for the same window compared to using *panes*. Contrary to *panes*, *pairs* has also been proposed for multi-query aggregation sharing where a large sequence of shared slices is decided at compilation time across shared sliding window aggregation queries in the same operator.

Slicing Limitations

While slicing offers the best known space and computational performance in sliding window aggregation, its applications are limited to periodic window queries since this is the only type of windows for which their beginning and end are predefined. The *Cutty* technique (Carbone et al., 2016) which is further analyzed in section “[Cutty: A Hybrid Approach](#)” avoids this strong assumption by letting user-defined functions signify during runtime when windows start or end. In the same work slicing is also combined with general pre-aggregation techniques (analyzed in section “[General Pre-aggregation](#)”) in order to combine the strongest characteristics of both domains of window optimization.

General Pre-aggregation

The main incentive of general pre-aggregation techniques is to be able to allow for arbitrary

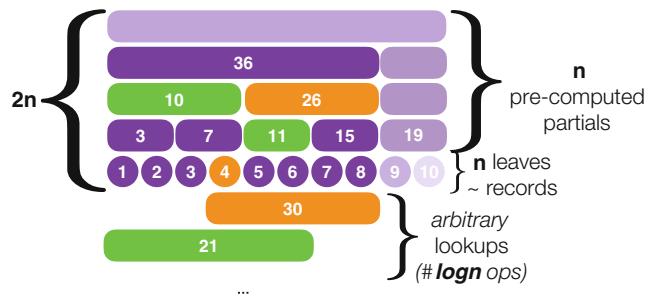

segment lookups in a stream (e.g., from external user queries) as depicted in Fig. 5.

The earliest work on general pre-aggregation was presented in *B-int* (Arasu and Widom, 2004) which precomputes eagerly higher-order partials on different segments of a stream. The application of *B-int* was meant to be fast aggregate retrieval for ad hoc stream queries (i.e., using CQL); however, the applicability of general pre-aggregation makes such techniques convenient for aggregating continuous sliding windows without a known range or slide or other periodicity assumptions. The Reactive Aggregator by IBM Research (Tangwongsan et al., 2015) exploits the properties of *B-Int* and introduces FlatFat: a fixed size circular heap binary tree of higher-order partials that “slides” together with the records of the stream.

General Pre-aggregation Limitations

General pre-aggregation offers fast retrievals of arbitrary windows on a stream at the cost of additional space and incremental update computation requirements. That is due to the fact that every time a new aggregate is added to the binary tree a sum of $\log(N)$ additional partial aggregations need to be employed in order to update all higher-order aggregates of the tree (given N : the number of active records/leaves in the tree). In summary,

Stream Window Aggregation Semantics and Optimization, Fig. 5
Example of a general pre-aggregation tree

the runtime costs of employing eager aggregation, which are also visualized in Fig. 5 are the following:

space: $2N$ partials need to always be kept on heap to hold the full aggregation binary tree.

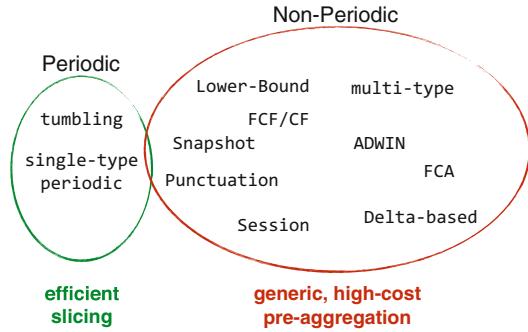

update/lookup: both update and full window lookup have $O(\log N)$ computational complexity. In the case of updates, the complexity is fixed ($\log N$) against slicing which typically involves a single aggregation per record.

All these costs pose an interesting trade-off when eager aggregation is employed per record in a data stream, which often results in more operations than a naive execution of each redundant window aggregation separately. As a result, it is likely that if general pre-aggregation is de facto applied, its runtime cost would never be amortized across a full run of a continuous application.

Nevertheless, the power of general pre-aggregation lies at the observation that it can be generally applied to any type of windows, thus, covering a large space of nonperiodic window types used within research and industrial applications, as depicted in Fig. 6.

Cutty: A Hybrid Approach

Slicing and general pre-aggregation are orthogonal techniques that can be potentially combined to support a wider variety of stream windows for aggregation. The *Cutty* aggregator (Carbone et al., 2016) employs such a hybrid approach that can lead to efficient aggregation of a broader number of window types than simply periodic. The main observation behind its design is that

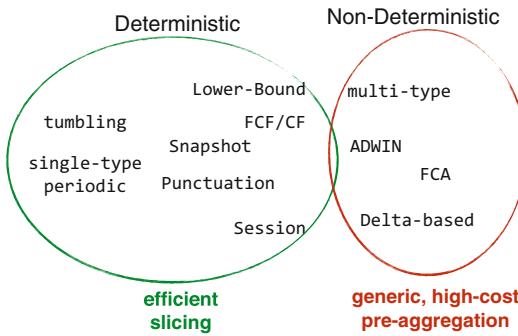

Stream Window Aggregation Semantics and Optimization, Fig. 6 Applicability of slicing and general pre-aggregation

there is an implicit class of windows (a superclass of periodic ones), termed *deterministic* which can be obtained by using the right core primitives in the programming model. Deterministic windows can be used to enable efficient shared aggregation without limiting window expressivity. Figure 7 shows the expressive power of deterministic windows, being able to provide optimal pre-aggregation to more than the limited periodic windows.

Deterministic Windows

The concept of deterministic windows stems from the observation that all it takes to achieve optimal slicing is not the *a priori* knowledge of the periodicity of windows (if any) but the *runtime* knowledge of where a new window starts. While partial aggregation is employed, as described in section “[Partial Window Aggregation](#)”, a single partial result can be kept in active memory until we receive a record that marks the beginning of a new window. Conceptually, a new window start means that

Stream Window Aggregation Semantics and Optimization, Fig. 7 Visualizing the expressive power of Deterministic Windows for Efficient Aggregation

we will later need a partial aggregate (or slice) starting at that point to evaluate the window that started there.

Cutty proposes user-defined windowing through the use of a *discretization function* f_{disc} , defined as follows:

$$f_{\text{disc}} : T \rightarrow \langle W_{\text{begin}} : \mathbb{N}, W_{\text{end}} : \mathbb{N} \rangle$$

where for each record $r \in T$: (i) W_{begin} is the number of windows beginning with r and (ii) W_{end} the number of windows ending with r .

Overview of Cutty

Optimal slicing with deterministic windows minimizes but does not eliminate redundancy. As an example, consider the slices produced by *Cutty* during the example execution of Fig. 4. A detailed observation of the slices used per window reveals a level of redundancy that cannot be handled by slicing. For example, slices $s[4, 6]$ and $s[7, 9]$ would have to be combined together twice: once for computing $f_a(s[1, 10])$ itself and once for computing $f_a(s[4, 13])$. Instead, if somehow the evaluation of $f_a(s[4, 9])$ was stored, it would not be necessary to repeat that aggregation.

Cutty utilizes general pre-aggregation (FlatFat) in order to further reduce the cost of full window aggregate evaluation and compute higher-order combinations of aggregates only once. This idea gives a new purpose to general pre-aggregation techniques and grants a low memory footprint since the space complexity of

the aggregation tree is bounded by the number of active slices (which is equivalent to the minimum number of nonoverlapping segments in a stream). A full example run of *Cutty* is visualized in Fig. 8, showing both slicing of deterministic windows and general pre-aggregation and evaluation on stored partials. In the same example, notice that the partial $P(s[6, 7])$ is computed once and reused for both $f_a(s[1, 5])$ and $f_a(s[1, 6])$.

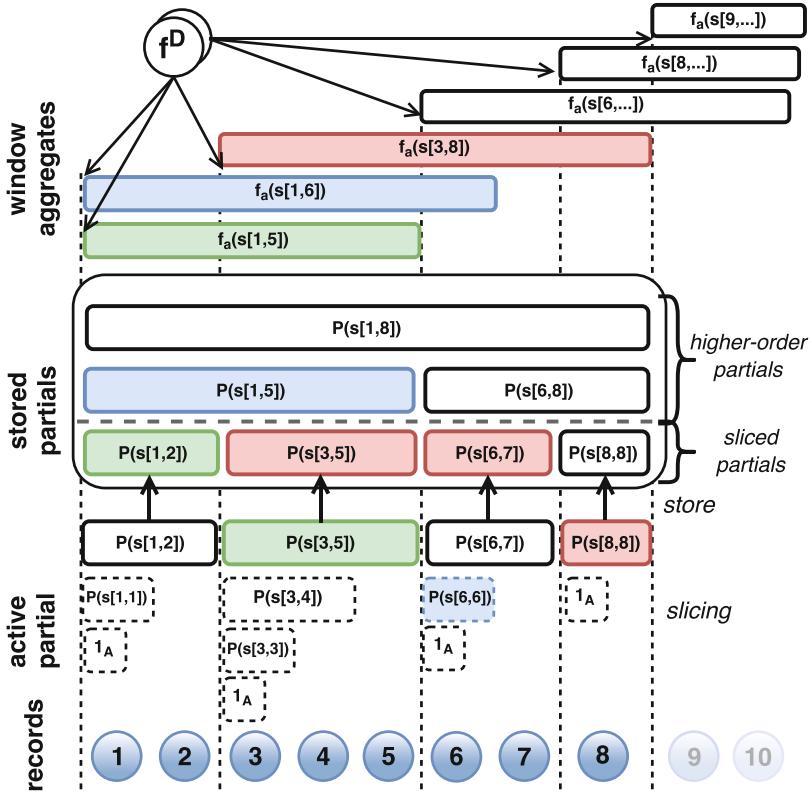

For nondeterministic windows, *Cutty* falls back to general pre-aggregation (simply using FlatFat) since slicing cannot be applied. Nevertheless, the generality and flexible (runtime specific) nature of this aggregation technique also enables the prospect of using it for applying operator sharing (Hirzel et al., 2014) on data streams. A full complexity and performance analysis and comparison are provided in the original *Cutty* paper (Carbone et al., 2016).

Further Works

Window aggregation is an interesting research topic, and there are many relevant proposed ideas to the ones presented here. For example, Li et al. (2005b, 2008a) classified window types by their evaluation context requirements, leaving the characterization of each class as an open research question. Performing certain types of aggregates in constant-time was recently proposed (Tangwongsan et al., 2017). Deterministic functions in *Cutty* subsume all forward-context-free windows (no future records are required to know when a window starts), while nondeterministic discretization functions are forward-context-aware. Heuristic-based plan optimizers have also been proposed (e.g., *TriWeave* Guirgis et al. 2012) to fine-tune the execution of periodic time queries dynamically using runtime metrics (i.e., input rate and shared aggregate rate).

Future Directions

Windowing semantics are becoming increasingly more complex and sophisticated as data stream

Stream Window Aggregation Semantics and Optimization, Fig. 8 An overview example of *Cutty*

processing is widely adopted. Aggregation techniques will have to follow the trends in windowing semantics and adapt to more dynamic, data-centric window types. One of the most prominent future directions in stream windowing is its standardization and encapsulation in stream SQL standards that are undergoing in open-source communities (e.g., the Calcite project and Google Dataflow Akidau et al. 2015). However, no significant efforts have been made to apply relational optimizations in stream windowing. Another future direction is to extend slicing capabilities beyond deterministic windows (if possible) and cover cases of fully data-driven windows without FIFO guarantees such as ADWIN (Bifet and Gavalda, 2007). Finally, general pre-aggregation data structures have to employ the notion of out-of-orderness (Traub et al., 2018). Currently, with existing out-of-the-box solution such as FlatFat, it is not possible to retract already evaluated window

aggregates, thus, making it impossible to use for systems like Beam and Flink with out-of-order logic.

Conclusions

Windows over streaming data continue to be the most central abstraction in data stream processing. Aggregation techniques aim to reduce the computational redundancy to the maximum extent possible for sliding windows. Most often, approaches to efficient aggregation are entangled with actual windowing semantics, such as assuming periodic queries to provide efficient pre-aggregation. Slicing techniques provide low memory footprint and generally good performance at the cost of limited applicability, while general pre-aggregation techniques can be employed for any window lookup at the cost of high computational and

memory footprint. Recent approaches aim for a hybrid solution by generalizing slicing further while combining data structures from general pre-aggregation. Sliding window aggregation remains a challenging topic today, and new challenges will arise with the adoption of richer and more complex windowing semantics and out-of-order streams.

Streaming Big Spatial Data

Ahmed R. Mahmood and Walid G. Aref
Purdue University, West Lafayette, IN, USA

Synonyms

Distributed spatial data streaming; Real-time big spatial data processing

Definitions

Recently, several big data stream management systems (DSMS, for short) have been developed to provide an infrastructure to process streamed big data. Big spatial DSMSs constitute a special class of big DSMSs that are optimized to process large amounts of spatial data streams. The main idea behind most big spatial DSMSs is to leverage the spatial properties of the incoming data stream to fairly distribute the workload across multiple distributed processes. When processing big spatial data streams, it is important to maintain high throughput and low latency.

Overview

Spatial data is ubiquitous. It is continuously being generated at a large scale. This is due to the popularity of GPS-enabled devices, e.g., smartphones, smart-watches, personal activity trackers, and GPS-navigation devices. Efficient processing of this streamed big spatial data requires higher computational resources than the resources that exist in a centralized system.

Big spatial DSMSs can be classified into the following two main categories: (1) *dedicated big spatial DSMSs* and (2) *spatial extensions to general-purpose big DSMSs*.

- *Dedicated big spatial DSMSs*. These systems are the first step toward scalable spatial data

stream processing. These distributed big spatial DSMSs are built from scratch with the sole purpose of processing streamed big spatial data. These systems often lack important features that exist in general-purpose big DSMSs, e.g., fault tolerance, and the ability to perform non-spatial data processing. Also, designers of these systems implement the communication protocols between the distributed processes. These communication protocols often require serialization, synchronization, and encryption. These requirements are orthogonal to big spatial data stream processing and require a substantial development overhead.

- *Spatial extensions to general-purpose big DSMSs*. In this widely adopted approach, general-purpose big DSMSs, e.g., Storm (Toshniwal et al., 2014), Spark-Streaming (Zaharia et al., 2012), and Yahoo S4 (Neumeyer et al., 2010), are extended with spatial distribution approaches to optimize the processing of spatial queries over spatial data streams. When extending an existing big DSMS with spatial capabilities, one inherits the features of the underlying general-purpose big DSMS, e.g., high scalability, fault-tolerance, and robust communication protocols.

The streamed spatial data is often associated with textual data, e.g., as in the case of tweets. A tweet contains textual data as well as the user's location where the tweet is issued. Big spatio-textual DSMSs are designed to account for the spatial and the associated textual attributes to optimize the processing of spatio-textual queries over spatio-textual data streams.

Key Scientific Findings

First, we describe the main query types over spatial data streams. Then, we give a historical background on general-purpose big DSMSs and centralized spatial DSMSs. Then, we focus on the categories of big spatial DSMSs.

Query Types over Spatial Data Streams

There is a wide range of spatial predicates that can be used when querying spatial data streams. The two main classes of spatial predicates are spatial selects and spatial joins.

1. *Spatial Select*: In a spatial select, given a spatial data stream and a spatial predicate, the spatial select produces as output the data tuples from the spatial data stream that satisfy the spatial predicate. Examples of a spatial select are the spatial range select and the top-k nearest neighbor select.

The range select predicate operates on a single spatial data stream and has a specific spatial range predicate. This select predicate identifies the streamed data tuples (i.e., the streamed spatial objects, e.g., cars or shops) that satisfy the spatial range predicate, i.e., the spatial objects that are located inside the specified spatial range.

The k-nearest-neighbor (kNN) select predicate operates on a single spatial data stream and has a focal point and a parameter k . The kNN spatial select identifies the k -nearest data objects to the focal point specified. The distance function used in measuring the distance from the focal point to the spatial data objects can vary. It can be the Euclidean distance or the distance over an underlying road network.

2. *Spatial Join*: In a spatial join, given two spatial data streams and a spatial join predicate, the spatial join produces as output data tuple pairs, one from each spatial data stream, such that each pair of tuples satisfies the spatial join condition. The spatial join has many flavors based on the type of spatial join predicate that is being used. The following are two popular spatial join operation.

The spatial range join: The spatial predicates can be of various forms. For example, one spatial predicate can be a distance threshold, say d . In this case, the spatial join will produce as output the pairs of objects, say (x_i, y_j) , where Object x_i from the first data source is within distance d from Object y_j from the second data source. This type of operation is referred to as a spatial range join operation.

The spatial k-nearest neighbor join (kNN-join): Depending on the spatial predicate involved, other types of spatial joins may be formed. For example, the spatial kNN-join operation produces as output the pairs of objects, say (x_i, y_j) , where Object y_j from the second data source is among the k -closest objects to Object x_i from the first data source. In addition to the two input spatial data streams, the number k is also specified as an input parameter to the spatial kNN-join operation. Any distance function can be used. Examples are the Euclidean or Manhattan distances or the distance over an underlying road network graph.

A single spatial data source may be used in the spatial join in contrast to two data sources. In this case, it is termed a spatial self-join. For example, in a spatial range self-join, pairs of spatial objects from the same source that are within distance d from each other are reported as output. For all the above operations, various distance functions can be used, e.g., the Euclidean, Manhattan, and road network distance metrics.

Continuous vs. Snapshot Spatial Queries

Spatial queries over data streams can either be evaluated as snapshot or continuous queries. A snapshot query operates on the current state of the spatial stream and produces a single resultset. In contrast, a continuous spatial query operates continuously for a relatively long duration, where the resultset of the continuous query is continuously updated to reflect the incoming spatial data from the streamed spatial data source.

To evaluate a snapshot spatial query, the state of the streamed spatial objects is maintained (usually using a spatial index). For example, consider a stream of location updates of moving objects. The state of the stream could be the current locations of the moving objects or a limited history of the trajectories of the moving objects. When a snapshot query arrives, it is evaluated once over the current state of spatial data stream and produces as output the spatial data objects that qualify the query. Finally, the snapshot query is completely evaluated, and it quits.

In contrast, when a continuous query arrives, it is stored into the system and is progressively evaluated against the incoming spatial data objects. The DSMS maintains a state for each of the continuous queries. This state may include some intermediate summary data as well as the current resultset of the query. For example, in the case of continuous query that contains a kNN select predicate, the DSMS maintains the current set of k spatial objects that are closest to the focal point. Because the query is continuous, as the objects move, the current set of k -nearest objects to the focal point continues to get updated.

Continuous spatial queries are often indexed (using a spatial index) to speed up the maintenance of the arriving spatial objects, e.g., the continuous updates of the locations of the spatial objects as they move in space. Having a spatial index facilitates the progressive evaluation of the continuous spatial query.

Static vs. Dynamic Spatial Queries

Continuous spatial queries over spatial data streams can either be static or dynamic. A static continuous spatial query does not change its input over time. For example, the spatial location of a kNN select predicate remains constant over time for the entire lifetime of the continuous spatial query. In contrast, a dynamic continuous spatial query may change its input parameters over time. For example, consider the following query: Find the three-closest gas stations to my current location while I am driving on the highway. This continuous query is composed of a kNN select predicate, where the focal point of the kNN select corresponds to the location of a moving object. Changes to the location of this focal point as the object moves may result in updating the query's resultset even without having any updates from the spatial data source.

Historical Background

General-Purpose Big DSMSs

Several general-purpose big stream management systems have been extended to support big spatial data stream processing. These systems provide an

infrastructure for the scalable processing of data streams. Generally, the main advantages of these systems are (1) hiding the complexity of transferring data between distributed processes, (2) high throughput, and (3) reliability and fault tolerance. Two main data processing models are currently being adopted by general-purpose big DSMSs, namely, *tuple-based* and *micro-batching*.

In the *tuple-based* streaming model, every tuple in the stream can be processed individually. Yahoo S4 (Neumeyer et al., 2010) and Apache Storm (Toshniwal et al., 2014) are examples of tuple-based big data streaming systems. The main advantage of the tuple-based model is the low processing latency of streamed tuples. The main limitation of this model is that a single tuple may be processed more than once in certain failure situations.

In the *micro-batching* streaming model, tuples are not processed individually but are rather buffered for a time duration (up to a few seconds) to create a micro-batch. M3 (Aly et al., 2012) is a main-memory map-reduce-based system that modifies (Apache Hadoop, 2017) in the following way. It removes the HDFS layer and replaces it by memory buffers that are maintained in a distributed layer of data nodes. Data continues to accumulate until the memory buffers are filled or until some maximum delay threshold is reached. Then, data is batched into the map-reduce layer. In M3, the disk layer between the mappers and the reducers is eliminated and is replaced by another layer of distributed memory buffers. Data is communicated between the mappers' and the reducers' distributed memory buffers using networking sockets. SparkStreaming (Zaharia et al., 2012) is another example of a micro-batching-based DSMS. SparkStreaming extends Spark, a general-purpose main-memory big data system. SparkStreaming inherits the resilient distributed datasets (RDD) and lineage from Spark to ensure fault tolerance in stream processing. RDD is an immutable main-memory data structure that represents a collection of objects. Processing in Spark and SparkStreaming is performed by applying transformations to RDDs. Lineage is a graph that represents transformations to RDDs. In failure scenarios, the lineage graph is consulted

to reconstruct the failed RDDs. SparkStreaming builds RDDs over micro-batches of streams every specific time duration (up to a few seconds). The main advantages of this model are high throughput and that every tuple gets processed exactly once even under failure scenarios. However, the main limitation of micro-batching is the high latency incurred while buffering streamed data to build a micro-batch.

Centralized Spatial DSMSs

Several centralized spatial data stream management systems have been developed to answer spatial queries over spatial streams. Examples of these systems include PLACE (Mokbel et al., 2004b), SINA (Mokbel et al., 2004a), SEA-CNN (Xiong et al., 2005), SOLE (Mokbel and Aref, 2008), and Gpac (Mokbel and Aref, 2005). These systems are not designed for scalability, and their performance is constrained by the resources of the single machine they run on.

Big Spatial DSMSs

We describe the main types of big spatial DSMSs below.

Dedicated Big Spatial DSMSs

Special-purpose big spatial DSMSs are distributed systems that can process only spatial data streams. These systems often address specific types of queries over spatial data streams. They focus on the scalability of spatial query processing and do not address other requirements of distributed big data processing, e.g., the efficient scheduling of distributed processes across the cluster of machines, reliability, fault tolerance, error recovery, or fair workload distribution across the processes. These systems are considered the first step toward big spatial DSMSs. Examples of these dedicated and spatial-purpose distributed big spatial DSMSs include PLACE* (Xiong et al., 2007), MobiPLACE (Zakhary et al., 2013), and MobiEyes (Gedik and Liu, 2006).

PLACE* (Xiong et al., 2007) use multiple servers to evaluate continuous moving range queries (dynamic queries) over moving objects in the Euclidean space. This system employs an incremental update model that updates query results only when there is a change to the resultset of the queries. MobiPLACE (Zakhary et al., 2013) applies the processing model of PLACE* over road networks.

MobiEyes (Gedik and Liu, 2006) use a centralized server and multiple small smart-mobile devices. To reduce the workload at the centralized server, MobiEyes offloads and distributes the processing of the continuous moving spatial range queries to the mobile devices.

Spatial Extensions to Big DSMSs

The most adopted approach in big spatial data streaming is to extend a general-purpose big data stream management system. This allows spatial extensions to inherit the scalability and reliability features of the underlying streaming platform. Spatial extensions to general-purpose big data stream management systems differ in the streaming model supported, i.e., tuple based or micro-batching based. These systems also differ in the type of spatial queries supported, the type of the spatial indexes used, and whether the spatial extension is adaptive and sensitive to the change in distribution of the data and the query workload of the spatial data stream or not.

Micro-Batching-Based Systems

Grid-based indexing on top of SparkStreaming (Choi et al., 2015; Lee and Song, 2015). These systems answer continuous range queries over spatial data streams on top of SparkStreaming. They use grid-based partitioning to distribute the streamed workload across the worker processes of the underlying cluster.

Cruncher (Abdelhamid et al., 2016). This system is an adaptive extension to SparkStreaming that addresses kNN and range queries over a spatial data stream. Cruncher keeps statistics about the spatial data and query workload to build a kd-tree-based (Ooi et al. 1987) spatial partitioning over the spatial data and queries. This partitioning is applied to every micro-batch to create

sub-micro-batches. These sub-micro-batches are fairly distributed across the worker processes of the underlying spark cluster. Cruncher also uses the spatial properties of continuous range queries to share the execution among the spatial queries that have overlapping ranges.

Tuple-Based Systems

Algorithms for spatial queries on top of Storm (Zhang et al., 2016). This approach develops algorithms to answer continuous spatial queries on top of Storm. The queries supported are the spatial range, kNN, and the spatial join. The current locations of the moving objects are maintained in separate Storm processes. Each Storm process is responsible for a specific set of moving objects. Within every Storm process, say P , a spatial index is used to maintain the current locations of the moving objects handled by P . Spatial queries are replicated to all Storm processes to produce partial results. Partial results of these queries are collected from the distributed Storm processes to be aggregated at dedicated aggregation processes. To process a spatial join operation, a different partitioning algorithm is used. Instead of partitioning the moving objects based on their identifiers, moving objects are partitioned spatially using grid-based partitioning. The range of a spatial join operation may span multiple Storm processes. Moving objects that overlap the spatial range of the spatial join operation are paired together to produce the final answer.

Continuous kNN-join processing on top of Storm (Song, 2016) This approach develops a parallel algorithm to evaluate continuous kNN-join operations on top of spatial streams. The algorithm uses data partitioning and replication of distributed processes to group in the same processes all the possible pairs that can be joined together. This algorithm is realized on top of Storm.

DSI: kNN processing on top of S4 (Yu et al., 2015). DSI is a distributed spatial partitioning mechanism that is realized on top of Yahoo S4 (Neumeyer et al., 2010). DSI processes snapshot kNN operations over the current locations of moving objects. DSI partitions the

space into horizontal and vertical strips. Every horizontal and vertical strip is assigned to a distributed process in S4. To process a kNN operation, partial kNN results are calculated from the strips. Then, a global kNN result is aggregated from all the partial results. DSI is adaptive and attempts to ensure fair workload distribution by updating the boundaries of the horizontal and vertical strips based on the changes in the workload.

kNN processing on top of IBM System S (Wu et al., 2012). In this approach, the continuous kNN operation is handled as a stateful operator, i.e., it maintains the current set of the k-nearest objects closest to the focal point of the continuous kNN operation. A distributed version of the kNN operation is realized using IBM System S. IBM System S is a proprietary general-purpose big data stream management system. To evaluate this kNN operation, location updates of moving objects are partitioned using a hash function to multiple processes. Then, an aggregation step is used to find the global kNN resultset.

Big Spatio-textual Data Streaming

Spatial data streams are often associated with a textual attribute. For example, tweets have both spatial and textual attributes. Several big spatial data stream management systems have been developed to process streamed spatio-textual data. The main feature in these systems is that they utilize the textual attribute of the spatio-textual data to optimize the processing of spatio-textual queries.

The two main spatio-textual queries being supported by big spatial data stream management systems are (1) *the continuous spatio-textual filter query* and (2) *the continuous top-k spatio-textual query*.

The continuous spatio-textual filter query has both an input spatial range and a set of input keywords. In this query, it is required to identify the streamed spatio-textual objects located inside the spatial range of the query and contain all of the keywords of the query. Tornado (Mahmood et al., 2015, 2017) and PS²Stream (Chen et al., 2017) are two big spatial data stream management sys-

tems that address these queries. Both systems extend Storm. The main idea behind these systems is to evenly distribute the spatio-textual data and queries over distributed Storm processes. This is performed using a global distribution layer that contains a spatio-textual distribution index. Within every worker process, continuous spatio-textual filter queries are indexed using an internal spatio-textual index.

The continuous top-k spatio-textual query. This query has an input focal point and an associated set of input keywords. This query maintains a time-sliding window over a spatio-textual data stream. In this query, it is required to continuously identify the most relevant spatio-textual data objects within the time-sliding window. Relevance between the objects and the query is calculated using a function of the spatial distance and the textual similarity between the spatio-textual data objects and the queries. DSkye (Wang et al., 2017) is an extension to Storm. DSkye uses a global spatio-textual distribution mechanism to distribute stream spatio-textual queries to worker processes. In worker processes, a local index stores the spatio-textual objects for a specific time-sliding window. For every incoming query, the distributed local indexes are searched to identify an initial list of the top-k relevant data objects. Then, the list of the top-k relevant data objects keeps being updated according to the incoming spatio-textual streamed data objects.

Examples of Applications

Many applications require the processing of this streamed big spatial data in real time. Example applications include finding travel companions; ride-sharing, e.g., Uber; real-time navigation and map services, e.g., Google Maps; and real-time traffic analysis. Nowadays, algorithms adopted in online advertisement targeting consider the locations of users to identify relevant local advertisements. Real-time analysis of microblogs, e.g., identify trending Twitter hashtags within a specific location, is one important

application of processing streamed spatio-textual data.

Future Directions for Research

One important research direction is online big spatial data analytics. The challenge here is to support a richer set of complex spatial predicates that also involves aggregations. One challenge of supporting these spatial predicates is to devise effective cost estimation techniques that can capture the varying overhead of these operations. These cost estimation techniques are crucial to maintaining workload balance over the distributed processes of the underlying spatial DSMSs.

Also, existing big spatial DSMSs do not efficiently support the temporal dimension. One example scenario of spatio-temporal and textual processing is the continuous aggregation of streamed spatial data based on their textual attributes over a time-sliding window. This type of data management requires novel distributed spatial-temporal and textual distribution, indexing, and query processing algorithms that account for the peculiarities of the temporal dimension.

Streaming Microservices

Ted Dunning and Ellen Friedman
MapR Technologies and Apache Software Foundation, Santa Clara, CA, USA

Synonyms

[Stream-based microservices](#); [Streaming architecture](#)

Definitions

Streaming microservices refers to a style of building large-scale software systems as a collection of independently deployable processes that commu-

nicate via persistent message streams rather than via remote procedure calls (RPC). A key distinction between streaming and RPC-based microservices is that streaming microservices provide a high degree of temporal decoupling between services. Not only does it not matter how a service does what it does, but it also matters much less exactly when it does it.

The use of streaming microservices is distinct from previous architectural trends such as Service Oriented Architecture (SOA) because the message streams used with streaming microservices are very simple, supporting little more than ordered delivery of messages organized into topics as opposed to the highly complex semantics supported by Enterprise Service Busses (ESB).

Historical Background

The term microservices as a style of systems architecture was introduced in 2011 at a conference in Venice and gained popularity around 2013–2014 (Fowler and Lewis, 2014) as people saw the success of this approach in large companies including Netflix, Amazon, and LinkedIn. Many of the core concepts underlying microservices for architecting large-scale systems go back at least a decade earlier, but the distinctive characteristics of microservice architectures were not well articulated until more recently.

The basic idea of microservices is to provide useful decompositions of large systems into independent services that could be started, stopped, and redeployed relatively independently. The key characteristic is that the implementation details of services are hidden. Virtues attributed to microservices include agility and flexibility in the development process by avoiding a monolithic approach with many development dependencies. Since services can be redeployed independently, the system is easier to upgrade progressively through evolutionary refinement of services one at a time. Teams working on different services can work to differing deadlines, thus avoiding many dependencies and schedule blocks.

In addition to the use of micro-services as a way to structure systems, they also define team organization. The result is that large systems devolve into a suite of loosely coupled small services, each built and run by a small, focused, cross-functional team. As originally viewed, microservices communicate via synchronous remote procedure calls (RPC), often implemented as REpresentation State Transfer (REST) (Fielding and Taylor, 2002) requests implemented over HTTP connections. More recently, asynchronous remote procedure calls have become much more common, especially in conjunction with node.js-based systems (Hughes-Croucher and Wilson, 2012).

The ability to deploy microservices independently makes development much easier than in a monolithic system or in a system that forces tight coupling between requestor and service. This is because individual services that can be upgraded independently also allow decoupling of development schedules. Additionally, using simple remote calls defined using systems like ProtoBufs, strict versioning of communication protocols is not necessary. Instead a more evolutionary soft-versioning approach can be taken that views all protocol changes as extensions and avoids complete redefinitions. Soft versioning of communication protocols provides additional decoupling of service development.

Decoupling of services also makes scaling easier, so explosive growth is a strong incentive to adopt microservice architectures. Selectively scaling individual services to match the scale of work that needs to be done by that service is much more efficient than scaling a monolithic service (Newman, 2015).

The final step to streaming microservices as opposed to RPC-based microservices is a much more recent development than the core concept of microservices. The fundamental addition that streaming brings is the idea that many services can actually be decoupled temporally as well as in terms of deployment. This sounds like a small change, but it substantially increases the scope of the microservice concept.

Foundations

Getting streaming microservices to work well requires a lexicon of high-level architectural patterns, a compatible underlying message transport, and methods for implementing the microservices themselves. This section describes each of these requirements in turn.

Emergence of Streaming Microservices

Widespread adoption of streaming microservices is a relatively recent trend in spite of the fact that the idea of moving data from one processing element to another is an old one (Johnston et al., 2004). What distinguishes modern streaming microservices from older dataflow concepts is that whereas dataflow was largely intended to build a system to execute a single computer program, a streaming microservices system is intended to support multiple high-level services that can be modified at any time. The idea of mutability of individual services leads directly to the requirement for hiding implementation details. Hiding implementation details such as timing leads to the use of persistent streams.

Existing messaging systems did not, however, support streaming microservices very well until recently. This prevented more than limited adoption of streaming microservices as a common architecture. This mirrors the way that early RPC mechanisms such as Java RMI and Corba were unsuitable for RPC-based microservices due to the way that changes in client or server were reflected through the remote call mechanism. True microservices could not really be built until more modern conventions for RPCs such as REST became widely accepted.

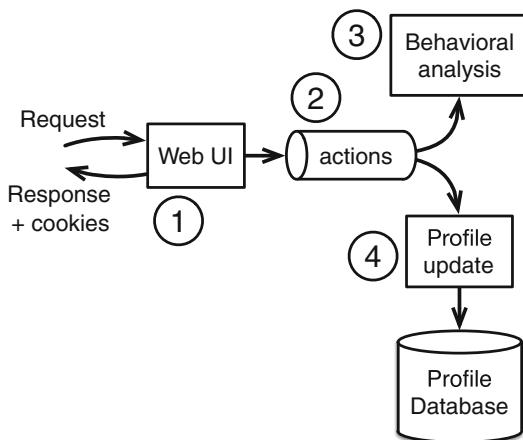

The problem with streaming microservices was that, until recently, message queuing systems put a premium on features that ensure that each message is processed exactly once. This exactly-once execution mirrors the way that a dataflow program executes. This mode of message consumption requires some kind of transaction per message and can severely limit the message rate and scalability (Videla and Williams, 2012; Snyder et al., 2011). More importantly, however, the transaction induces coupling between message

producers and consumers and between different consumers, which degrades the isolation necessary for real microservices.

The release of Apache Kafka (Narkhede et al., 2017) provided an alternative approach to messaging that has proven more fertile for microservices. With Kafka, neither producers nor consumers have any idea how many consumers there are, and messages are kept in order and are retained for a configurable (and typically relatively long) period of time with no regard to whether they have been processed. Consumers are responsible for maintaining a history of which messages they have processed, although the framework does have a provision for consumers to record their consumption point back into the stream. Kafka guarantees that all consumers will see messages in the same order within the same partition of a topic but does little else to support the context of consumers. This same model, and indeed, the same API, have been adopted by commercial vendors such as MapR in their streams technology.

Pattern: Do Some, Defer Some

In microservice-based systems, some work typically has to be done by a service to produce a response, but it is also common that a significant amount of work involved in the request can be deferred to another time, possibly when a larger batch of such deferred tasks can be executed at the same time. It is a rather natural step to put the data associated with these deferred tasks into a message stream. Each message specifies a unit of work to be done when the message is read from the stream. Such a do-some/defer-some pattern is illustrated in Fig. 1. Here, we have three microservices: one is the web UI (labeled 1 in the figure) implemented as a synchronous RPC-based microservice, and the other two (labeled 3 and 4 in the figure) are implemented as streaming microservices. The web UI can respond to requests as quickly as possible and can have a simpler implementation because it only needs to focus on the minimal amount of processing necessary to provide a response. By recording a summary of the request it just processed as an event in a message stream, the web UI enables

Streaming Microservices, Fig. 1 In a typical design of a web service, the web UI (1) is implemented as a conventional microservice that accepts requests and returns responses in a synchronous fashion. In addition, the web UI defers some work by putting an event into a message stream (2). At a later time, other microservices such as a behavioral analysis (3) or a profile database update (4) process these events. Using streaming microservices here avoids impact on the latency of the original web UI request and improves the isolation of all three services

other microservices to do additional processing outside the critical path of responding to web UI requests. Because the web UI doesn't even necessarily know of the existence of these other services, the implementation and operation of the web UI are highly decoupled from them. This decoupling means that each of the three services can be updated and redeployed independently of the other services.

In this example, the web UI doesn't need to wait for confirmation that the work of the other services has completed nor does it rely on the actual results of that work. All it needs is certainty that the deferred work has been persisted in the message stream and will get done eventually. In fact, the web UI can often be implemented with no knowledge of these other microservices. The decoupling benefits of not depending on direct results and relaxed temporal dependency suggest that connecting services with message streams is a useful alternative to the more widely known RPC-based connected microservices. This style of design was called “event sourcing” by Fowler in Fowler (2005) and later called “streaming

architecture” or “streaming microservices” (Dunning and Friedman, 2016).

One of the major advantages of streaming microservices over conventional RPC-based microservices is that streaming microservices allow temporal decoupling of services in addition to the ability to independently deploy and upgrade services. Temporal decoupling means that there is little dependency in time of computation for producers of messages and consumers. This decoupling allows major implementation details such as whether a producer or consumer runs intermittently or continuously to be hidden from other services. In the ultimate case of hiding implementation details, a consumer may not even have been implemented when messages are emitted by a producer. In that case, the producer cannot depend on the implementation details of the consumer since the consumer literally does not even exist when the message is produced by the producer.

Message Transport

The messaging technology used to communicate between streaming microservices has some key requirements that derive from the basic definition of microservices. Earlier messaging tools generally required a trade-off between performance and message persistence and induced coupling between producers and consumers, between producers on the same stream and between multiple consumers due to the semantics of the messaging system itself. These limitations made streaming microservices difficult to apply across a wide range of applications and thus substantially limited the uptake of streaming microservice architectures.

The effectiveness of the Kafka style of message streaming for microservices can seem a bit paradoxical; by providing fewer features and simpler semantics, it makes streaming microservices more practical. There are several major requirements that Kafka-esque systems satisfy, including:

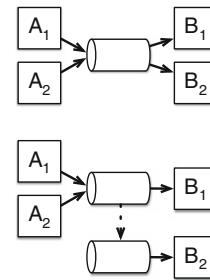

Persistence Messages are persisted in the message stream. This is logically required to enable service independence since there is no guarantee

that both producer and consumer are even running at the same time. Message persistence also improves failure recovery since a consumer can checkpoint input offsets and internal state, allowing clean restart on failure. Traditionally, however, persistence has been difficult to achieve at high performance levels.

Performance It is important that the message transport be fast enough for essentially any operational requirement. If this is not true and widely recognized, implementers will tend to proactively code around perceived performance risks. Wide adoption of streaming microservices can quickly lead to message throughputs in the millions of messages per second even at modest scale. It is not true, however, that all streaming microservices will require such high message rates. It is simply true that *some* applications will require such rates and using different streaming mechanisms for different applications or changing streaming technologies as services scale breaks down service independence because of a lack of pervasiveness.

Pervasive A key benefit of a microservices approach is that services can universally interoperate. For RPC oriented microservices, organizations typically standardize on a single RPC technology for this reason. For streaming microservices, similar standardization is required to gain adoption and allow interoperation of services. As such, any messaging system used has to meet technical requirements such as persistence and performance, but also social requirements like universal adoption within a set of services, that is, it must be pervasive. Put another way, if different services use different streaming technologies due to different performance levels, this introduces implementation coupling between systems that could be avoided with a single streaming system.

Ultimately, these properties of the underlying streaming technology result in a system that can allow services to function without knowledge of the implementation details of other services. In the upper part of Fig. 2, for example, services A_1 and A_2 can be producing data for B_1 . Service B_2 can then be brought into operation without

Streaming Microservices, Fig. 2 Examples of decoupling between processes. In the top example, producers A_1 and A_2 and consumers B_1 and B_2 operate independently and can be deployed without affecting any of the other services. In the bottom example, A_1 and A_2 produce data that is consumed by B_1 and B_2 from different replicas of the same stream. Producers and consumers in the two examples can't tell the difference between the two configurations

B_1 or either producer being aware. In the lower example, geographical separation can also be introduced by replicating the stream without any of the services being affected, except possibly by small differences in the latency for messages arriving at B_1 and B_2 .

Service Implementation

Streaming microservices can be implemented in a wide variety of ways. Particularly at the lower performance levels, it is possible to build reliable services using simple single-threaded code that reads units of work from a stream, performs the work and occasionally commits the current input point. This simple approach needs to be augmented with some sort of orchestrator such as Kubernetes that can restart or migrate the service as necessary. At slightly higher throughput levels, input streams can usually be partitioned to allow multiple processes to cooperate in a “consumer group.” By subscribing as part of the same consumer group, these processes will be assigned different partitions. The worker processes have to handle out-of-band messages notifying them of changes of partition control, but the basic structure is extremely simple, at least as long as the necessary processing on each unit of work is relatively simple.

As the required complexity of a service’s task goes up, it can be advantageous to use more

advanced systems to implement services. Options include Apache Spark's continuous streaming component (Apache Software Foundation, 2016b) or Apache Flink (Apache Software Foundation, 2016a; Friedman and Tzoumas, 2016). These more complex systems can handle complex joins and windowed transformations of streaming data while maintaining failure tolerance and high throughput.

Complementary Roles of the Message Stream and Database

In streaming microservices, message streams are used for communication between services, while databases are typically considered better for retaining state within a service. Often, a service will have a database that contains the latest state received via message stream. The sequence of states of such a database is, in some sense, equivalent to the messages in the stream. The primary difference is that the stream inherently retains the notion of time and all previous states but is difficult to probe for the latest value of any quantity. In contrast, the database makes probing for the latest value easy but loses information about previous states. As such, databases of this kind and the streams that update them can be seen as complementary views of the same data.

The virtue of storing state in a private database is that services can become decoupled in terms of time. If two consumers of a message stream update private databases in identical ways, there is no guarantee that at any given time that the two databases will have identical values because there is no guarantee that the two services will process messages at the same rate. We can guarantee, however, that both services will agree about the state of their databases relative to identical offsets in the message stream. This idea of equivalent, but not time-aligned, state is important because it allows much of the power of database transactions to be had without the abstraction destroying qualities of shared databases.

It should be noted that, as recommended by Fowler in his description of event sourcing, the messages in a message stream should generally be couched as heavily denormalized business-

level events rather than table level updates. The concept of "business-level event" is not particularly well defined, but it is very close to the concept of REST in that the message should contain everything that is needed to describe the event in a self-contained way. The purpose of using RESTful messages of this type is that it is relatively easy to translate such messages into corresponding low-level table updates, but it is much more difficult to translate a collection of table updates into business-level event descriptions. This means that using RESTful messages makes it so that different services can easily have different data models in their private databases, which makes their implementations more loosely coupled.

Key Applications

The streaming style of microservices has widespread application, especially associated with more back-end systems such as analytical systems in which throughput and aggregated analytical results at scale are particularly important (Dunning and Friedman, 2016). Streaming microservice applications often involve situations in which delayed processing is acceptable.

In general, situations in which the flexibility of a stream-based overall architecture is desired may benefit from a streaming microservices style of work. An example where a streaming microservices style approach would be particularly useful is in analysis of IoT (Internet of Things) sensor data.

Streaming Process Discovery and Conformance Checking

Andrea Burattin
DTU Compute, Software Engineering, Technical University of Denmark, 2800 Kgs. Lyngby, Denmark

Synonyms

Online conformance checking; Online process discovery; Online process mining

Definitions

Streaming process discovery, streaming conformance checking, and streaming process mining in general (also known as *online process mining*) are disciplines which analyze event streams to extract a process model or to assess their conformance with respect to a given reference model. The main characteristic of this family of techniques is to analyze events immediately as they are generated (instead of storing them in a log for late processing). This allows to drastically reduce the latency among phases of the BPM lifecycle (cf. Dumas et al. 2013), thus allowing faster process adaptations and better executions.

Overview

A possible characterization of process mining algorithms is based on how they consume event data. Specifically, most of the algorithms focus on a (static) *event log*; however, there are algorithms which focus on *event streams*. An event log is a finite sampling of activities observed in a given time frame. An event stream, on the other hand, is an unbounded *sequence* of events, which contains events as they are executed.

Event streams, in fact, are specific types of data streams, where each data point refers to an event. General data streams have been investigated since many years, mainly to tackle problems such as frequency counting, classification, clustering, approximation, time series analysis, and change diagnosis (also known as novelty detection or concept drift detection) as summarized in Widmer and Kubat (1996), Gama (2010), Gaber et al. (2005), and Aggarwal (2007). To tackle these problems, it is possible to devise techniques in a data- or task-based orientation. *Data-based techniques* aim at extracting a significantly representative finite subset of the data stream, which is used for the analysis. *Task-based techniques*, on the other hand, adapt the computation to this new data modality, in order to minimize time and space complexity of the analysis.

The streams these algorithms have to deal with can be characterized based on their *operations model*. In particular, we might have:

- insert-only stream model (once an element is seen, it cannot be changed);
- insert-delete stream model (cf. n elements can be deleted or updated);
- additive stream model where seen item refers to numerical variables which are just incremented.

In the context of process mining, all available techniques assume the insert-only model: observations refer to activities which have been executed. The data mining literature, for example, in Golab and Özsu (2003) and Bifet et al. (2010), informally, defines data streams as a *fast sequence of data items*. However, in Bifet and Kirkby (2009), several assumptions on the data stream are reported, such as the following: the data is assumed to have a small and fixed number of attributes; the number of data points is very large; and the stream concepts (in the process mining context, the *concept* is the model underlying the events being generated) are assumed to be stationary or evolving. These assumptions make the processing of data streams very different from conventional relational models. Specifically, as detailed in Gama (2010, Table 2.1), the data elements arrive online, with no control by the system, in an unbounded amount. This imposes the analysis to be incremental: once an element is received, it is discarded or analyzed. If it is

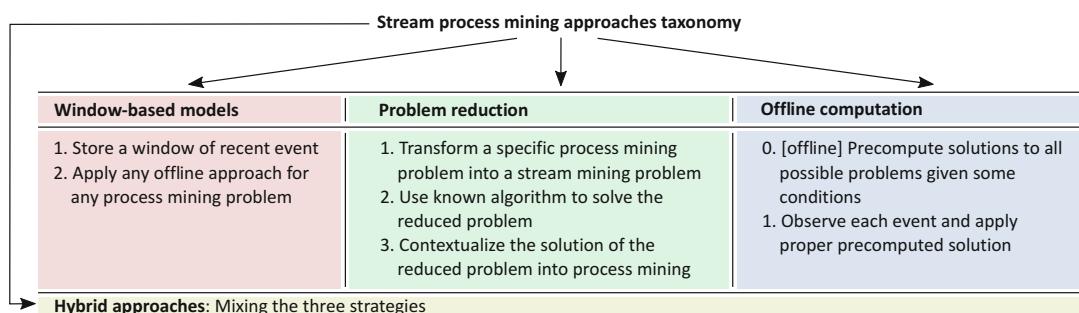

analyzed, it cannot be explicitly retrieved again afterward (i.e., its information is aggregated and summarized). Additionally, to cope with concept drifts, old observations should be replaced by new ones, and it is not possible to have one-time queries but a continuous “querying mechanism” is necessary.

Key Research Findings

This section provides some general ideas on how to tackle the problem of process mining from an event stream. Three general strategies are sketched, and in the upcoming subsections, details regarding actual instantiations of the ideas are reported.

Figure 1 depicts a taxonomy of the different approaches investigated so far. In this text, we will not focus on hybrid approaches: they are characterized by very heterogeneous solutions and therefore there is no proper generalization possible.

Window models. In order to perform process mining on a stream of event, the simplest approach is to devise a data-based technique to store only the set of most recent events observed and periodically analyze them. Whenever there is no more memory available, the oldest event is discarded. This approach, called *window model*, is described in Algorithm 1. The algorithm enters an endless loop where, at each iteration, a new event is observed. Then, the system checks whether it is necessary to remove old events or not, and

Streaming Process Discovery and Conformance Checking, Fig. 1 Taxonomy of the different approaches to solve the different stream process mining problems. For each technique, corresponding general steps are sketched

Algorithm 1: Window model

Input: S : event stream
 M : memory model
 \max_M : maximum memory
 A : additional information (e.g., a reference model), can be \emptyset

```

1 forever do
2   // Observe a new event
3    $e \leftarrow \text{observe}(S)$ 
4   // Memory update
5   if  $\max(M) \geq \max_M$  then
6     |  $\text{dequeue}(M)$  // Forgetting
7   end
8    $\text{insert}(M, e)$ 
9   // Mining update
10  if  $\text{perform mining}$  then
11    | // Memory into event log
12    |  $L \leftarrow \text{convert}(M)$ 
13    |  $\text{ProcessMining}(L, A)$ 
14  end
15 end

```

then the new event is inserted. Periodically, the system converts the memory into a standard event log, and classical process mining algorithms are applied on it. The literature, in Babcock et al. (2002), identifies at least two memory models capable of storing event: *sequence based* and *timestamp based*. The first approach (which is typically implemented with *sliding windows*) consists of a FIFO queue of fixed size. The observed events are stored in the window, and once the maximum capacity is reached, the oldest event is removed. In a timestamp-based window model, the approach is very similar, but the memory size is not fixed. Instead, the removal is based on the “age” of the observation: the memory keeps only the events observed within the given time span.

This approach comes with several advantages, such as the possibility to reuse every mining algorithm already available for event logs. However, the memory management is extremely problematic and has a huge impact on the performance of the approach. Specifically, all window-based approaches have poor summarizing capabilities since, for example, duplicate events require two “memory slots,” even though they may not provide new information.

Algorithm 2: Lossy counting

Input: S : data stream
 ϵ : maximal approximation error

```

1  $T \leftarrow \emptyset$  // Initially empty set
2  $N \leftarrow 1$  // Number of observed events
3  $w \leftarrow \lceil \frac{1}{\epsilon} \rceil$  // Bucket width
4 forever do
5   |  $e \leftarrow \text{observe}(S)$ 
6   |  $b_{curr} \leftarrow \lceil \frac{N}{w} \rceil$ 
7   | /* Is there a tuple in  $T$  with  $e$  as
8   |   first component? */ *
9   | if  $e$  is already in  $T$  then
10  |   | Increment the frequency of  $e$  in  $T$ 
11  | else
12  |   | Insert  $(e, 1, b_{curr} - 1)$  in  $T$ 
13  | end
14  | if  $N \bmod w = 0$  then
15  |   | forall the  $(a, f, \Delta) \in T$  s.t.  $f + \Delta \leq b_{curr}$  do
16  |   |   | Remove  $(a, f, \Delta)$  from  $T$ 
17  | end
18 end

```

Problem reduction. The second possible way of tackling the streaming process mining problems is to employ a task-based technique. For example, it is possible to *reduce* the process mining problem to another well-established problem and therefore reuse algorithms specifically devised and optimized for the necessity at hand. Of course, it is also possible to devise a completely new algorithm specifically tailored to solve the given situation. This approach, for example, has been used to reduce the problem of streaming process discovery to the *frequency counting problem*. This problem consists of counting the frequencies of given variables over a stream. In order to reduce the process discovery to such problem, it is important to understand *what is* a variable in the process mining context and whether it is possible to identify it.

An example of efficient algorithm for the approximated frequency counting problem is Lossy Counting, here summarized in Algorithm 2 and described in Manku and Motwani (2002). The idea is to conceptually split the observed stream in buckets, each with a fixed size. The approach takes as input the stream and the maximal approximation error on the counting $\epsilon \in [0, 1]$, which drives the size of each bucket. The approach stores entries in a data structure T where each

component (e, f, Δ) provides the element e of the stream, the estimated frequency for it f , and the maximum number of times it could have occurred Δ . When a new event is observed in the stream, the algorithm checks if it is already in T and, in case, it increments its counter f by one. Otherwise a new entry in T is created. Periodically (i.e., every time a new conceptual bucket starts), the algorithm cleans the memory, by removing elements not frequently observed. This algorithm has no memory bound. Specifically, the size of the data structure T depends on the stream and on the approximation error. However, a variation of the algorithm to enforce fixed amount of memory is described in Da San Martino et al. (2012).

The most relevant benefit of the problem reduction approach is that, once the process mining problem has been reduced to the new one, it is possible to use algorithms already devised for the reduced problem. However, such reduction might not be trivial and all assumptions of the used approach have to be met.

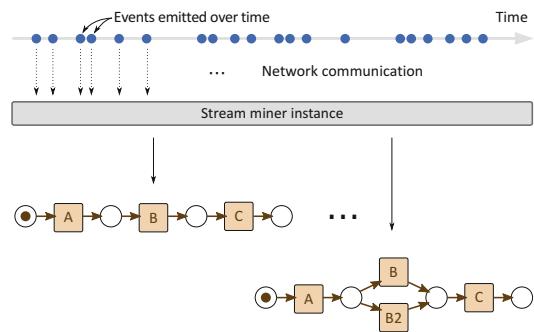

Offline computation. The last approach we present consists of moving the computation of the solutions to the given problem from online setting to offline. In other words, the idea is to identify and solve all subproblems the stream may provide. Adopting this approach will help us in dealing with all situations we are going to observe, still keeping the complexity of the online processing constant.

The advantage of this approach is the possibility of having extremely expensive solutions “cached” in advance which are then just reused whenever needed. Though there are several drawbacks, it is not possible to apply this approach to all online process mining problems. Additionally, by computing everything in advance, we lose the possibility of adapting the precomputed solutions to the contextual information, which might be uniquely specific to the running process instance.

In the upcoming subsections, one example of each technique will be presented and detailed by presenting two process mining activities.

Process Discovery

The first problem we present is the online process discovery. A graphical conceptualization of the

Streaming Process Discovery and Conformance Checking. Fig. 2 Conceptualization of the streaming process discovery idea as in Burattin et al. (2014b)

problem is reported in Fig. 2. The idea is to have a source which is generating an event stream. This event stream is consumed by a miner which generates a representation of the underlying process model and keeps it up-to-date with respect to the observed behavior.

The first approach available to tackle this problem is reported in Burattin et al. (2012, 2014b). In their works, authors employ a problem reduction strategy. Specifically, they reduce the Heuristics Miner algorithm, described in van der Aalst and Weijters (2003), to the frequency counting problem. To do that, they assume *direct following relationships* as variables, and by counting them, they are able to use the Heuristics Miner’s metric to reconstruct the high-level business patterns in terms of Heuristics Net or Petri Net. Authors test different algorithms to solve the frequency counting problem, such as Lossy Counting and Lossy Counting with Budget. As baseline approach, authors use a sliding window mechanism where Heuristics Miner is iteratively applied. The sliding window approach is constantly outperformed by other approaches which provide a better usage of the available resources. A similar approach, called StrProM, tracks the direct following relationships. This approach, presented in Hassani et al. (2015), keeps an updated prefix tree by deriving a solution based on Lossy Counting with Budget. The direct following relationships are then used to construct a process model using the set of rules of Heuristics Miner.

As for the previously mentioned approaches, in Maggi et al. (2013) and Burattin et al. (2014a, 2015), authors investigate the problem of discovering a process represented in Declare (cf. Pesic et al. 2007). Specifically, their idea is to instantiate several “replayers,” one for each Declare template to mine. Then, specific behavior for each template is implemented. To keep track of the replay statuses, authors use Lossy Counting-based strategies. Authors apply sliding window as baseline, and again, the performances of the Lossy Counting strategies are better with respect to the simple application of offline approaches over a sliding window.

In Redlich et al. (2014b), authors present the adaptation of CCM to cope with event streams. The basic idea of CCM (cf. Redlich et al. 2014a) is to identify subsequences of events in order to identify footprints of specific process patterns. In CCM, relevant patters and corresponding footprints are described. Aging factors are employed to the collected information in order to give more importance to recent behavior.

The most recent work tackling the online process discovery is reported in van Zelst et al. (2017b). In their paper, authors generalize previously instantiated concepts: they present an architecture, namely, S-BAR, which keeps an updated abstract representation of the stream (e.g., direct follow relationships), and they use it as starting point to infer an actual process model. In their work, authors present the adaptations of different mining algorithms: α (cf. van der Aalst et al. 2004), Heuristics Miner (cf. van der Aalst and Weijters 2003), and Inductive Miner (cf. Leemans et al. 2013). To show the generability of their abstract representation, authors also show a miner based on region theory (cf. van der Aalst et al. 2008). In order to keep their abstraction updated, authors reduce their problem to frequency counting, thus using Lossy Counting, Space Saving (cf. Metwally et al. 2005), and Frequent (cf. Karp et al. 2003).

Conformance Checking

The problem of online conformance checking has received attention in the declarative domain. In this case, it used to be called *operational support*,

and its aim is to understand whether a set of constraints is being violated or not. To achieve that, in Maggi et al. (2011, 2012), authors devise an approach to represent the behavior as an automaton and executions are replayed on it. Additionally, each process instance is labeled with one of four possible fulfillment states: permanently/temporarily violated/fulfilled.

Concerning imperative models, online conformance checking received less attention. At present time, only two approaches have been specifically designed to tackle the online conformance checking problem. One approach, described in van Zelst et al. (2017a), aims at reusing the concept of *alignment* in order to compute the optimal alignment just for the prefix of the trace seen up to a given point in time. To this end, authors first devise a technique to compute prefix alignments. Authors prove the optimality of the prefix alignment they discover. Up to this point, their approach is incremental but not really online (i.e., it is able to work on partial cumulative information, but in theory they need infinite memory to backtrack in order to find the optimal alignment). To solve this issue, authors mention the possibility to implement memory management, either falling into a window-based model or as problem reduction. Authors, however, do not implement or test either memory management approach. However, they test their technique against different number of backtracking steps required to find the prefix alignment.

Another conformance checking approach belongs to the offline computation category and is described in Burattin and Carmona (2017) and Burattin (2017). In this case, given a Petri Net as input, authors describe a technique to elicit a transition system containing all possible transitions from one marking to another one, even those which are not described by the original model. Each transition in this elicited model is then associated with a cost. Transitions allowed by the original Petri Net have cost 0; all others have cost > 0 . This way, by replaying a trace on such transition system and summing the costs, authors show that conformant traces will have cost 0 and non-conformant trace always have cost larger than 0. Additionally, authors ensure the

determinism of such transition system and the possibility, from each state, to have one transition for each possible activity. These two last properties guarantee the suitability of the approach for online settings.

Another conformance checking approach is presented in Weber et al. (2015). In this case, authors propose a RESTful service which performs a token replay on a BPMN model. In particular, authors implemented a *token pull mechanism*. Authors refer this approach as online primarily because of its interface, while no explicit guarantee is mentioned in terms of memory usage and computational complexity.

Other Applications

Online process mining has been applied also to discover cooperative structures out of event streams. For example, in van Zelst et al. (2016), authors are able to process an event stream and update the set of relationships of a cooperative resource network.

Additionally, in order to conduct research on stream process mining, it is useful to simulate an event stream for which we know the actual original source. To achieve that, mainly two approaches are available. The first is a tool called PLG2 (<http://plg.processmining.it/>), described in Burattin (2016). It allows to generate a random model or to load a BPMN file and stream events referring to actual executions. The stream is sent over a TCP/IP connection, and the tool allows different configurations in terms of noise and concept drift. The second tool is described in van Zelst et al. (2015). This tool allows researchers to design a model – as Petri Net – in CPN (<http://www.cpntools.org/>) and then import it into ProM (<http://www.promtools.org/>) where the XSEventStream Publisher plugin can be used to simulate a stream. Please note that, in this case, the stream exists just within ProM.

Key Applications

Due to the novelty of the topic, we are not aware of any deployment of streaming process min-

ing techniques in real settings. However, more generally, online process mining techniques are relevant in all cases where it is important to have results in real time, to immediately enact proper responses. In this section, examples related to IT setting will be provided, but business-oriented applications are absolutely possible and relevant as well.

Online process discovery might be useful in settings where it is important to analyze immediately the behavior of the system. For example, reconstructing the behavior of the services used in a website might be useful in order to see what is currently under stress and what is going to be used afterward. Exploiting this information could improve the resource allocation (e.g., upscaling or downscaling the server capacity on the fly).

Online conformance checking is also useful whenever it is important to immediately detect deviations from reference behavior to enact proper countermeasures. For example, the kernel of an operating system exposes some services for applications. These services should be combined in some specific ways (e.g., a file should be `open()` and then either `write()` or `read()` or both appear, and eventually the file should be `close()`) which represent the reference behavior. If an application is observed strongly violating such behavior, it might be an indication of strange activities going on, for example, in order to bypass some imposed limitations or privileges.

S

Future Directions for Research

As previously mentioned, online process mining is a relatively new area of investigation. Some techniques are available for the discovery of the process (both as imperative and declarative models). Very recently, online conformance checking also received attention, but several improvements are still needed.

First of all, techniques should improve their efficiency, for example, in terms of memory consumption. This represents an important research direction since, in the online setting, the amount of available memory is fixed, thus representing a

key resource. To tackle this problem, it is necessary to work on the summarization capabilities used by the algorithms in order to find more compact ways of storing the same information.

Related to the previous point is the quality and quantity of information, and contextual data algorithms are able to extract out of the same event stream. For example, a process discovery algorithm might be extended to extract more complex control flow patterns, or the algorithm might be modified to return not just the result but the confidence on the provided outcomes.

Additionally, there are more technical issues that algorithms should be able to cope with, for example, dealing with a stream where the arrival time of events does not coincide with their actual execution. In this case, it would be necessary to reorder the list of events belonging to the same process instance before mining them. Please note that assuming different orders implies a sort of different element models of the stream (i.e., it becomes an “insert-delete stream model,” where the order of events can change). Another relevant issue might be the inference of the termination of a process instance.

S

Introduction

During the past decade, we have been witnessing a massive growth of data. In particular the advent of new mobile devices such as smartphones, tablets and online services like Facebook and Twitter created a complete new era for data processing. Although there exist already well-established approaches such as MapReduce (Dean and Ghemawat, 2008) and its open-source implementation Hadoop (2015) in order to cope with these large amounts of data, there is a recent trend of moving

away from batch processing to low-latency online processing using event stream processing (ESP) systems. Inspired by the simplicity of the MapReduce programming paradigm, a number of open-source as well as commercial ESP systems have evolved over the past years such as Apache S4 (Neumeyer et al., 2010; Apache, 2015) (originally pushed by Yahoo!), Apache Storm (2015) (Twitter), and Apache Samza (2015) (LinkedIn), addressing the strong need for data processing in near real time.

Since the amount of data being processed often exceeds the processing power of a single machine, ESP systems are often carried out as *distributed systems* where multiple nodes perform data processing in a cooperative manner. However, with an increasing number of nodes used, the probability for a failure increases which can lead either to partial or even full system outages. Although several well-established approaches to cope with system failures for distributed systems are known in literature, providing fault tolerance for ESP systems is challenging as those systems operate on constantly flowing data where the input stream cannot be simply stopped and restarted during system recovery.

One possibility for providing fault tolerance in ESP systems is the usage of checkpointing and logging, also known as *rollback recovery-passive replication* in literature where the state of an operator is periodically checkpointed to some fault-tolerant stable storage and so-called in-flight events are kept in in-memory logs at upstream nodes (upstream backup) (Hwang et al., 2005; Gu et al., 2009). During system recovery, the most recent checkpoint is being loaded, and previously in-flight events are replayed. An alternative to rollback recovery is *active replication* (Schneider, 1990; Martin et al., 2011a) where two identical copies of an operator are deployed on different nodes performing redundant processing. If one of the two copies crashes, the system continues to operate without having to initiate a long recovery procedure as in passive replication.

Although active replication provides the quickest recovery, it requires almost twice the resources, while passive replication consumes only little resources; however, it suffers from

long recovery times. Despite the fact that both fault tolerance approaches have different characteristics with regard to recovery times and resource overhead, both require a *deterministic* processing of events. Deterministic processing ensures that all replicas process events in the same predefined order which is important in order (i) to reliably filter out duplicated events when using active replication and (ii) to provide reproducibility of events needed in order to recover precisely (i.e., neither loosing any events nor processing events twice) using passive replication. However, the use of deterministic execution imposes a non-negligible overhead as it increases processing latency and lowers throughput at the same time due to the cost of event ordering.

Key Research Findings

This chapter presents three approaches to reduce the overhead imposed by fault tolerance in ESP systems. They are presented in the following order: First,

1. the architecture and implementation of STREAMMINE3G are discussed, an ESP system that was built from scratch to study and evaluate novel fault tolerance and elasticity mechanisms,
2. an algorithm to reduce the overhead imposed by deterministic execution targeting commutative tumbling windowed operators and improving the throughput by several orders of magnitude when used with passive and active replication,
3. an approach to improve the overall system availability by utilizing spare but paid cloud resources, and
4. an adaption-based approach that minimizes the operational costs by selecting the least expensive fault tolerance scheme at runtime based on user-provided constraints.

Roadmap section “[STREAMMINE3G Approach](#)” introduces the reader to the architecture and implementation of STREAMMINE3G, the ESP system used for evaluating the proposed approaches. In section “[Lowering Runtime Overhead for Pas-](#)

sive Replication”, an approach is presented that lowers the overhead of event ordering by introducing the notion of an *epoch* and evaluated it for the use with passive replication. An extension of this approach is discussed in section “Lowering Runtime Overhead for Active Replication” for the use with active replication by proposing an epoch-based merge algorithm and a lightweight consensus protocol. Next, section “Improving Resource Utilization and Availability Through Active Replication” details how to improve system availability by using a hybrid approach of passive standby and active replication by utilizing spare but paid cloud resources, while in section “Adaptive and Low-Cost Fault Tolerance for Cloud Environments”, an adaptation approach for fault tolerance is presented that allows to lower the overall resource consumption while still satisfying user-specified constraints such as recovery time and recovery semantics. Finally, the chapter concludes in section “Conclusions” with a short summary of the approaches and the contributions.

STREAMMINE3G Approach

The following section provides a brief overview about STREAMMINE3G, the ESP system used to implement and evaluate the proposed approaches.

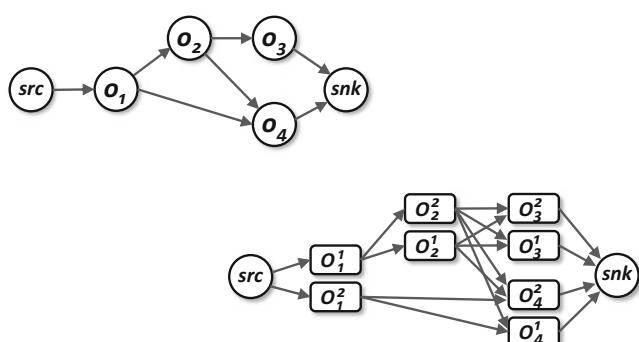

STREAMMINE3G is a highly scalable ESP system targeting low-latency data processing of streaming data. In order to analyze data, users can either opt for writing their own custom operators using the provided MapReduce-like interface and implementing a user-defined function (UDF) or

choose from an existing set of standard complex event processing (CEP) operators such as filter, join, aggregation, and others. In addition to the operators, users must specify the order events are supposed to traverse the previously selected operators using a topology. A topology in STREAMMINE3G is represented by a directed acyclic graph (DAG) where each vertex, i.e., an operator, can have multiple upstream and downstream operators as shown in Fig. 1 (left). In order to achieve scalability, operators in STREAMMINE3G are partitioned as depicted in Fig. 1 (right). Each partition processes only a subset of events from the incoming data stream. For data partitioning, users can either implement their own custom partitioner as in MapReduce or use the provided hash-based or key-range-based partitioner.

A typical STREAMMINE3G cluster consists of several nodes where each node runs a single STREAMMINE3G process hosting an arbitrary number of operator partitions, named slices as shown in Fig. 2. One of such nodes takes up the role of a manager which is responsible for placing operator partitions across the set of available nodes as well as moving partitions (through a migration mechanism) to other nodes for load balancing in situations of overload or underutilization. An overload can be detected by the manager node by analyzing the system utilization of each node, which is periodically reported through heartbeat messages exchanged between nodes.

In order to prevent the node hosting the manager component being the single point of failure, the state of the component is stored in Zookeeper (Hunt et al., 2010) upon each

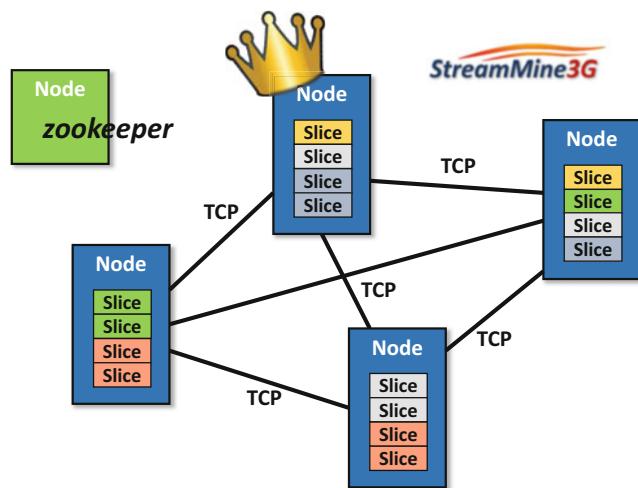

StreamMine3G: Elastic and Fault Tolerant Large Scale Stream Processing,
Fig. 1 Logical (top left) and physical (bottom right) representation (with two partitions for each operator) of a query graph

StreamMine3G: Elastic and Fault Tolerant Large Scale Stream Processing,

Fig. 2 A

STREAMMINE3G cluster. One node acts as a master/manager, while others serve as workers hosting an arbitrary number of slices (operator partitions)

reconfiguration of the system. In the event of a crash of the node, another node can transparently take over the role of the manager by simply recovering with the previously persisted state.

Lastly, STREAMMINE3G supports the implementation of stateless and stateful operators. However, contrary to other ESP systems such as Apache S4 and Storm that have either no, or only limited, state support, STREAMMINE3G offers an explicit state management interface to its users. The interface frees the users from the burden of having to implement their own bridle locking mechanism to ensure consistent state modifications when processing events concurrently (to exploit multiple cores) and provides a full stack of mechanisms for state checkpoints, recovery, and operator migration. In order to use these mechanisms, users are only required to implement appropriate methods for serialization and de-serialization of the state that can comprise arbitrary data structures.

Lowering Runtime Overhead for Passive Replication

In the following section, an approach for lowering the overhead for passive replication by introducing the notion of an epoch is presented.

Introduction and Motivation

ESP applications are often long-running operations that continuously analyze data in order to carry out some form of service. In order to identify patterns and correlations between consecutive events, operators are often implemented as stateful components. One way for providing fault tolerance for such components is to combine periodic checkpointing with event logging for a later replay. However, since events may arrive in different orders at an operator during a recovery than they would have arrived originally due to small delays in network packet delivery, the immediate processing of such events would lead to possibly inconsistent results. One way of preventing such situations is to *order events* prior to the processing in order to ensure a deterministic input to the operator code at all times. However, the ordering of events is costly as it introduces latency and lowers throughput as shown later.

Fortunately, many ESP operators used in ESP applications share the property of *commutativity* and operate on jumping windows where the order of processing within such windows is irrelevant for the computation of the correct result. Examples for such operators are joins and aggregations. However, processing the same event twice or even missing an event may still distort the result of those operators. Hence, determinism is still needed in order to provide *exactly once processing semantics*.

Approach

Based on the observation that many operators are commutative and operate on jumping windows, the notion of an *epoch* is introduced. An epoch comprises a set of events based on their timestamps and matches the length of the window an operator is working on. In order to assign events correctly to those epochs, i.e., the time-based windows, events are equipped with monotonically increasing timestamps. The key idea of the approach is to process events within such epochs, i.e., windows in *arbitrary order*, however, *processing epochs itself in order*. Exactly once semantics can now be provided by solely performing checkpointing and recovery at *epoch boundaries* as at those points in time the system still provides a deterministic snapshot.

Evaluation and Results

For the evaluation of the approach, a canonical streaming word count application has been implemented that consists of two operators: a stateless map operator that splits lines read from a Wikipedia corpus file into individual words which are then accumulated by a stateful reduce operator. The stateful operator summarizes the word frequencies using a jumping window, i.e., an epoch where the length of the epoch is defined in terms of file position the word originated from in the source file. The performance of the epoch-based approach has been evaluated by comparing

it with an execution that does not perform any event ordering and an execution that performs a strict event ordering. In strict ordering, every single event is ordered rather than applying the weak ordering scheme based on epochs. The results of the measurements are shown in Fig. 3.

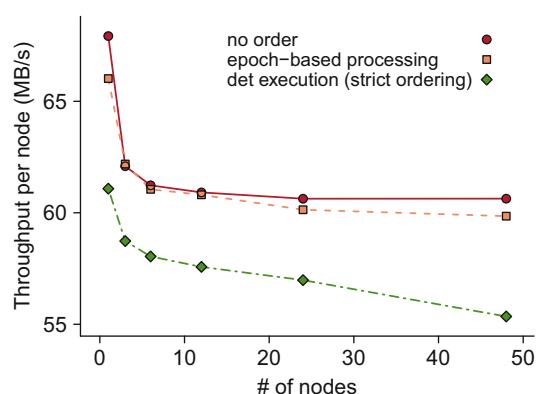

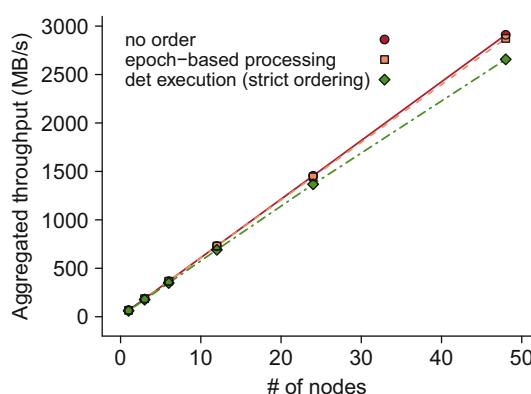

Figure 3 (left) shows the accumulated throughput for the experiment running on a 50-node cluster, while Fig. 3 (right) depicts the per node throughput. The experiments reveal that using the proposed weak ordering scheme, a similar throughput as when not applying any ordering can be achieved, however, providing precise recovery semantics as when using strict ordering, i.e., deterministic execution.

Lowering Runtime Overhead for Active Replication

In the previous section, an approach for reducing the overhead of event ordering was presented that provides *exactly once processing semantics* and *precise recovery* when used with passive replication which is traditionally based on checkpointing and in-memory event logging. In this section, an extension will be presented that can be used with active replication.

Introduction and Motivation

Active replication is a useful approach to recover applications that accumulate large portions of state as the secondary instance is holding the

StreamMine3G: Elastic and Fault Tolerant Large Scale Stream Processing, Fig. 3 Aggregated (left) and per node throughput (right) with increasing number of

nodes. The epoch-based approach significantly outperforms deterministic execution

state already in memory rather than reading it from disk during a recovery. However, in order to use active replication, a costly atomic broadcast or deterministic execution (i.e., strict event ordering) is needed in order to ensure consistent processing across all replicas. However, when using commutative and windowed operators, event ordering solely serves the purpose of maintaining consistency across replicas but does not have any impact on correctness due to the commutativity.

Approach

Inspired by the previous epoch-based processing approach, the following approach can be considered as an extension as it performs an *epoch-based deterministic merge* that ensures correctness for active replication, however, at a much lower cost than a strict event order/merge. The key idea of the approach is to merge epochs rather than individual events which is far less costly than a strict per event merge as shown in the evaluation below.

In order to perform an epoch-based deterministic merge, events arriving from different upstream channels are enqueued on a per epoch basis in separate so-called *epoch bags* first. Once an epoch completes, i.e., all channels have passed the epoch boundary, the content of the epoch bags is merged by processing the bags in the order of predefined channel identifiers. Since the channel identifiers are globally defined and events from upstream operators are delivered in FIFO order

through TCP, the final sequence of events is identical and deterministic for all replicas.

In case upstream operator replicas or sources deliver identical but differently ordered sequences of events and in order to reduce latency caused by stragglers, a *lightweight consensus protocol* can be used that selects for the available upstream replicas the set of bags to merge so that all downstream peers process the same sets of events. The protocol stops furthermore the propagation of non-determinism while decreasing latency at the same time.

Evaluation and Results

For the experimental evaluation of the approach, a canonical application operating on jumping windows was implemented that consists of three operators, a partitioned source operator, an equijoin that combines the output from the source operator, and a sink. In order to assess the performance of the approach, it was compared with an out-of-order execution, a strict ordering, the epoch-based merge, and the consensus-based protocol. The outcome of the experiments is depicted in Fig. 4.

Figure 4 (left) depicts the accumulated throughput for the experiment running on a 50-node cluster, while Fig. 4 (right) depicts the per node throughput. As shown in the figures, the epoch-based deterministic merge has a noticeable higher throughput than strict determinism (ordering), while there is only a

# of nodes	det execution (strict ordering)	no order	no order no duplicates	epoch-based processing	epoch-based det merge	epoch-based det merge + con
1	~100	~100	~100	~100	~100	~100

marginal difference for the consensus-based variant in comparison to the epoch-based deterministic merge without agreement.

Improving Resource Utilization and Availability Through Active Replication

While the objective of the previously presented approaches was to minimize the runtime overhead for fault tolerance by introducing a weak ordering scheme based on the notion of epochs, the approach presented next improves system availability by efficiently using spare but paid resources in commonly available cloud environments.

Introduction and Motivation

ESP systems are naturally highly dynamic systems as they process data often originating from live data sources such as Twitter or Facebook where the streams have highly varying data rates that may change by several orders of magnitude within relative short periods of time. In order to cope with those peak loads and to prevent the unresponsiveness of the system, the systems are usually run at conservative utilization levels often as low as 50%. Although the cloud computing model enables customers to acquire resources quite easily, migration and rebalancing mechanisms are still not fast enough to accommodate sudden load spikes forcing the service providers to run their applications at low utilization levels. However, cloud users are nevertheless charged by full hours regardless of the actual resource consumption of their virtual machines.

Approach

In order to fully utilize all available resources a virtual machine offers, a *hybrid approach* is used for fault tolerance where a transition between *active replication* and *passive standby* based on the utilization of the system is made. In order to transition between the two states, a *priority scheduler* is used that prioritizes the processing of the primary and transparently pauses secondaries once resources are exhausted. Hence, the system

transparently transitions between active replication and passive standby where the secondary is paused until sufficient resources become available again. In order to keep the secondary up-to-date during high system utilization, the state of the primary is periodically checkpointed to the memory of the secondary which allows the secondary to prune enqueued but not yet processed events from queues. Using an interleaved partitioning scheme for the placement of primary and secondaries across the cluster, the overhead imposed on nodes during system recovery can furthermore be decreased.

Evaluation and Results

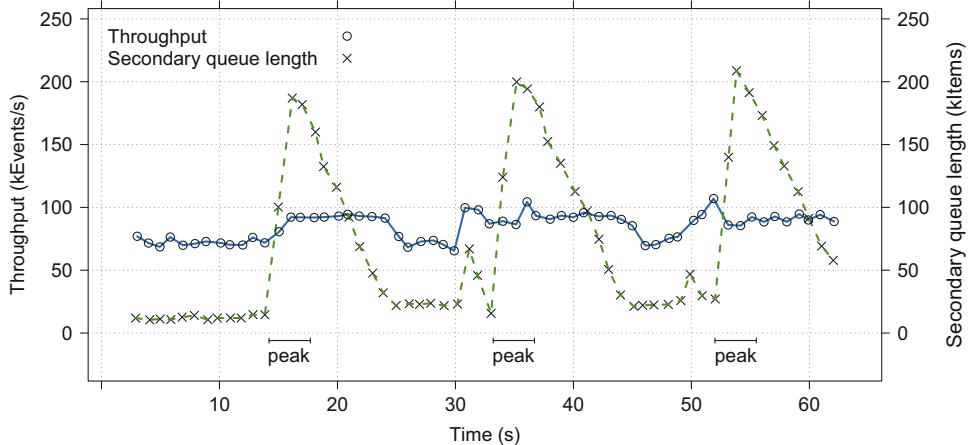

In the following experiment, the system behavior of the proposed solution has been investigated in the event of load peaks. To simulate spikes, a load generator to emit events at different rates for pre-defined periods of time was used. Figure 5 depicts the aggregated throughput for a single node and the status of the input queues of secondary slices on that node over time. In this experiment, the load generator introduced load spikes every 20 s for 2 s.

During a load peak, no events at the secondary slices on that node are being processed; hence queues grow quickly. Once the load decreases, secondaries resume the processing of events; hence, the amount of events in the queues of the secondary slices shrink. Note that the aggregated throughput of the node remains high until the shrinking process has been fully completed. During the spike, the aggregated throughput was higher due to the increase in load on the primary slices; after the spike, the throughput is higher due to the accumulated load on the secondary slices.

S

Adaptive and Low-Cost Fault Tolerance for Cloud Environments

In the previous section, an approach to utilize spare but already paid resources was presented that improves system availability by dynamically transitioning between active replication and passive standby during runtime. The following

StreamMine3G: Elastic and Fault Tolerant Large Scale Stream Processing, Fig. 5 Event throughput and queue length behavior of secondary slice queues with induced load spikes

section presents an approach that lowers the overall resource consumption by selecting the fault tolerance scheme at runtime that consumes the least amount of resources while still guaranteeing user-defined constraints such as *recovery time* and *recovery semantics*.

Introduction and Motivation

Fault tolerance in ESP systems can be carried out through various mechanism and replication schemes. For example, in *active replication*, redundant processing is used as a mechanism to carry out fault tolerance whereas in *passive replication*, a combination of periodic checkpointing and event logging is used in order to mitigate system crashes. Although active replication provides a quick recovery, it comes with a high price as it consumes almost twice of the resources, while passive replication consumes only little resources; however, it suffers from a long recovery time. Besides active and passive replication, there exist several more schemes to carry out fault tolerance such as *active and passive standby* where recovery time is traded by resource usage.

Choosing the right fault tolerance scheme is not trivial as all those schemes have different resource footprints and recovery times. Moreover, the footprint and recovery time for those schemes are not static as they strongly depend on system parameters that can greatly vary during the course

of processing. For example, the recovery time for passive replication strongly depends on the size of the checkpoint that must be read during a recovery. However, the size of a checkpoint strongly depends on the incoming data rate when considering a stateful sliding window operator.

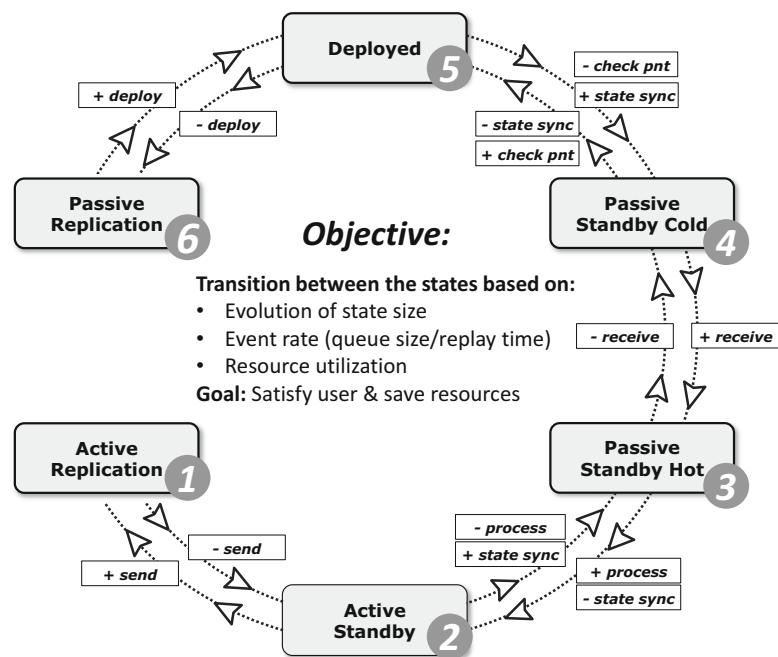

Approach

In order to free the user from the burden of choosing an appropriate fault tolerance scheme for his application, a *fault tolerance controller* that takes decisions on behalf of the user at runtime can be utilized. The controller takes into account user-provided constraints such as the desired *recovery time* and *recovery semantics*, i.e., precise or gap recovery.

Therefore, STREAMMINE3G was extended to support six different fault tolerance schemes the controller can choose from as shown in Fig. 6: ① *active replication*, ② *active standby*, ③ *passive standby hot* and ④ *cold*, ⑤ *deployed*, and ⑥ *passive replication*. The schemes have different characteristics with regard to resource consumption of CPU, memory, network bandwidth, the amount of nodes used, and recovery time. In order to choose the correct scheme, the controller uses an estimation-based approach where historically collected measurements are continuously

StreamMine3G: Elastic and Fault Tolerant Large Scale Stream Processing,

Fig. 6 Fault tolerance schemes state transition wheel: active replication, active standby, passive standby hot and cold, deployed, and passive replication

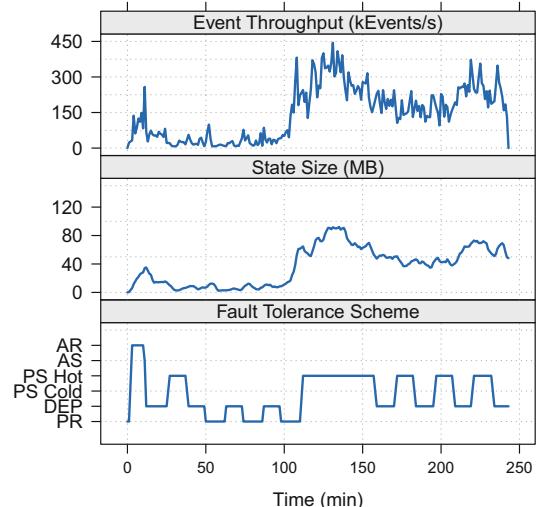

evaluated for an estimation of the expected recovery time for each of the available schemes.

Evaluation and Results

The approach has been evaluated with regard to the amount of resources that can be saved in comparison to a conservative use of full active replication. Figure 7 shows the runtime behavior of the system.

At the top graph, the throughput and how it varies over time are shown. Since the operator used for evaluation is a sliding window operator that accumulates events of the past 20 s, the size of the state follows the pattern of the throughput curve. At the bottom graphs, the chosen fault tolerance scheme is shown for each time slice. As shown in the plot, the system starts with active replication (AR), as it is the safe choice. Once enough measurements have been collected, the controller quickly switches to the deployed state replication scheme (DEP) as the state size and the throughput are quite low and, hence, recovery from disk and replay from upstream nodes can be easily accomplished within the user's specified recovery time threshold. However, as spikes occur which let the state and upstream queues

StreamMine3G: Elastic and Fault Tolerant Large Scale Stream Processing, Fig. 7 Throughput, state size, and fault tolerance scheme evolution over time using Twitter workload with a recovery threshold set to 5.5 s

grow, the controller switches between passive replication (PR) and deployed replication scheme (DEP). A cooldown time of 5 s prevents the system from oscillating due to sudden load spikes which are common in workloads originating

from live data sources such as Twitter streams. In summary, the controller chose a combination of passive replication and deployed during the first half of the experiment, whereas the second half was dominated by passive hot standby (PS Hot).

Conclusions

This chapter presented several approaches for lowering the overhead imposed by fault tolerance mechanisms in ESP systems. First, a brief overview of STREAMMINE3G was provided, the ESP system used to study and evaluate the presented approaches, followed by the first approach that allowed to reduce the overhead of event ordering required to recover applications in a precise manner and to ensure reproducibility through the use of *epochs* for *commutative* and *tumbling windowed operators* (Martin et al., 2011b). In order to apply this concept also for actively replicated operators, an extension to this approach was presented where the processing of epochs is delayed and by performing an *epoch-based deterministic merge*. In conjunction with a *lightweight consensus protocol*, latency as well as the propagation of non-determinism can be reduced and prevented, respectively.

Next, an approach to increase system availability by efficiently using spare but paid cloud resources (Martin et al., 2011a) was presented. The approach combines the two replication schemes *active replication* and *passive standby* where the system transparently switches between the two states using a *priority scheduler*. The evaluation showed that the system maintains responsiveness while still providing high availability through active replication at (almost) no cost.

As a last approach, a *fault tolerance controller* (Martin et al., 2015) was presented that selects an appropriate fault tolerance scheme on behalf of the user at runtime based on previously provided constraints such as recovery time and recovery semantics. The evaluation revealed that a considerable amount of resources can be saved

in comparison to the conservative use of active replication using this approach.

Definitions

Bloom filter (Bloom 1970): Bloom filter is a bit-vector data structure that provides a compact representation of a set of elements. It uses a group of hash functions to map each element in a data set $S = \{s_1, s_2, \dots, s_m\}$ into a bit-vector of n bits.

LSM tree (O’Neil et al. 1996): The LSM tree is a data structure designed to provide low-cost indexing for files experiencing a high rate of inserts and deletes. It cascades data over time from smaller, higher performing (but more expensive) stores to larger less performant (and less expensive) stores.

Skip list (Black 2014): Skip list is a randomized variant of an ordered linked list with additional, parallel lists. Parallel lists at higher levels skip geometrically more items. Searching begins at the highest level, to quickly get to the right part of the list, and then uses progressively lower level lists. A new item is added by randomly selecting a level, then inserting it in order in the lists for that and all lower levels. With enough levels, the time complexity of searching is $O(\log n)$.

Hash table (Cormen et al. 2009): Hash table is a dictionary in which keys are mapped to array positions by hash functions. Having the keys of more than one item map to the same position is called a collision. There are many collision resolution schemes, but they may be divided into open addressing, chaining, and keeping one special overflow area.

S

Overview

This subject is mainly toward data structures for large data sets, e.g., web pages, logs, and IoT (Internet of Things) sensing data. With the rapid development of big data applications such as web and IoT applications, people have to deal with massive data that cannot be efficiently processed and stored using traditional data structures.

This entry focuses on some typical structures that have been widely used for big data representation and organization. Differing from traditional structures such as B+-tree, the structures

discussed in this entry are specially designed for large data sets. After a brief description on the key ideas of the big-data-oriented structures, some examples of application are presented. And finally, this entry suggests a few future research directions in this field.

Key Data Structures

Large data sets introduce new challenges for the underlying structures for organizing data. First, the high velocity of big data calls for write-optimized data structures that can offer a high throughput for data insertions and deletions. Second, querying processing on large data sets costs more time, which seriously throttles read performance. Thus, most of structures for large data sets aim to improve the write and read performance on big data. However, many of them focus on finding a tradeoff between read optimization and write optimization, because many structures are not possible for optimizing both read performance and write performance. On the other hand, real applications usually exhibit an asymmetric property in read and write requests, i.e., some applications are write-intensive, while others are read-intensive. To this end, we can choose specifically optimized structures for different applications on large data sets.

In this section, we present some existing structures that are proposed for read/write optimization on large data sets.

Write-Optimized B+-tree

The B+-tree is a disk-based, paginated, dynamically updateable, balanced, and tree-like index structure (Liu and Özsü 2009). It supports point queries in $O(\log_p n)$ I/Os, where n is the number of records in the tree and p is the page capacity in number of records.

While the B+-tree provides efficient and stable performance for point queries, it has poor insertion performance. Each insertion in the B+-tree has to search from the root node to the appropriate leaf node, which costs $O(\log_p n)$ I/Os. In addition, it may incur iterated update of the B+-tree in order to keep the properties of the

tree such as balanced structure and approximately half filling-rate of each node.

Some write optimizations for the B+-tree are as follows (Bender and Kuszmaul 2013; Graefe 2004).

Insert in sequential order. The B+-tree is a couple of orders of magnitude faster at inserting data in sequential order compared to the random order. This is because once we insert a row into a leaf node, that leaf node is in memory, and since the next run of rows are destined for the same leaf, they can all be inserted cheaply.

This property of B+-tree leads many people to bend over backwards trying to keep insertions sequential. In many applications, this is not a natural or easy thing to do, and causes all sorts of problems elsewhere in the system.

Use a write buffer. This optimization stores up a bunch of insertions in a write buffer. When the buffer is full, we pick a leaf and write all the rows to the leaf.

This optimization works when we get to pick a bunch of stored rows that are going to the same leaf. When this happens, we see a speedup: you get to accomplish a bunch of work just for touching a leaf once.

The problem of this optimization is that we have to query the write buffer when answering queries, because the update-to-date rows may resist in the write buffer. However, as memory access is far fast than disk IOs, this approach can still have good read performance.

Write-optimized B+-trees received much attention in recent years, because of the popularity of the B+-tree in data management. It is a straightforward way to improve the B+-tree to meet the special needs of big data management. So far, write-optimized B+-trees are demonstrated advantageous for big data management, especially for streaming big data arriving at a high speed. The high throughput of insertion in write-optimized B+-trees makes it possible to meet the “velocity” challenge of big data.

The limitation of write-optimized B+-trees is that most of them sacrifice the read performance, which is not a good choice for read-intensive applications. As a result, it is necessary to devise

read/write-optimized B+-trees for big data management in future.

LSM-Tree

The Log-Structured Merge-Tree (or LSM-tree) (O’Neil et al. 1996) is a data structure proposed for highly inserted data, such as transactional log data. LSM-tree maintains data in two or more separate structures, each of which is optimized for its respective underlying storage medium. Data is synchronized in batches between the two structures efficiently.

One simple version of the LSM-tree is a two-level LSM-tree. A two-level LSM-tree comprises two tree-like structures, called C0 and C1. C0 is smaller and entirely resident in memory, while C1 is on disk. New records are first inserted into C0. If the insertion causes C0 to exceed a certain size threshold, a contiguous part of entries is removed from C0 and merged into C1 on disk. The LSM-tree has high update performance because movements from C0 to C1 are performed in batches, which implies that most writes to storage media are sequential writes.

Most implementations of LSM-tree used in practice employ multiple levels. Level 0 is kept in main memory and might be represented using a tree. The on-disk data is organized into sorted runs of data. Each run contains data sorted by the index key. A run can be represented on disk as a single file, or alternatively as a collection of files with nonoverlapping key ranges. To perform a query on a particular key to get its associated value, one must search in the Level 0 tree and each run.

The most significant advantage of the LSM-tree is its high performance of writing, because the writes from one level to its next level are always performed in sequential order. Thus, the LSM-tree is much suitable for big data applica-

tions with high-velocity data streams. The problem of the LSM-tree is its read performance. A read request in the LSM-tree may result in a few IOs to the levels which are maintained in disks.

Tree Structures Optimized for New Storage

Traditional structures were mainly proposed for magnetic disks. Disk IOs causing significant access latency become a bottleneck of big data storage and management. Recently, the advent of new storage such as flash memory and phase change memory introduces new opportunities for accelerating the performance of accessing big data. In this section, some typical tree structures proposed for the context of big data and new storage are described, including FD-tree, HybridB-tree, and Bloom-tree.

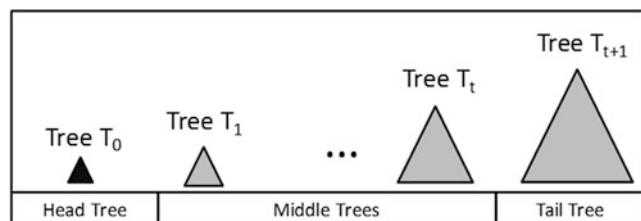

FD-Tree

The idea of FD-tree is to change random writes to an index into sequential ones (Li et al. 2010). FD-tree was originally proposed for flash memory. However, as random writes are also slower than sequential writes in hard disks, FD-tree can work on different types of storage.

FD-tree is a multi-layer tree index (as shown in Fig. 1), where the top layer is a two-level B+-tree called head tree, and each of the other layers consists of a sorted list. The updates to FD-tree are initially performed on the head tree, and then are gradually moved to the sorted lists at the lower levels. The key point of FD-tree is that each sorted list is organized as sequential pages that are contiguously stored in flash memory. Therefore, when flushing the updates to the index to flash memory, FD-tree only involves sequential writes to flash memory. As sequential writes to flash memory are more efficient than random writes, FD-tree can improve the overall

Structures for Large Data Sets, Fig. 1

Structure of the FD-tree

time performance by transforming random writes to sequential ones.

HybridB Tree

The HybridB tree (Jin et al. 2015) was designed for solid-state drives (SSD) and hard disks (HDD) based hybrid storage systems. It is an optimized structure of the B+-tree. In the HybridB tree, all the interior nodes are stored on SSD. Compared with leaf nodes, interior nodes in the HybridB tree are more possible to be read, because each read to a leaf node has to incur several reads to the interior nodes on the path from the root to the leaf node. On the other hand, all the updates, insertions, and deletions to the index are first focused on leaf nodes. Although there are possible updates to some interior nodes when updating a leaf node, these updates to interior nodes are much less than those to leaf nodes. As one major objective of the HybridB tree is to reduce random writes to SSD, it is more appropriate to put leaf nodes on HDD.

The structure of the HybridB tree is shown in Fig. 2. The leaf nodes in the tree are designed as *huge leaf* nodes (the yellow parts in Fig. 3), which are distributed among HDD and SSD. An interior node contains exactly one page, but a *huge leaf* node includes two or more pages. Each

page in a *huge leaf* node can be a *leaf-head* node, a *leaf-leaf* node, or a *leaf-log* node. The reason of introducing the *huge leaf* nodes in the HybridB tree is to reduce the splits/merges to the index, because these operations will incur many random writes to SSD.

The HybridB tree has the similar search cost with the B+-tree on SSD/HDD. However, owing to the use of the huge nodes, it has fewer random writes to SSD compared with the B+-tree on SSD/HDD. Generally, the HybridB tree can achieve better overall performance than the B+-tree, especially in a big data environment, because it can get more benefits over the B+-tree when the height of the tree increases.

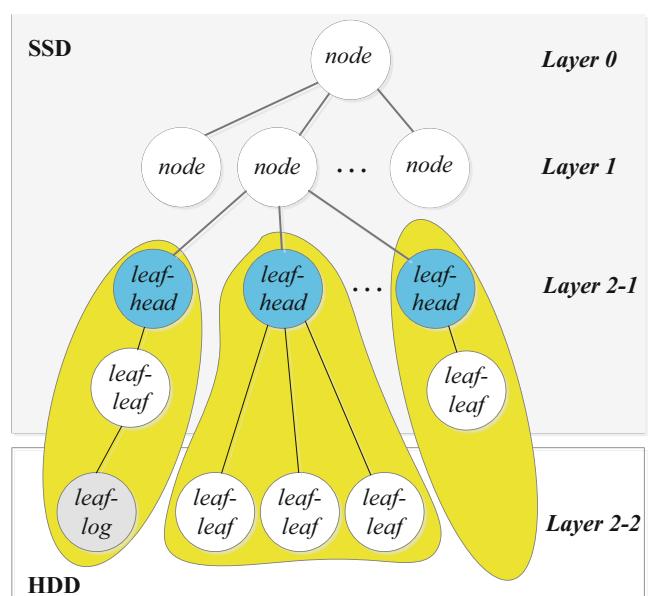

Bloom-Tree

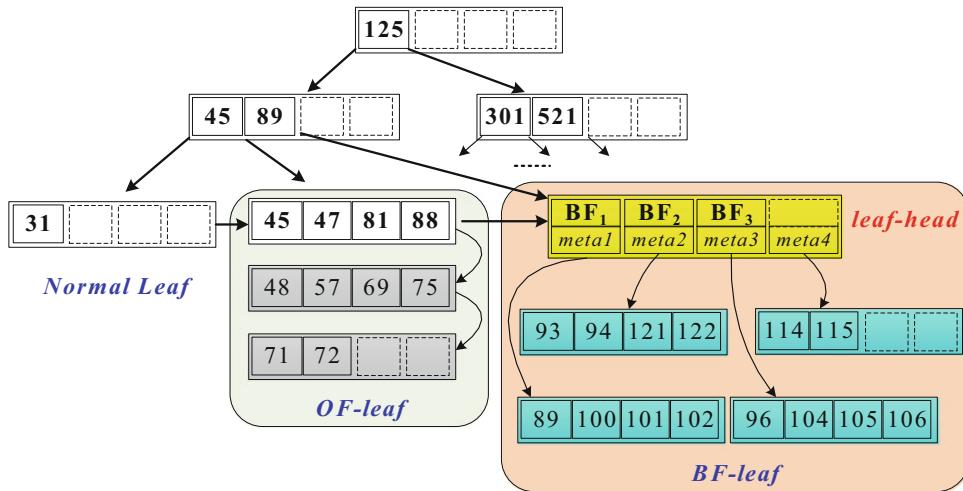

The Bloom-tree (Jin et al. 2016) is an efficient index structure proposed for large data sets on flash memory. It is a read/write-optimized tree structure of the B+-tree.

B+-tree has been demonstrated as an efficient tree index that has fast search performance on block-based storage such as hard disks. However, updates on B+-tree will incur a substantial number of page writes to disks in order to maintain its key features of balanced tree and half node-filling. As random writes are much slow on flash

Structures for Large Data Sets, Fig. 2

Structure of the HybridB tree

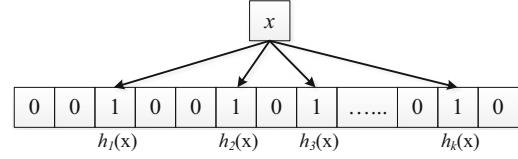

Structures for Large Data Sets, Fig. 3 Structure of the Bloom-tree

memory, many previous researches have shown that B+-tree will result in poor overall performance when directly used for flash memory (Roh et al. 2009).

In order to optimize B+-tree for flash memory, one solution is to cache the updates to the tree in a write buffer. Then, the cached updates can be merged and flushed into flash memory w.r.t. some optimal policy to reduce the overall writes on the tree index. However, even a write buffer is used for adapting B+-tree for flash memory, split operations on the tree will still lead to many page writes, as a split operation usually incurs propagating updates from a leaf node to the root of B+-tree. An intuitive way for this problem is to allow overflow pages for leaf nodes. Thus, newly inserted records can be put in overflow pages and splits will not be triggered by insertions.

So far, most flash-memory-oriented indices are designed based on the write buffer and/or the overflow page idea, aiming to reduce writes on the B+-tree. However, these solutions typically have to introduce many additional read operations. Meanwhile, modern flash disks show a close gap between their read and write speed, thus read operations on flash memory are becoming a critical factor affecting the overall time performance on flash memory. As a consequence, how to optimize flash-memory-aware indices by

Structures for Large Data Sets, Fig. 4 Element map to a Bloom filter

reducing both write and read costs is becoming an open challenge.

The Bloom-tree is able to control read costs while reducing writes to flash memory. In particular, it uses an update buffer and overflow pages to reduce random writes to flash memory and further exploits bloom filter to reduce the extra reads to the overflow nodes in the tree. With this mechanism, it constructs a read/write-optimized structure that can obtain better overall performance than previous flash-aware indices.

Figure 4 shows the structure of Bloom-tree. It improves the traditional B+-tree with two new designs. First, it introduces three kinds of leaf nodes, namely *Normal Leaf*, *Overflow Leaf (OF-leaf)*, and *Bloom-Filter Leaf (BF-leaf)*. Second, it proposes to construct bloom filters in *BF-leaf* nodes and use overflow pages in *OF-leaf* nodes.

A normal leaf node is the same as a leaf node on the traditional B+-tree, and it occupies exactly one page. An *OF-leaf* node contains overflow

pages. However, an *OF-leaf* node contains not more than three overflow pages in order to reduce read costs on *OF-leaf* nodes. If an *OF-leaf* node expands up to more than three pages, it will be transformed into a *BF-leaf* node, which can provide more efficient organization for overflow pages. A *BF-leaf* node is designed for organizing leaves with more than three overflow pages. As shown in Fig. 3, it contains several data pages and a *leaf-head* page maintaining the bloom filters and metadata about the data.

Hashing Structures for New Storage

The idea of hashing has emerged as a basic tool in data structures and algorithms. A wide range of algorithmic problems can be solved by using hash-based structures.

A hash table is a data structure that can map keys to values (Cormen et al. 2009). A hash table uses a hash function to map a set of keys to an array of buckets. By using hash tables, people can efficiently perform searching on large data sets. For example, if you need to find out in web logs the IP address with the highest access frequency to a specific website, a hash table can be used to partition all the possible IP addresses (2^{32}) into 1024 (or more) buckets. These buckets can be maintained in memory, and the IP address with the highest frequency can be easily computed.

The hash function for a hash table is expected to map each key to only one bucket. However, in many cases, the hash function may generate the same bucket number for several keys. This causes hash collisions in hash tables (Knuth 1998). There are two basic ways to resolve hash collisions. The first way is called *separate chaining*. In this method, each bucket is appended with a list of entries. If a few keys fall in the same bucket, they will be put into the list of the bucket. The separate chaining approach will introduce extra search costs for the list lookup. The second way is called *open addressing*. In this strategy, all entry keys are stored in the bucket itself. When a new key has to be inserted, the buckets are examined, starting with the hashed-to bucket and proceeding in some probe sequence, until an unoccupied bucket is found. When searching for an entry, the buckets are scanned in the same

sequence, until either the target record is found or an unused bucket is found, which indicates that there is no such key in the hash table. The name “*open addressing*” means that the address of a key is not determined by its hash value.

In recent years, there are some studies focusing on optimizing hashing structures for new storage such as flash memory. Flash memory has faster read speed than disks, but its random write speed is slower. Thus, hashing structures for flash memory mostly aim to reduce random writes to flash memory. MicroHash (Zeinalipour-Yazti et al. 2005) is an efficient external memory index structure for wireless sensor devices, which stores data on flash by time or value. MLDH (Multi Level Dynamic Hash index) (Yang et al. 2009) is a multi-layered hash index, and the capacity of each level in MLDH is twice as its upper level. Updates to MLDH are first buffered in an in-memory structure. When the memory structure is full, the memory data are merged with the hash index on flash memory and a new hash index is built. Wang et al. proposed a flash-based self-adaptive extendible hash index where each bucket occupies a block (erase unit) of flash memory (Wang and Wang 2010). A bucket consists of both data region and log region. The log region serves updates and deletes, so in-place updates to the data region can be delayed. In addition, a Split-or-Merge (SM) factor, which is dynamically adjusted according to the log/data ratio, is introduced to make the index self-adaptive. Hybrid Hash Index (Yoo et al. 2012) delays split operations which cause additional writes and erasure operations by using overflow buckets. Li et al. proposed a lazy-split hashing scheme to reduce writes at the expense of more reads (Li et al. 2008). They declared that the lazy-split hashing can adapt itself dynamically to different search ratios. Yang et al. proposed SAL-Hashing (Self-Adaptive Linear Hashing) (Yang et al. 2016) to reduce small random-writes to flash memory that are caused by index operations.

In-Memory Structures for Large Data Sets

In-memory data placement and processing has been regarded as a basic principle for ensuring fast read/write speed in big data management.

For this purpose, efficient in-memory structures are needed to be specially designed. This issue is especially important as the memory size is increasing with time. In this section, several structures proposed for in-memory data placement and accesses are discussed, including Bloom filter and Skip list.

Bloom Filter

Bloom filter is a space-efficient in-memory data structure to represent a set to which we can add elements and answer membership queries approximately (Bloom 1970). It has been extensively used as auxiliary data structures in database systems. Bloom filter is a bit-vector data structure that provides a compact representation of a set of elements. It maps each element in a data set $S = \{s_1, s_2, \dots, s_m\}$ into a bit-vector of n bits, which is denoted by $\text{BF}[1], \dots, \text{BF}[n]$ with a default value of 0. In this mapping procedure, we use a group of independent hash functions $\{h_1, h_2, \dots, h_k\}$. For a given element in S , each hash function maps it into a random number within the set of $\{1, 2, \dots, n\}$. If a hash function returns i , we set $\text{BF}[i]$ to 1. Figure 4 shows the mapping idea of Bloom filter.

For an element $x \in S$, the algorithm to compute its bloom filter includes two steps. First, it calculates the k values of hash functions $h_1(x), h_2(x), \dots, h_k(x)$. Second, it sets all bits $\text{BF}[h_i(x)]$ to 1.

For answering a membership query like “Is $y \in S?$,” the algorithm first calculates the k values of hash functions $h_1(y), h_2(y), \dots, h_k(y)$. Then, it checks all the Bloom filters of each element in S to see whether all the $\text{BF}[h_i(y)]$ in an existing Bloom filter are 1. If not, y is not a member of S . If all the $\text{BF}[h_i(y)]$ are 1, y may be within S . Due to the possible collisions of hash functions, there is a *false positive* rate when evaluating membership queries on Bloom filters. Given n, k , and m , the false positive probability of a Bloom filter can be computed by Eq. (1). Further, it is demonstrated that the false positive probability is minimalized when $k = 0.7 \cdot \frac{m}{n}$, which is approximately $0.6185^{\frac{m}{n}}$ (Bloom 1970).

$$f^{BF} = \left(1 - e^{-\frac{nk}{m}}\right)^k \quad (1)$$

Bloom filter is space efficient in representing elements. In addition, it is time efficient for inserting elements and answering membership queries. However, Bloom filter does not support deletions on elements. A revised version enhances Bloom filter with deletions (Bonomi et al. 2006).

Skip List

Skip list is a linked-list-like in-memory structure that allows fast search in memory (Pugh 1990). It consists of a base list holding the elements, together with a tower of lists maintaining a linked hierarchy of subsequences, each skipping over fewer elements.

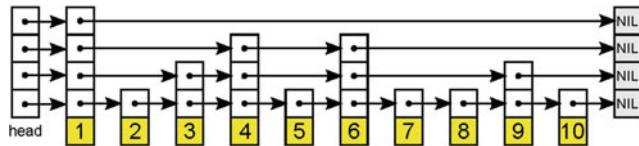

Skip list is a data structure that can be used in place of balanced trees. It uses probabilistic balancing rather than strictly enforced balancing and as a result the algorithms for insertion and deletion in skip lists are much simpler and significantly faster than equivalent algorithms for balanced trees. Skip lists are built in layers, as shown in Fig. 5. The bottom layer is an ordinary ordered linked list. At a high level, a skip list is just a sorted, singly linked list with some “shortcuts” (additional pointers that allow traveling faster. An element in layer i appears in layer $i + 1$ with some fixed probability p (two commonly used values for p are $1/2$ or $1/4$). On average, each element appears in $1/(1-p)$ lists, and the tallest element (usually a special head element at the front of the skip list) in all the lists.

A search for a target element begins at the head element in the top list and proceeds horizontally until the current element is greater than or equal to the target. If the current element is equal to the target, it has been found. If the current element is greater than the target, or the search reaches the end of the linked list, the procedure is repeated after returning to the previous element and dropping down vertically to the next lower list.

Indeed, a skip list is really just a simulation of a binary search tree using multiple linked lists running in parallel. Of course, trying to maintain a perfectly balanced binary search tree using this simulation is still expensive, and it is still complicated. However, by viewing a skip list as

Structures for Large Data Sets, Fig. 5

Structure of skip lists

a single sorted linked list, where each node has a column of links to other nodes in the list, it is easy to see how randomly choosing a height for each new column could potentially produce the same good behavior as a balanced skip list.

The original design of the skip list was as a randomized data structure, much like randomized binary search trees. By eschewing a logarithmic bound guarantee in favor of a logarithmic bound with high probability, a skip list can enjoy the performance properties of a well-balanced binary search tree (on average) while avoiding many disadvantages of tree structures.

Compared with the balanced trees, the skip list has the following advantages:

1. It is relatively easy to design and implement the algorithm. The implementation of the skip list is direct and easier than the balanced trees.
2. It is efficient. Insertion and deletion do not need to be balanced again. Indeed, the skip list serves as an alternative to the binary search trees which become unbalanced after several insertion and deletion operations.
3. The memory requirements of skip lists are less than that used for balanced trees.

In the big data scope, the skip list is commonly employed as an efficient structure for organizing memory data. For example, it has been implemented in a couple of NoSQL database engines like LevelDB, Redis, and MemSQL as the primary memory structure.

Examples of Application

In many cases, hash tables are more efficient than trees or any other table structures. For this reason, they are widely used in many kinds of computer software, particularly for associative arrays, database indexing, caches, and large sets.

Recent research by Google (Henzinger 2006; Das et al. 2007) showed that using deep learning approach can optimize hash functions by orders of magnitude in space usage savings and improve retrieval speed as well.

Hash tables may also be used as disk-based data structures and database indices. In multi-node database systems, hash tables are commonly used to distribute rows among nodes, reducing network traffic for hash joins (Karger et al. 1997).

Hashing is also commonly used in information retrieval. One early application in this field is identifying near-duplicate web pages in Altavista using min-wise hashing (Broder et al. 1998). Another application is HyperANF (Boldi et al. 2011), which was used to compute the distance distribution of the Facebook social network. In the field of machine learning, random mappings of data to lower-dimensional vectors that are easier to handle is of increasing importance for big data applications. This is because that machine learning algorithms often work with kernelized feature vectors with high dimensions. Designing randomized mappings that meet the criteria of machine learning applications has been an active research area in recent years (Wang et al. 2016).

A key application of Bloom filters is in the field of content delivery networks, which deploys web caches around the world to cache and serve web content to users with greater performance and reliability. Bloom filters are used to efficiently determine which web objects to store in web caches (Maggs and Sitarasan 2015). To prevent caching one-hit-wonders (accessed by users only once and never again), a Bloom filter is used to keep track of all URLs that are accessed by users. A web object is cached only when it has been accessed at least once before. With this mechanism, one can significantly reduce the disk write workload, since one-hit-wonders are never written to the disk cache. Further, filtering out the

one-hit-wonders also saves cache space on disk, increasing the cache hit rates.

Bloom filters can also be organized as distributed data structures to perform fully decentralized computations of aggregate functions (Pournaras et al. 2013). Decentralized aggregation makes collective measurements locally available in every node of a distributed network without involving a centralized computational entity for this purpose.

The LSM-tree is now used in many database products such as Bigtable, HBase, LevelDB, MongoDB, SQLite, RocksDB, WiredTiger, Apache Cassandra, and InfluxDB. The LSM-tree is especially suitable for write-intensive workloads. Certainly, LSM implementations such as LevelDB and Cassandra regularly provide better write performance than single-tree based approaches. Yahoo! developed a system called PNUTS, which combines the LSM-tree with the B-trees and demonstrates better performance (Cooper et al. 2008).

It is also worth considering the hardware being used. Some expensive solid state disks, like FusionIO, have better random write performance. This suits update-in-place approaches. Cheaper SSDs are better suited to the LSM-tree, because it can avoid small random writes to SSDs.

Skip list has been implemented in many systems such as LevelDB, MemSQL, and Redis. Specially, Redis adds a backward pointer for each skip list node to traverse reversely. Also there is a span variable in level entry to record how many nodes must be crossed when reaching to next node. Actually, when traverse list, we can accumulate span to get the rank of a node in sorted set. In LevelDB, skip lists are used to organize the MemTable in memory. In MemSQL, skip lists are used as the prime indexing structure for databases.

Future Directions for Research

Data structures are one of the most critical parts for big data representation, processing, and storage. In addition to the structures explained

in this article, there are some future research directions in this field.

Firstly, the existing tree structures like LSM-tree and HybridB-Tree are mainly toward write-intensive workloads. Although it is a major objective to reduce random writes to new storage such as flash memory, it is valuable to devise read/write-friendly structures in the future.

Secondly, traditional database researches suppose that data are stored in external disks. However, big data applications call for in-memory data processing and storage. Thus, how to make data structures suit for in-memory data management is an important issue in the big data era.

Finally, recently nonvolatile memory (NVM) has received much attention from both academia and industries (Li et al. 2016; Chen et al. 2014). This will lead to reformation of memory architecture. Therefore, developing NVM-oriented structures is a potential research direction in the future.

Acknowledgments

We would like to thank University of Science and Technology of China for providing the environment where the study described in this entry was completed. The work involved in this entry is partially supported by the National Science Foundation of China (No. 61672479).

System Under Test

Francois Raab
InfoSizing, Manitou Springs, CO, USA

Synonyms

Measured system; SUT; Target environment; Test object; Tested environment

Definitions

A System Under Test (SUT) is a complete system that comprises hardware, software, and connectivity components; that is the object or target of a performance measurement test or benchmark.

Historical Background

While the term System Under Test is somewhat generic in nature, it was formalized in the early 1990s by industry consortiums with the mission of defining industry standard performance benchmarks, such as the Transaction Processing Performance Council (TPC – www.tpc.org), the Standard Performance Evaluation Corporation (SPEC – www.spec.org), and the Storage Performance Council (SPC – www.storageperformance.org).

Foundations

The purpose of a test or benchmark is to determine how a target environment behaves under a controlled load or in response to specific requests. As such, the definition of the System Under Test plays a key role in a benchmark specification. The SUT's definition discusses the inclusion or exclusion of hardware, software, and connectivity components. It also defines the measurement boundaries. For benchmarks that mandate some pricing metrics, the SUT defines which components must be included in this pricing.

Hardware Components

The definition of the SUT includes a number of hardware components. These components can be specific or generic. Specific components can be chosen to define a fixed set of hardware on which to measure different software variations. By keeping the hardware as a constant while varying the software, the outcome of the test can be fully attributed to changes in the software environment. Alternatively, the hardware components can be defined in generic terms, giving some latitude in their selection. This latitude can be limited to some portion of the SUT or can be applied to all hardware components in the SUT. For example, the SUT's definition may require the configuration of a single server node with specific attached storage and a specific number of processor sockets, while giving latitude in the choice of processor types. Such a SUT definition would focus the results of the test of the

processor's capabilities. Alternatively, the SUT's definition may give full latitude in the selection of the server's internal architecture, system topology (single-node, cluster, client–server, etc.), and storage subsystem; giving the test an opportunity to compare widely diverging solutions to a common workload requirement, or analyzing non-hardware criteria, such as price, value (price/performance), scalability, or portability.

Software Components

The definition of the SUT generally includes a number of software components or a software stack. Few tests solely focused on a hardware component (e.g., a simple storage device) and do not require any software as part of the SUT. But, in most cases, one or more software components are needed to assemble the SUT. There is a degree to the role that software can play in the SUT. Software can be part of the SUT to simply tie together the hardware components targeted by the test. In the case of system testing, software components are just as important as hardware components for the tested system, literally a System Under Test. And for tests that directly target software, rather than hardware, the software components are the object of the test and the hardware components merely provide a platform for the software to execute.

Connectivity Components

The definition of the SUT may include a number of connectivity components. These are used to allow the hardware components to communicate. Such connectivity might be in the form of a general-purpose network (e.g., Ethernet over Fibre Channel) or in the form of a proprietary interconnect (e.g., AMD's HyperTransport bus). Many test environments use some connectivity components to provide a communication channel between the SUT and the test harness. These communication channels may or may not be included as part of the SUT. One criteria to include such communication channel in the SUT is whether they are also used for communication between other components inside the SUT.

Measurement Boundary

The boundary between a test driver (also called measurement harness) and the target of the measurement (i.e., the SUT) is the point where the driver applies a stimulus to the SUT and where the driver measures the SUT's response to that stimulus. This measurement boundary is also where the test driver ends and the SUT starts. In some cases, the measurement boundary is virtual in that the driver uses resources from components that are part of the SUT. In other cases, the boundary is physical in that no components, other than a communication channel, are shared between the driver and the SUT.

Pricing Metrics

When benchmarks results are used for competitive analysis, it may be relevant to include some pricing metrics. The purpose of such metrics is to provide information about the cost associated with the performance capabilities of the SUT. These metrics are generally expressed in terms of straight total price, in terms of ratio between total price and measured performance, or both. For example, the TPC-A metrics include the total cost of ownership of the SUT and the associated cost per unit of performance, expressed in cost/tps (transaction per second). The definition of the SUT is a key to defining which components are included in these cost calculations.

Key Applications

First Formal Use

The first formal use of the term SUT was found as part of the initial release of TPC Benchmark A (TPC-A) (Huppler 2009), published by the TPC in 1990. This online transaction processing (OLTP) benchmark provided an industry-sanctioned specification of the loosely defined and widely used DebitCredit (Anon 1985) workload. The TPC-A specification defined the term SUT as including the following components:

- *One or more processing units (e.g., hosts, front-ends, and workstations.), which will run the transactions [. . .].*

- *The hardware and software components of all networks required to connect and support the SUT components.*
- *Data storage media sufficient to satisfy both the scaling rules [...] and the ACID properties [...].*
- *The host system(s) including hardware and software supporting the database employed in the benchmark.*

Generic Terminology

Following in the footsteps of TPC-A, subsequent benchmark specifications released by industry standard consortia have been using the term SUT, or one of its synonyms, to identify the performance measurement target specific to each benchmark. The term SUT, by itself, does not describe the tested environment. Instead, the term is used as a container to encapsulate the set of hardware, software, and connectivity components that are being targeted for measurement. As such, each benchmark specification includes its own formal definition of the term SUT.

In some instances, the term used to name the target environment of a test is synonymous with System Under Test. For example, SPEC does not consistently use the term SUT in its benchmark specifications. However, the consortium uses the term SUT to name the set of configuration components that can be chosen as filters for queries against its database of benchmark publications.

Benchmark Adoption and Longevity

The SUT's definition is a key factor in a benchmark's adoption and longevity. According to (Huppler 2009), all “good” benchmarks share the same primary characteristics of being *relevant, repeatable, fair, verifiable, and economical*. A careful definition of the SUT will contribute to improving each one of these characteristics.

- Relevant: The SUT's primary components are those for which test results are in demand.
- Repeatable: The SUT's definition has tight requirements for components that impact the test results, and gives flexibility for components that are result neutral.
- Fair: Components of the SUT are limited to those that can be compared on an even playing field.
- Verifiable: The availability of the components used and their configuration is such that others can easily recreate the SUT to repeat the test.
- Economical: The cost of assembling the SUT does not create a prohibitive limit on who can reasonably execute the test.

Big data necessitates the use of very large memories that can bring about other uses of such units, say, for storing precomputed values of functions of interest, to improve speed and energy efficiency.

Overview

Until the 1970s, when compact and affordable digital scientific calculators became available, we relied on pre-calculated tables of important

functions that were published in book form (e.g., Zwilfinger 2011). For example, base-10 logarithm of values in [1, 10], at increments of 0.01, might have been given in a 900-entry table, allowing direct readout of values if low precision was acceptable or use of linear interpolation to obtain greater precision. To compute $\log 35.419$, say, one would note that it is $1 + \log 3.5419 = 1 + \log 3.54 + \varepsilon$, where $\log 3.54$ is read out from the said table and ε is derived based on the small residual 0.0019 using some sort of approximation or interpolation. Once everyone became equipped with a sophisticated calculator and, later, with a personal computer, the use of tables fell out of favor. Table-based computation returned in at least two different forms in the 1990s. One was to speed up normal, circuit-based computations by providing an initial estimate that would then be refined. The other was to reduce complexity and power consumption.

Implications of High Volume for Big Data

Studies at IBM and Cisco Systems show that as of 2012, we generated 2.5 exabytes of data per day (Cisco Systems 2017; Jacobson 2013) [1 exabyte = 1 quintillion or 10^{18} bytes = 1 gigagigabyte], and this is set to explode to 40 yottabytes per day [1 yottabyte = 1 septillion or 10^{24} bytes = 1 teraterabyte] by 2020. Multiply the latter number by 365 and then by the number of years, and the extent of data becomes even

more mind-boggling. Organizing, managing, and updating such large volumes of data will be quite challenging.

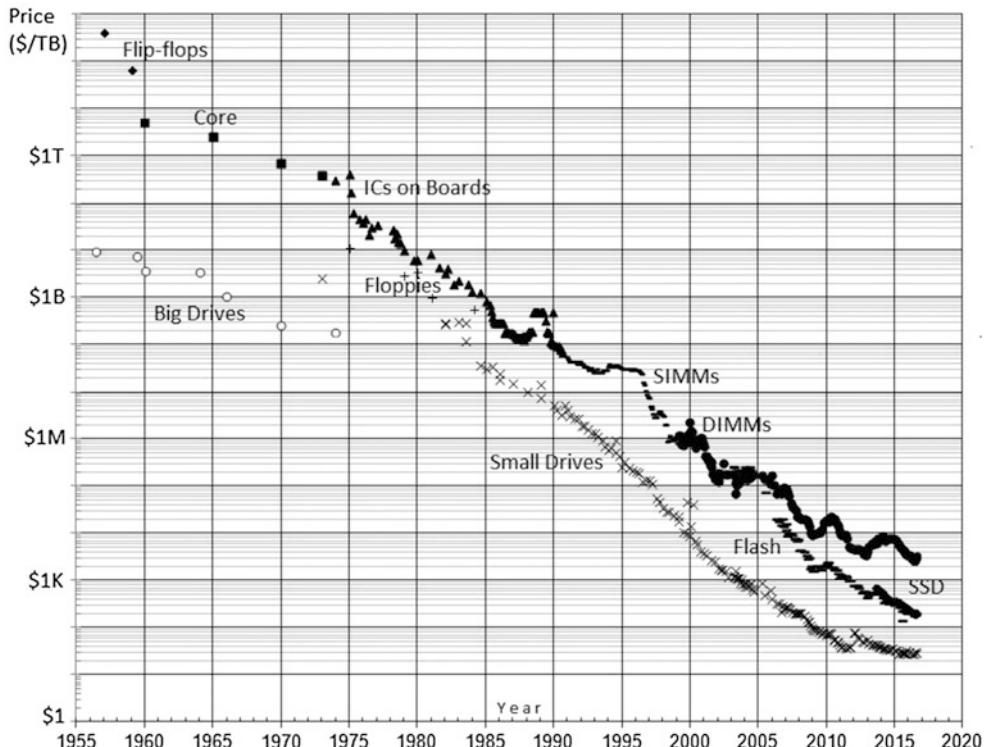

A direct consequence of high data volume is high computational load, as confirmed by a simple back-of-the-envelope calculation. Processing 1 petabyte of data, at around 100 clock cycles or instructions per byte, means a processing time of 10^{17} clock cycles. With an optimistic clock rate of 10 GHz (10^{10}), we will need a processing time of 10^7 s (~ 4 months). This is already impractically long, and it becomes even more so for data volumes much larger than a petabyte. It follows that replacing many cycles of computation with a single table lookup will offer immense performance benefits.

Simultaneously with the exponential growth of data production rate (Chen and Zhang 2014; Hilbert and Gomez 2011), we have been experiencing an exponential reduction in the cost of computer memory and storage, as depicted in

Fig. 1 (McCallum 2017). The reduced cost of memory and storage, combined with more advanced data compression schemes (Storer 1988), renders big-data applications feasible while also enabling new categories of applications, which would not even be contemplated in the absence of inexpensive storage. One such area is increased reliance on large-scale tables for performing or facilitating computation.

Why Table-Based Computation?

Function evaluation methods are studied in the field of computer arithmetic (Parhami 2010), dealing with algorithms and hardware designs for performing computations within arithmetic/logic units found as components of CPUs in general-purpose computer architectures (Parhami 2005), as well as within more specialized computational structures, such as graphic processing units or GPUs (Owens et al. 2008).

Tabular Computation, Fig. 1 Exponentially declining cost of computer memory and storage (McCallum 2017)

Computing any function requires time and other resources, such as energy. If a particular function value, say, $f(a)$, is needed many times in the course of different computations or the same computation performed on different inputs, it makes sense to store the computed value and use it any time $f(a)$ is needed, without having to recompute. Storage can be accomplished via conventional tables that are accessed by operand values used as index into the table or may entail some form of cache structure (Smith 1982) that is consulted before triggering the requisite calculations in the event of a cache miss (Gabbay and Mendelson 1998).

One way to reduce the required table size is to subject the operands to some preprocessing or to allow some post-processing of the value(s) read out from the table(s). This kind of indirect table lookup provides a range of trade-offs between pure table lookup and pure computational or circuit-based approach. For example, the two-operand multiplication operation $p(a, b) = ab$ can be performed via two accesses to a smaller squaring table, using the formula $ab = [(a + b)^2 - (a - b)^2]/4$, whose use entails two additions in the preprocessing phase and one addition along with a 2-bit right shift in the post-processing stage. Additional optimizations can be applied to this method (Vinnakota 1995).

Reading a stored value requires less energy than recomputing it, and reading may also be faster, particularly for a computationally complex function. Because table size grows exponentially with the number of bits in the input operand(s), the scheme is particularly efficient for low-precision data, although continual increase in size and reduction in cost of memory is expanding the method's applicability.

Low-precision computation, as embodied in the rapidly expanding field of approximate computing (Mittal 2016), is an increasingly important part of the workload in modern computing. One advantage of table-based approximate computing is that the exact error for each table entry is knowable, whereas in a circuit-based approach, often a bound on the error is the best we can provide.

Lookup Table Implementation Options

The conceptually simplest method for implementing a lookup table is to allocate 2^u words, each v bits wide, if there are u input operand(s) bits and the result is to be v bits wide. The table can then be filled with precomputed function values, essentially resulting in an electronic version of the mathematical tables of yore found in pages of handbooks.

This is rarely practical or efficient. One optimization is to allocate space for all table entries but only fill them when the values become needed for the first time. In this way, the table will act as a sort of cache memory which will generate a “miss” upon first access to a particular entry. When a miss is encountered, the requisite computation is performed to derive the value, which is then forwarded to both the computation that led to the miss and to the corresponding table entry for possible future use.

A second optimization is to look for simple transformations in the input operands that can be performed efficiently in terms of time and energy while leading to substantial savings in table size. If a two-operand function is symmetric, for example, the table size can be cut in half by determining which operand is larger and ordering the operands. Such optimizations are function-dependent and provide a wide range of trade-offs between computation time and lookup table size.

A third optimization is to divide the domain of interest into a number of subranges and implement a separate lookup scheme for each subrange. For subranges where the function variations are less pronounced, smaller tables will do, whereas subranges with significant variations necessitate larger lookup tables. Related to this last optimization is segmenting the domain of interest in a nonuniform manner, using a special mechanism to map input values into corresponding subranges and thus associated lookup tables (Lee et al. 2003).

An attractive alternative to parallel-access tables, with original or transformed operand bits presented in parallel to form an index into the

table, is a combination of bit-serial computation with table lookup. The scheme, known as distributed arithmetic (White 1989), allows certain computations to be implemented through table lookup, despite the large number of input values involved. The speed of distributed arithmetic can be respectable and the implementation cost modest if the computation is pipelined at a high clock rate. It is also possible to do intermediate schemes where the computation is not fully serial, but nibble- or byte-serial.

Table-based methods can be implemented in a variety of ways and new schemes continue to emerge in light of ongoing research. To keep our discussion manageable, we focus on the basics of two general methods, the interpolating memory scheme and multipartite table method, in the following two sections. More details on these methods, including additional references, as well as other pure and hybrid methods can be found in books, periodicals, and conferences on computer arithmetic (e.g., Parhami 2010).

Interpolating Memory

One can combine the lookup process for reading out approximate function values with the interpolation scheme needed for greater precision into a single-hardware unit, dubbed interpolating memory (Noetzel 1989).

Consider the computation of $f(a)$, where the parameter a falls between x_i and x_{i+1} , two consecutive lookup table indices, that is, $x_i < a < x_{i+1}$. Then, using linear interpolation, the value of $f(a)$ can be approximated as

$$f(a) = f(x_i) + (a - x_i) \times f'(x_i)$$

where $f'(x_i)$ is the derivative or slope of the function at x_i . More generally, the values $A_i = f(x_i)$ and $B_i = f'(x_i)$, or a value that better approximates intermediate values between $f(x_i)$ and $f(x_{i+1})$, are stored, with a post-processing circuit computing $f(a) = A_i + (a - x_i) \times B_i$.

Practically, x_i corresponds to several leading bits of a and $a - x_i$ is represented by the remaining

bits of a . This scheme simplifies the implementation and reduces its complexity. Let a_u be defined by a few upper bits of a , and let a_r be the value represented by the remaining bits of a , so that a_u and a_r collectively span all the bits of a . Then, $f(a) = f(a_u) + s(a_u) \times a_r$.

One can increase the computational precision by using second- or third-degree interpolation, which, for the same precision, would need smaller tables (Noetzel 1989) but requires more external circuitry, providing a spectrum of implementation options. For example, with second-degree interpolation, we have $f(a) = f(a_u) + s(a_u) \times a_r + t(a_u) \times a_r^2$. With the latter formula, a squarer and two multipliers are needed for highest-speed implementation. Alternatively, one can use a single multiplier to perform the operation $a_r \times a_r$, and the other two multiplications sequentially. If the function must be evaluated for several different x values, the computation can be pipelined, so that the maximum processing rate is achieved while using only a single multiplier and one adder.

Bipartite and Multipartite Tables

Interpolating memory, discussed in the preceding section, requires the use of a multiplier to achieve the greater precision afforded by linear interpolation. Multiplication is time-, cost-, and energy-intensive compared with addition, so table lookup schemes that avoid multiplication would be desirable if they offer adequate precision using only addition as pre- and post-processing operations. Schemes in this category are known as multiplier-less methods (e.g., Gustafsson and Johanson 2006).

Bipartite tables (Das Sarma and Matula 1995) offer one such scheme. Consider a k -bit operand divided into a few of its most-significant bits, x_u , a few middle bits, x_m , and the rest of the bits x_r , collectively spanning the entire width of the operand x . We can approximate $f(x)$ as the sum $g(x_u, x_m) + h(x_u, x_r)$. Essentially, the decomposition into x_u , x_m , and x_r creates intervals corresponding to different values of x_u

and subintervals corresponding to different values of x_m . Function values are stored for each subinterval in the table $g(x_u, x_m)$. The ingenuity of the method is that instead of storing slopes for the various subintervals, as in interpolating memory, a common slope for each interval is stored, allowing the multiplication of the slope $s(x_u)$ and the displacement x_r to be performed by the second lookup table which yields the value $h(x_u, x_r)$. Selection of the number of bits in x_u and x_m offers various tradeoffs in precision and table size, allowing the designer to choose an optimal scheme, given application requirements.

The basic ideas discussed above have been extended and refined in a variety of ways. Bipartite tables can be optimized by taking advantage of symmetry (Schulte and Stine 1999; Stine and Schulte 1999). Extension to tripartite (Muller 1999) and multipartite tables (De Dinechin and Tisserand 2005; Kornerup and Matula 2005) has also been attempted.

Iterative Refinement Methods

Table lookup can be used in conjunction with iterative refinement methods to obtain results of higher precision that are impossible or cost-ineffective to derive via pure table lookup. The iterative refinement process essentially replaces an interpolation scheme that would be much more complex, if the same precision were to be achieved. We present just one example, but there are many more.

Consider finding the square root of z , starting with an initial approximation $x(0)$. The following iterative scheme yields an approximation $x(j+1)$ with maximum error 2^{-2k} from a previous approximation $x(j)$ with maximum error 2^{-k} :

$$x(j+1) = \frac{1}{2}(x(j) + z/x(j))$$

The scheme's quadratic convergence ensures that a small number of iterations will suffice. For example, if an initial table entry provides the square root of z with 16 bits of precision, one iteration produces a 32-bit result and two iterations will yield a 64-bit result. The method just discussed has many variations and alternatives,

including versions that are division-free (Cray Research 1989), given that division is a slower and more complicated operation compared with multiplication.

Future Directions

After decades of being restricted to low-precision arithmetic, table lookup is emerging as a feasible method of attack to higher-precision computation, aided by the lower cost and higher density of memory devices as well as improved algorithms for reducing the required table size via advanced pre- and post-processing schemes.

In addition to general techniques discussed in the preceding sections, a large number of special algorithms and associated tweaks can be used to make implementations more efficient or better-suited to specific application domains. Methods such as multilevel table lookup (Parhami 1997); bit-level, application-specific optimization of lookup tables (Parhami and Hung 1994); and accurate error analysis (Tang 1991), accompanied by further reduction in memory cost and increase in memory density, will enable an expansion of application domains that lend themselves to table lookup processing. Advances in lookup table size and performance may also lead to the adoption of logarithmic number representation (Chugh and Parhami 2013) in lieu of the currently prevalent floating-point representation, which would lead to additional side benefits.

TARDiS: A Branch-and-Merge Approach to Weak Consistency

Natacha Crooks

The University of Texas at Austin, Austin, TX, USA

Synonyms

[Causal consistency](#); [Distributed systems](#); [Eventual consistency](#)

Definitions

This article targets applications that adopt weaker consistency in large-scale distributed systems in favor of higher availability and better performance.

Overview

In light of the conflicting goals of low latency, high availability, and partition tolerance (Brewer 2000; Gilbert and Lynch 2002), many wide-area services and applications choose to renounce strong consistency in favor of eventual (Vogels 2008) or causal consistency (Ahamad et al. 1994); COPS (Lloyd et al. 2011), Dynamo (DeCandia et al. 2007), Riak (Basho 2017), and Voldemort (2012) are among the many services (Lloyd et al. 2011) that provide a form of weak consistency to applications. Applications that make this decision are often referred to as ALPS applications (**a**vailability, **l**ow **latency**, **p**artition **t**olerance, and **h**igh **s**calability). Distributed ALPS applications, however, are hard to reason about: eventual consistency provides no guarantee on the ordering of operations when these are replicated to other sites. Causal consistency (Ahamad et al. 1994; Lloyd et al. 2011) attempts to mitigate this programming complexity: unlike eventual consistency, causal consistency preserves operation ordering and gives Alice assurance that Bob, whom she has defriended before posting her Spring-break photos, will not be able to access her pictures, even though Alice and Bob access the photo-sharing application using different replicas (Bailis et al. 2012; Cooper et al. 2008; Lloyd et al. 2011).

Nonetheless, programming on top of causal consistency remains complex: causal consistency allows geographically distinct replicas to issue conflicting operations, and the read-write and write-write conflicts that can ultimately result from these operations may cause replicas' states to diverge. To insulate applications from this complexity, systems like COPS (Lloyd et al.

2011) or Dynamo (DeCandia et al. 2007) attempt to preserve the familiar abstraction that an application evolves sequentially through a linear sequence of updates: they aggressively enforce per-object convergence, either through simple deterministic resolution policies or by asking the application to resolve the state of objects with conflicting updates as soon as conflicts arise. These techniques, however, provide no support for meaningfully resolving conflicts between concurrent sequences of updates that involve *multiple* objects: in fact, they often destroy information that could have helped the application in resolving those conflicts. For example, as described further in section “[The Pain Point of Conflicting Write Operations](#)”, deterministic writer-wins (Thomas 1979), a common technique to achieve convergence, hides write-skew from applications, preventing applications from even detecting the anomaly, let alone resolve it. Similarly, exposing multivalued objects without context as in Dynamo (DeCandia et al. 2007) obscures cross-object semantic dependencies.

The rest of this article describes a concrete example of an anomaly that current approaches to merging cannot detect or repair (section “[The Pain Point of Conflicting Write Operations](#)”). It then sketches the design of TARDiS (**t**ransactional **a**synchronously **r**eplicated **d**ivergent **s**tore), a data store explicitly designed for weakly consistent systems that allows for simpler and better merging, through exposing the state of the system as a set of, possibly conflicting, *branches* (section “[A Solution: TARDiS](#)”).

T

Key Research Findings

[The Pain Point of Conflicting Write Operations](#)

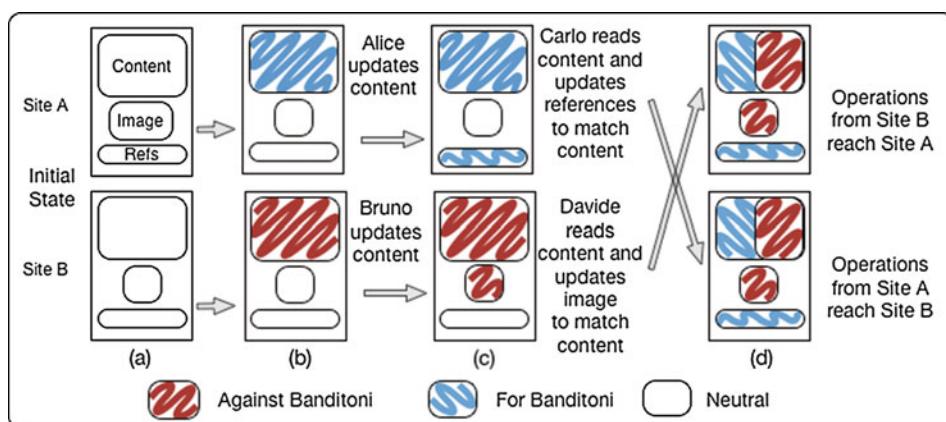

In the classic example used to illustrate the virtues of causal consistency, Alice gains assurance that Bob, whom she had defriended before posting her Spring-break photos, will not be able to access her pictures, even though Alice and Bob access the photo-sharing application using different sites (Bailis et al.

2012; Cooper et al. 2008; Lloyd et al. 2011). ALPS applications, however, face another class of anomalies – write-write conflicts – that causal consistency cannot prevent, detect, or repair.

To illustrate, consider the process of updating a Wikipedia page consisting of multiple HTML objects (Fig. 1a). The page in this example, about a controversial politician, Mr. Banditoni, is frequently modified and is thus replicated on two sites, A and B. Assume, for simplicity, that the page consists of just three objects – the content, references, and an image. Alice and Bruno, who, respectively, strongly support and strongly oppose Mr. Banditoni, concurrently modify the content section of the web page on sites A and B to match their political views (Fig. 1b). Carlo reads the content section on site A, which now favors Mr. Banditoni, and updates the reference section accordingly by adding links to articles that praise the politician. Similarly, Davide reads the update made by Bruno on site B and chooses to strengthen the case made by the content section by updating the image to a derogatory picture of Mr. Banditoni (Fig. 1c). Eventually, the operations reach the other site and, although nothing in the preceding sequence of events violates causal consistency, produce the inconsistent state shown in Fig. 1d: a content section that exhibits a write-write conflict, a reference section in favor of Mr. Banditoni, and an image that is against him.

Worse, there is no straightforward way for the application to detect the full extent of the inconsistency: unlike the explicit conflict in the content sections, the discrepancy between image and references is purely semantic and would not trigger an automatic resolution procedure. This scenario presents an open challenge to current causally consistent systems. These systems struggle to handle such write-write conflicts for two reasons: they choose to syntactically resolve conflicts and do not consider cross-object semantics.

Syntactic conflict resolution. The majority of weakly consistent systems use fixed, syntactic conflict resolution policies to reconcile write-write conflicts (Lloyd et al. 2011; Apache 2017) to maintain the abstraction of sequential storage. Returning to the previous example of the popular merging policy of deterministic writer-wins (DWW): DWW resolves write-write conflicts identically at all sites and ensures that applications never see conflicting writes, which guarantees eventual convergence. In the Wikipedia example, however, guaranteeing eventual convergence would not be sufficient to restore consistency: this policy would choose Bruno's update and ignore the relationship between the content, references, and images of the web page. Such greedy attempt at syntactic conflict resolution is not only inadequate to bridge this semantic gap but in fact can also lose valuable

TARDiS: A Branch-and-Merge Approach to Weak Consistency, Fig. 1 Weakly consistent Wikipedia scenario – a web page replicated on two sites with asyn-

chronous replications. The end state is a write-write conflict on the content and an inconsistent web page

information for reconciliation (here, Alice’s update).

Lack of cross-object semantics. Some systems, like Dynamo (DeCandia et al. 2007) or Bayou (Terry et al 1995), allow for more expressive conflict resolution policies by pushing conflict resolution to the application (DeCandia et al. 2007; Terry et al 1995) but on a per-object basis only. This approach allows for more flexible policies than a purely syntactic solution but reduces conflict resolution to the merging of explicitly conflicting writes. As a result, it is often still overly narrow. For example, it would not detect or resolve inconsistencies that are not write-write conflicts but instead result indirectly from conflicts between two writes, such as the one between the references and the image. Per-object reconciliation policies fail to consider that the effects of a write-write conflict on an object do not end with that object: Carlo and Davide update references and images as they do because they have *read* the conflicting updates to the original content section. Indeed, any operation that depends on one of two conflicting updates is potentially incompatible with all the operations that depend on the other: the shockwaves from even a single write-write conflict may spread to affect the state of the entire database.

There is currently no straightforward way for applications to resolve consistently the kind of multi-object, indirect conflicts that this example illustrates. Transactions (Lloyd et al. 2011, 2013), an obvious candidate, are powerless when the objects that directly or indirectly reflect a write-write conflict are updated, as in the Wikipedia example, by different users. After Bruno’s update, the application has no way to know that Davide’s update is forthcoming: it must therefore commit Bruno’s transaction, forcing Bruno’s and Davide’s updates into separate transactions. Nor would it help to change the granularity of the object that defines the write-write conflict – in the example, by making that object be the entire page. It would be easy to correspondingly scale up the example, using distinct pages that link each other. Short of treating the entire database as the “object,” it is futile to try to define away

these inconsistencies by redrawing the objects’ semantic boundaries.

In essence, conflicting operations fork the entire state of the system, creating distinct *branches*, each tracking the linear evolution of the data store according to a separate thread of execution or site. The Wikipedia, for example, consists of two branches, one in support of Banditoni at site A and one against the politician (site B).

A Solution: TARDiS

As suggested in section “[The Pain Point of Conflicting Write Operations](#)”, conflicting operations fork the entire state of the system, creating distinct *branches*. These branches have traditionally been hidden or greedily merged by systems’ syntactic and per-object resolution strategies, that try, at all cost, to maintain the abstraction of a sequential view of the world. The lack of support for enforcing the cross-object consistency demands expressed in many application invariants thus makes conflict resolution more difficult and error-prone, as the Wikipedia example highlights.

Attempting to isolate applications from the reality of conflicting write operations is therefore, we believe, a well-intentioned fallacy. Conflicting writes “contaminate” data in a way that the storage system cannot understand: application logic is often indispensable to resolve those conflicts. Replicas, however, only see a sequence of read/write operations and are unaware of the application logic and invariants that relate these operations. The storage system should avoid deterministic quick fixes and instead give applications the information they need to decide what is best. The question becomes: how can one provide applications with the best possible system support when merging conflicting states?

TARDiS (Crooks et al. 2016) attempts to provide an answer to this question. TARDiS is an asynchronously replicated, multi-master key-value store designed for applications built above weakly consistent systems. TARDiS renounces the one-size-fits-all abstraction of sequential storage and instead exposes applications, when appropriate, to concurrency and distribution. TARDiS’ design is predicated on a simple notion:

to help developers resolve the anomalies that arise in such applications, each replica should faithfully store the full context necessary to understand how the anomalies arose in the first place but only expose that context to applications when needed. By default in TARDiS, applications execute on a branch and hence perceive storage as sequential. But when anomalies arise, TARDiS reveals to the users the intricate details of distribution. TARDiS hence gives applications the flexibility of deciding if, when, and how divergent branches should be merged.

TARDiS provides two novel features that simplify reconciliation. First, it exposes applications to the resulting independent branches and to the states at which the branches are created (fork points) and merged (merge points). Second, it supports atomic merging of conflicting branches and lets applications choose when and how to reconcile them. Branches, together with their fork and merge points, naturally encapsulate the information necessary for semantically meaningful merging: they make it easy to identify all the objects to be considered during merging and pinpoint when and how the conflict developed. This context can reduce the complexity and improve the efficiency of automated merging procedures, as well as help system administrators when user involvement is required. Returning to the Wikipedia example, a Wikipedia moderator presented with the two conflicting branches would be able to reconstruct the events that led to them and handle the conflicting sources according to Wikipedia’s guidelines (Wikipedia 2017). Note that merging need not simply involve deleting one branch. Indeed, branching and merging states enables merging strategies with richer semantics than aborts or rollbacks (Sovran et al. 2011). It is TARDiS’s richer interface that gives applications access to content that is essential to reasoning about concurrent updates, reducing the complexity of programming weakly consistent applications. In many ways, TARDiS is similar to Git (2017): users operate on their own branch and explicitly request (when convenient) to see concurrent modifications, using the history recorded by the underlying branching storage to help them resolve conflicts.

Unlike Git, however, branching in TARDiS does not rely on specific user commands but occurs implicitly, to preserve availability in the presence of conflicts. Two core principles underpin TARDiS: branch-on-conflict and inter-branch isolation. Branch-on-conflict lets TARDiS logically fork its state whenever it detects conflicting operations and store the conflicting branches explicitly. Inter-branch isolation guarantees that the storage will appear as sequential to any thread of execution that extends a branch, keeping application logic simple. The challenge is then to develop a data store that can keep track of independent execution branches, record fork and merge points, facilitate reasoning about branches, and, as appropriate, atomically merge them – while keeping performance and resource overheads comparable to those of weakly consistent systems.

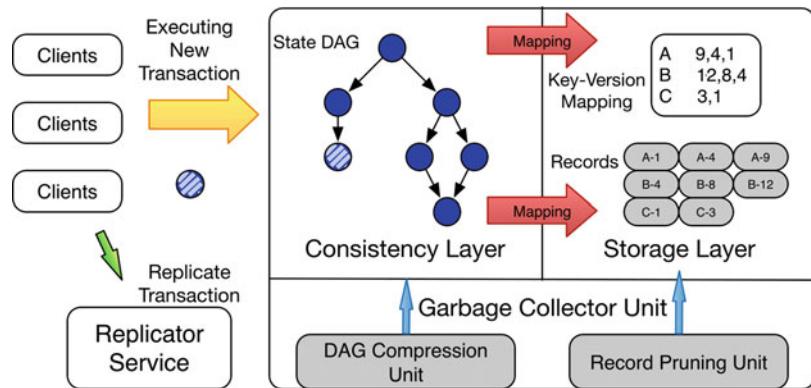

TARDiS uses multi-master asynchronous replication: transactions first execute locally at a specific site and are then asynchronously propagated to all other replicas Fig. 2. Each TARDiS site is divided into two components – a *consistency layer* and a *storage layer*:

- *Consistency layer.* The consistency layer records all branches generated during an execution with the help of a directed acyclic graph, the *state DAG*. Each vertex in the graph corresponds to a logical state of the data store; each transaction that updates a record generates a new state.
- *Storage Layer.* The storage layer stores records in a disk-based B-tree. TARDiS is a multiversioned system: every update operation creates a new record version.

Much of TARDiS logic is geared toward efficiently mapping the consistency layer to the storage layer and maintaining low metadata overhead. Two techniques are central to the system’s design – *DAG compression* and *conflict tracking*:

- *DAG compression.* TARDiS tracks the minimal information needed to support branch

TARDiS: A Branch-and-Merge Approach to Weak Consistency, Fig. 2
TARDiS architecture

merges under finite storage. It relies on a core observation: most merging policies only require the fork points and the leaf states of a given execution. All intermediate states can be safely removed from the state DAG, along with the corresponding records in the storage layer.

- *Conflict tracking.* To efficiently construct and maintain branches, TARDiS introduces the notion of conflict tracking. TARDiS summarizes branches as a set of fork points and merge points only (a *fork path*) and relies on a new technique, *fork point checking* to determine whether two states belong to the same branch. Fork paths capture *conflicts* rather than dependencies. As such, they remain of small size (conflicts represent a small percentage of the total number of operations) and allow TARDiS to track concurrent branches efficiently while limiting memory overhead. This is in contrast to the traditional dependency checking approach (Du et al. 2014; Lloyd et al. 2011; Mahajan et al. 2011), which quickly becomes a bottleneck in causally consistent systems (Bailis et al. 2012; Du et al. 2014).

This article does not attempt to further discuss the details of these techniques and defer the reader to the corresponding SIGMOD paper (Crooks et al. 2016). Generally though, the system is promising: using TARDiS, for instance, rather than BerkeleyDB (Olson et al. 1999) to implement CRDTs (Shapiro et al. 2011) – a

library of scalable, weakly consistent datatypes – cuts code size by half and improves performance by four to eight times.

Future Directions for Research

Branches are a useful abstraction for reasoning about weakly consistent systems and implementing such systems. Can they be useful in other settings? Strongly consistent geo-distributed systems face many of the same challenges of weakly consistent systems. Concurrent conflicting writes at different replicas, for instance, still arise in strongly consistent systems, though they are hidden from the application. Can the cost of synchronizing across replicas on every write operation be mitigated by using branches? Moreover, many consistency definitions like causal consistency, snapshot isolation (Berenson et al. 1995), or parallel snapshot isolation (Sovran et al. 2011) allow, implicitly, for a small degree of branching (the ability to read from a stale state can be viewed as a limited form of branching). Can we simplify the formulation of these guarantees by using branches?

Tools and Libraries for Big Data Analysis

Shadi Khalifa

Queen's University, Kingston, Canada

Overview

With almost everything now online, organizations look at the Big Data collected to gain insights for improving their services. The Big Data analysis pipeline consists of a number of processes requiring different tools. The Big Data analysis pipeline processes can be summarized as follows:

- *Data Exploration*: analysts go through the data, using ad hoc queries and visualizations, to better understand the data.
- *Data Engineering*: analysts clean, prepare, and transform the data for modeling using batch processing to run computational and input/output (IO) intensive operations.
- *Modeling/Scoring*: data models are trained, using iterative processing, on the prepared data, and trained models are used to score the unlabeled data.

For each Big Data analysis process, using the right tool(s) can significantly reduce the processing time and would generate better insights. Some of the still-useful tools are those inherited from the pre-Big Data era, where data could fit in a single node memory. These tools provide a huge set of algorithms, but they do not scale to meet the Big Data requirements.

To handle Big Data, tool developers went into two separate ways. Some developed new scalable tools designed to handle Big Data. Others went after making pre-Big Data era tools parallel, distributed, and scalable to handle Big Data and benefit from what these tools have to offer.

In this chapter, the most popular Big Data analysis tools and libraries are presented, and their limitations are highlighted. However, not all tools are covered in this chapter due to space limitations. Interested readers can check our survey paper (Khalifa et al. 2016) for a more comprehensive list of tools and libraries.

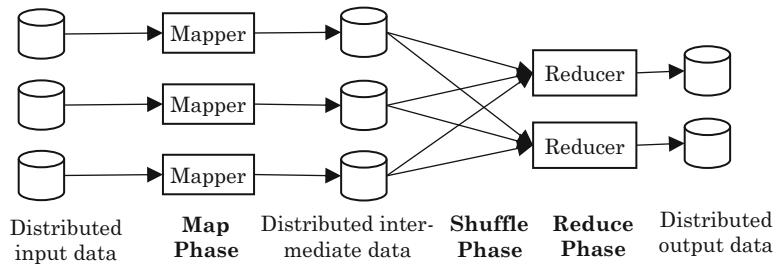

The Big Data Era Tools

To solve the scalability problem, *Google* introduced the *MapReduce* (Dean and Ghemawat 2004) platform to manage and process large heterogeneous datasets. Following that, *Yahoo!* developed *Hadoop* (White 2009), an open-source implementation of MapReduce and later incubated by *Apache*, allowing everyone to benefit from it. *Apache* also incubated the *Spark* (Zaharia et al. 2010) project for in-memory computations, which is now the main rival to *Hadoop*.

MapReduce, as presented in Fig. 1, consists of *Map*, *Shuffle*, and *Reduce* phases, which are executed sequentially, utilizing all nodes in the cluster. In the *Map* phase, the programmer-provided *Map* function (*Mapper*) processes the input data and outputs intermediate data in the form of $\langle key, value \rangle$ tuples which get stored on disk. The *Shuffle* phase then groups values to the same key together and sends them to the reduce nodes over the network. Finally, the programmer-provided *Reduce* function (*Reducer*) reads the intermediate data from disk, processes it, and generates the final output. The *Map/Reduce* functions are executed in parallel over a set of distributed data files in a single program multiple data (SPMD) paradigm.

Apache Spark follows the *MapReduce* paradigm except that it runs with one *reducer*, which can be a bottleneck. *Spark* uses read-only Resilient Distributed Datasets (RDDs) to

    SELECT <t.rowid>, <m.label>, <m.score>
    FROM <testing_dataset_table> t LEFT OUTER JOIN
        <model name> m ON (<<t.feature>> = <<m.feature>>)) ;
```

Tools and Libraries for Big Data Analysis, Fig. 3 Prediction using Hivemall

provide in-memory support for iterative jobs. RDDs can also reconstruct themselves in case of failure to provide fault tolerance without disk checkpointing. *Spark*, however, is restricted to the size of available memory and has to reconstruct the RDDs from disk if it runs out of memory. *Spark* does not run *Hadoop* jobs; however, they can coexist on the same cluster using *Apache Mesos* (Hindman et al. 2011).

A number of libraries have been developed to provide a scalable distributed implementation of the analytics algorithms, so that analysts do not have to write the MapReduce procedures themselves. *Apache Mahout* is a scalable distributed machine learning library, where the machine learning algorithms are implemented as a sequence of MapReduce jobs with an outside driver program to control loop execution. *Apache Pig* uses the *Pig Latin* language (Olston et al. 2008) to abstract coding MapReduce analytics jobs without using the Java MapReduce idioms. *Apache Hive* (Thusoo et al. 2009) uses *HiveQL*, an SQL-like query language, to create MapReduce batch jobs. *Hivemall* (Yui and Kojima 2013)

extends *HiveQL* with a scalable machine learning library. Thus, machine learning models can be trained (Fig. 2) and scored (Fig. 3) from within the *HiveQL* SQL-like statements. The *HiveQL* queries are then translated to MapReduce batch jobs for execution.

For *Spark*, *Spark SQL* (previously known as *Shark*) (Xin et al. 2013) allows using SQL statements to query structured data inside Spark programs. *MLBase* (Talwalkara et al. 2012) uses the *Mlib* (Sparks et al. 2013) library to provide distributed machine learning at scale on *Spark*. *Cloudera Oryx* forks from *Apache Mahout* to run on *Spark*. *Oxdata H2O* provides in-memory machine learning and predictive analytics using *Spark*. *Deeplearning4j* provides deep learning algorithms implementation on *Hadoop* and *Spark*.

The introduced libraries provide an easy-to-use scalable distributed implementation of the analytics algorithms; they require none to minimum MapReduce knowledge and are optimized for parallel processing.

MapReduce is a popular batch processing approach because of its scalability, fault tolerance,

ease to program, and flexibility. However, batch processing is designed to execute one or more jobs without manual intervention. This makes it perfect for scenarios where a program needs to have a single run on a huge dataset. However, not all Big Data analysis tasks can be efficiently executed on MapReduce.

Stream Analytics Tools

Unlike MapReduce that is designed to analyze data at rest, stream analysis tools analyze data in motion where the utility of data points declines quickly. Some use cases are analyzing monitoring logs, sensor network feeds, and high-volume news feeds like twitter. Stream Analytics can be in the form of *stream processing* or *micro-batch processing*.

Stream processing provides low latency as data is analyzed as soon as it arrives. However, it is technically challenging to support certain types of analytics like time series analysis since the analysis runs on the records as they arrive and not wait for the complete transaction.

Apache Storm is a distributed streaming solution that can be used with any programming language and can scale to massive numbers of messages per node per second. After the analyst designs the analysis pipeline, *Storm* uses a pull model where the receiving nodes pull the data when they can process it.

Apache Samza is another open-source distributed stream processing framework. It comes as part of *Hadoop2.0 (YARN)* and uses *Apache Kafka* publish/subscribe messaging system to guarantee that data is processed in the order it arrives and that no data is ever lost.

Google has the *MillWheel* (Akidau et al. 2013) in-house system that allows analysts to create stream graphs and define the application code for each graph node, while it handles the continuous data flow, data persistence, and failure recovery.

IBM InfoSphere Streams is a component of the *IBM* analytics solution. It supports analyzing data continuously at high rates using real-time machine learning. *InfoSphere Streams* supports runtime modifications, where input streams, output streams, and operations can be added or removed dynamically without restarting the system. It also

allows embedding user-defined Java and C++ analytics routines.

Micro-batch processing presents a middle ground between streams and batch processing. It has higher latency than streams as it buffers the input and only processes it when the buffer is full. However, micro-batching is less technically challenging as it allows the use of existing batch algorithms.

Using this approach is *Yahoo! Nova* (Olston et al. 2011) which allows analysts to create workflows of *Pig* programs to process continually arriving data. Also, *Spark Streaming* extends *Spark* to allow joining stream data with historical data using the same *Spark* code written for batch processing.

Visual Analytics Tools

With Big Data, analysts can drown in the excessive volumes of data. This can lead to analyzing the wrong or incomplete set of attributes or becoming frustrated with the whole analytics process. Visualization solutions are designed for business analysts to allow them to have an interactive conversation with their data.

IBM Watson Analytics (Rais-Ghasem et al. 2013) allows analysts to go from data to analysis in seconds without any setup or configuration. It allows analysts to use visualization and natural language to understand their data. It relies on *IBM SPSS Analytics Server* and *IBM Big Insights* to automatically build and use data models. On the down side, *Watson Analytics* requires data to be pre-cleaned outside the *Watson* framework. It does not output an analytic model to use for further analysis, and it does not specify how the analysis outputs were achieved making it hard to trust the outputs.

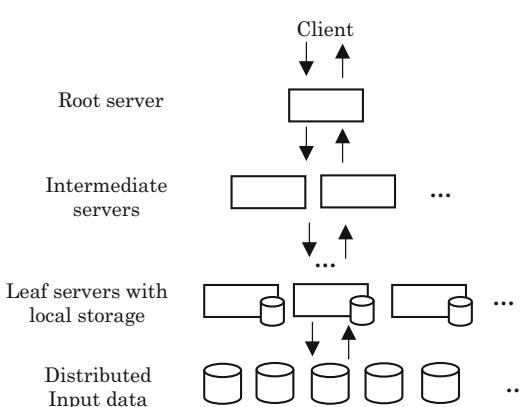

SAS Visual Analytics powered by the *SAS Analytics framework* is designed to empower business analysts with limited technical skills to do analytics using *Hadoop* without any programming. In addition to data exploration, analysts can do sophisticated analytics like forecasting using a drag-and-drop approach.

MicroStrategy and *Tableau* allow analysts to access data from multiple sources (spreadsheets, databases, or distributed filesystems) and present them in interactive visualizations for analysis. The analytics capabilities of those solutions are limited as they do not implement machine learning techniques. Their power comes from their availability on mobile devices and allowing analysts to share visualizations.

Exploratory Analytics Tools

The frequent writing to disk and the extensive communication between nodes in the MapReduce shuffle phase to support fault tolerance hinder efficient support for interactive tasks required in the data exploration phase. Some solutions are proposed to support interactive exploratory analytics.

Google Dremel (Melnik et al. 2010) (aka *Google BigQuery*) leverages massive parallel processing, nested data modeling, and columnar storage to improve retrieval efficiency for interactive analytics scenarios. *Dremel* is a *Google* proprietary solution that executes its query in parallel without being translated to a sequence of MapReduce jobs. *Dremel* uses multilevel tree processing (Fig. 4). Leaf servers only scan the needed columns in parallel. Intermediate servers carry out parallel aggregation on the scanned data. Finally, the root server aggregates the intermediate results.

Tools and Libraries for Big Data Analysis, Fig. 4
Dremel query execution flow

However, with columnar storage the number of columns accessed affects performance. *Google* has introduced *PowerDrill* (Hall et al. 2012) to have data in-memory for faster computations. However, this makes it constrained to the available memory.

Dremio, *Apache Drill*, and *Cloudera Impala* offer open-source implementations of *Google Dremel*. They support querying and joining data of different formats from different sources. These solutions support dynamic schema discovery, where users can define the schema (column name, data type, length) in the query or let the tools discover the schema from the metadata for self-describing data formats like JSON, thus, no need for the Extract-Transform-Load operations for consolidating data from multiple silos. They also provide a JDBC/ODBC interface to connect to Business Intelligence and visualization tools. On the downside, they adopt an optimistic execution model and do not persist intermediate data, making them fault-intolerant.

In the data exploration phases, there are a lot of trial and error of different operations. Processing the entire dataset every time can be very time consuming with Big Data. To speed up this process, a set of tools were developed to provide a quick retrieval of approximate results to help analysts decide if an operation is useful or not.

The *Early Accurate Result Library (EARL)* (Laptev et al. 2012) extends *Hadoop* to allow early termination and incremental computation, along with providing an online indicator to estimate the achieved accuracy so far. *EARL* provides early approximate results by iterating over data samples and aggregating the results until an acceptable accuracy is reached.

BlinkDB (Agrawal et al. 2013) extends *Hive* to provide fast approximate results with statistical error guarantees. *BlinkDB* uses a dynamic sample selection strategy to select an appropriately sized sample based on the desired query accuracy or response time. *BlinkDB* maintains a set of precomputed and carefully chosen data samples, so that when a query arrives, it can be directly executed on the appropriate sample. Samples in *BlinkDB* are chosen using an optimization formula that considers the data distribution, past queries, stor-

age constraints, and several other system-related factors.

Pre-Big Data Era Tools

The pre-Big Data era tools are thesis still-useful tools inherited from the pre-Big Data era, where data could fit in a single node memory. These tools provide a huge set of algorithms, but they do not scale to meet the Big Data requirements. With the growing popularity of *MapReduce*, the pre-Big Data era tools started adding support for *MapReduce* to enhance their scalability.

For a lot of people, doing analysis means using *Microsoft Excel*. Thus, *Microsoft* extended *Excel* with *Excel Analytics (Power Query, Data Analysis Expressions (DAX) Language, Data Mining add-in)*, where analysts can use the *Power Query* Sheet GUI to fetch and merge data from different sources and do data preparation and transformation. The *DAX* language keeps track of all executed steps to support undos, and the *Data Mining add-in* sends the prepared data to the SQL server for modeling. *Power Query* is limited to a maximum of 1,000,000 records per dataset. For that, *Microsoft* offers *Microsoft Tabular*, a server-based solution for *in-database* analytics on structured data. *Microsoft* also offers *Daytona* (Barga et al. 2012) to offload *Excel*'s operations to *MapReduce* on the cloud for distributed processing.

Google OpenRefine is a browser-based, spreadsheet-style tool designed for data exploration and preparation but does not support data modeling. Unlike *Excel's Power Query*, *OpenRefine* supports interactivity and can handle any number of records by only showing a data sample to analysts. However, *OpenRefine* still runs on a single machine and is thus limited to the machine's memory and computational resources.

IBM Cognos provides a simple GUI for manipulating data in the form of spreadsheets and data cubes. As with previous solutions, *Cognos* runs on a single machine, making it limited to small and medium datasets. For that, *IBM* offers the *BigInsights BigSheets* which is a browser-based, spreadsheet-style tool in the *IBM InfoS-*

phere BigInsights solution that enables business analysts to explore, manipulate, and analyze Big Data using the underlying *Hadoop* layer for distributed processing.

IBM also offers the *SPSS Modeler* which supports a wide range of advanced algorithms and techniques for text analytics, decision management, predication, and optimization. The *SPSS Modeler* provides a drag-and-drop interface for the analytics operations where almost no programming is required. While the *SPSS Modeler* runs on a single machine, the *IBM Analytic Server* extends it to run scalable distributed analytics on *Hadoop*.

A yet another very popular drag-and-drop solution is *RapidMiner*. It supports sub-workflows, wizards, and quick fixes extensively, making complex workflows easier to design and interpret. *Radoop* (Prekopsak et al. 2011) extends *RapidMiner* to run on *Hive*, *MLib*, and *Mahout* to support Big Data analysis. Also, the *streams library* plug-in (Bockermann and Blom 2012) adds stream analytics capabilities to *RapidMiner*. It provides generic streaming wrappers of the *RapidMiner* operations to make them run on partially available data and feed them the rest as it arrives.

For programming savvies, there are a number of popular analytics programming languages and application programming interfaces (APIs). There is *R* made by and for statisticians and *Weka* made for data miners. While these tools provide a large set of algorithms, they only run on a single machine, making them unsuitable to use with Big Data. *RHadoop* extends *R* and allows running *R* code on *Hadoop*. *DistributedWekaHadoop* and *DistributedWekaSpark* (Koliopoulos et al. 2015) packages extend *Weka* to access *Hadoop* and *Spark*, respectively.

Recently, *Python* has become one of the most widely used languages for analytics. A large number of analytics libraries have been developed for *Python*, like *scikit-learn* and *TensorFlow*. This creates a single environment, where analysts can do both, general-purpose programming and analytics. Following the same trend, *Microsoft* offers *F#*, a cross-platform functional language. *F#* provides libraries for fetching data

from different sources and allows analysts to use the .NET machine learning libraries to do analytics with simple code. Programmers, however, need to write their own MapReduce functions to execute their code in parallel.

Future Big Data Analysis Tools

There has been a continuous improvement in analysis tools to address different analytics scenarios; however, there are still some gaps. In this section, we highlight some principles for future Big Data analysis tools to consider. Following these principles would improve the tools and allow them to broader support different analytics scenarios.

1. *Extensibility.* Tools can become obsolete if they are designed to only support a fixed number of data stores and analytics techniques. It is thus crucial for future tools to have a plug-in architecture to support adding new algorithms and data stores with minimal modifications to the core code.
2. *Distributed processing.* To handle Big Data, future tools need to seamlessly distribute the processing among many nodes with minimum to no user involvement.
3. *Approximate processing.* While designing the analytics process, users are not usually sure of which operation to use and how it is going to affect the results. This makes them try different operations, which can be time consuming if they run on the whole dataset. Thus, future tools need to provide quick retrieval of approximate results from a small representative sample to give users an indication of an operation's results without running it on the entire dataset.
4. *Execution and storage optimization.* Having the data distributed among cloud nodes requires optimizing the analytics execution to utilize the shared resources while minimizing data movement. Future tools need to predict what data will be needed by future operations and make sure that this data is available on the underutilized nodes for the future operations.

They also need to provide an abstraction layer to hide the heterogeneity of the data stores so that users can seamlessly join data from multiple sources with minimum data movement.

5. *Fault tolerance.* Big Data analysis can run for long periods. Having to restart from the beginning in case of failure is not acceptable. Future tools need to support fault tolerance while minimizing its impact on performance. Fault tolerance can be in the form of *validation* that includes checking input compatibility to operations and that computational and storage resources are available prior to execution. It can also be in the form of *masking operation failure* by trying to re-execute it, executing it on an alternate resource, using checkpoints to save processed data, executing an alternate implementation, executing multiple redundant copies, and executing user-defined exception handling methods.
6. *Intelligent assistance.* With the huge set of available analytics techniques, even experts sometimes need help. Intelligent assistance can aid users in choosing and configuring the analytics operations based on the input dataset and the analysis goals. Assistance can range from recommending operations to generating full analytics workflows. Providing intelligent assistance in future tools is important for analytics to be more accessible, to minimize the time-to-insights, and to enhance the quality of analytics.
7. *Multiple user interfaces.* For future tools, a combination of user interfaces should be provided to meet the needs of users of different skillsets. They should provide the flexibility and the extensibility of the programming languages, the ease of use of drag-and-drop interfaces, the ad hoc capabilities of the SQLs, and the familiar environment of the spreadsheets.

Performance Consortia; Transaction Processing Performance Council

Definitions

A nonprofit corporation founded to define transaction processing and database benchmarks and

to disseminate objective, verifiable TPC performance data to the industry.

Historical Background

Originally formed in 1988, the Transaction Processing Performance Council (TPC) is a non-profit corporation focused on defining database processing benchmarks and disseminating objective, verifiable performance data to the IT industry. The TPC was originally founded in response to a growing trend at the time, known as “benchmarketing.” Effectively, this was a common practice of vendors publishing unverifiable claims based on their own price and performance data in order to present their systems in the best possible way to improve the market’s perception of their product.

“Benchmarketing” effectively enabled vendors to exaggerate performance and even reliability claims in order to boost sales. The need for a vendor-neutral standards organization that focused on creating and administering fair and comprehensive benchmark specifications to objectively evaluate database systems under demanding but consistent and comparable workloads quickly became apparent. Several influential database academics and industry leaders began working to establish an organization charged with leading the effort to impose order and consistency to the process of benchmarking products fairly and objectively – this effort ultimately culminated in the formation of the TPC.

Foundations

The TPC has a long history in benchmarks. Figure 1 shows the current TPC benchmark timeline. Its benchmarks are used by hardware and software providers for internal and external purposes. Internally, they are used during product development to measure the performance of existing and planned products. Externally, they are used to provide reliable, verifiable, comparable, and relevant performance data to

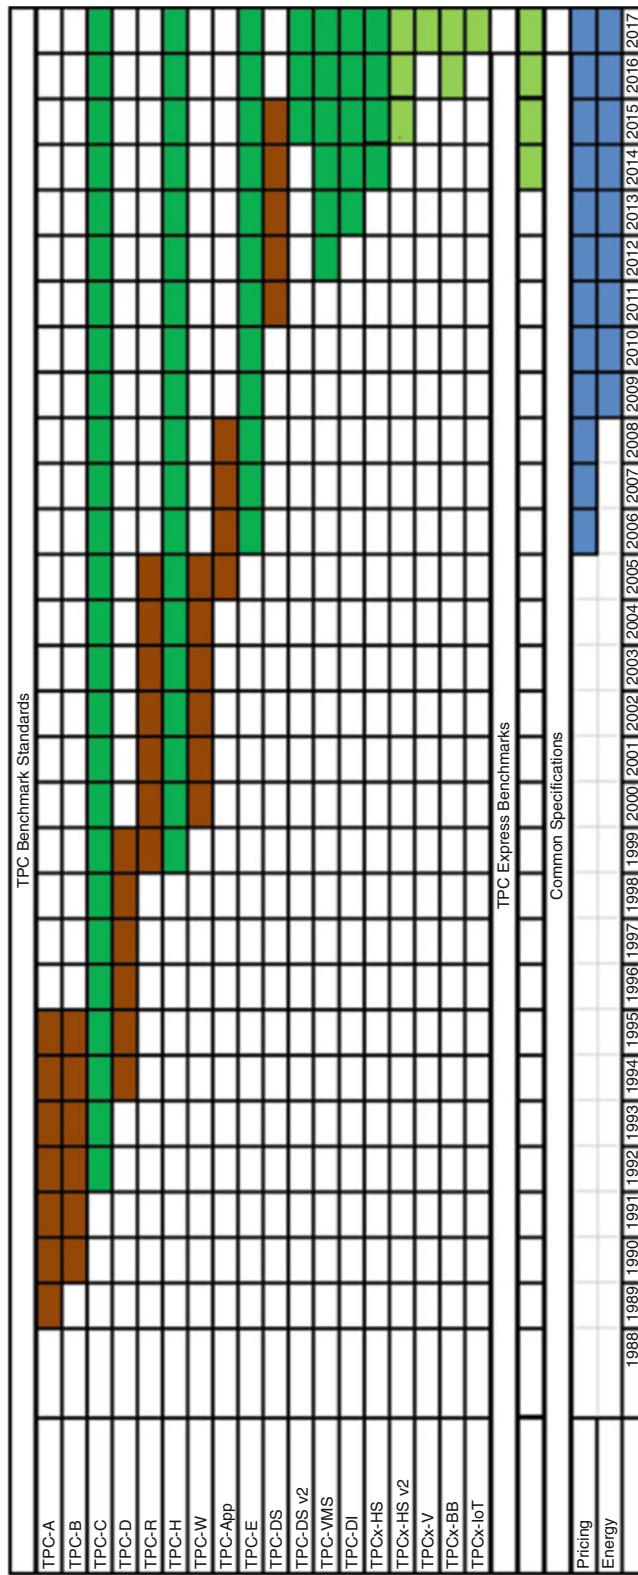

advertise their products. Customers use TPC performance data to make purchase decisions.

To date the TPC has approved a total of 18 benchmark standards and 2 common specifications to measure energy and guarantee fair pricing for benchmarked systems. Of the 18 benchmark standards, TPC-E [19, 21], TPC-C [17], TPC-H (Nambiar and Poess 2006), TPC-DS (Poess et al. 2002; Poess et al. 2007; Nambiar and Poess 2006; Poess et al. 2017), TPC-DI (Poess. et al. 2014), TPC-VMS, TPCx-V, TPCx-BB, TPCx-HCI, and TPCx-IoT (Poess et al. 2018) are currently active standards.

Benchmark History

TPC-C and TPC-E are online transaction processing (OLTP) benchmarks. **TPC-C** simulates a complete computing environment where a population of users executes transactions against a database. The benchmark is centered around the principal activities (transactions) of an order-entry environment. These transactions include entering and delivering orders, recording payments, checking the status of orders, and monitoring the level of stock at the warehouses. While the benchmark portrays the activity of a wholesale supplier, TPC-C is not limited to the activity of any particular business segment but, rather, represents any industry that must manage, sell, or distribute a product or service. TPC-C involves a mix of five concurrent transactions of different types and complexity either executed online or queued for deferred execution. It does so by exercising a breadth of system components associated with such environments, which are characterized by:

- The simultaneous execution of multiple transaction types that span a breadth of complexity
- Online and deferred transaction execution modes
- Multiple online terminal sessions
- Moderate system and application execution time
- Significant disk input/output

TPC, Fig. 1 Current TPC benchmarks

- Transaction integrity (ACID properties)
- Nonuniform distribution of data access through primary and secondary keys
- Databases consisting of many tables with a wide variety of sizes, attributes, and relationships
- Contention on data access and update

TPC-C performance is measured in new-order transactions per minute. The primary metrics are the transaction rate (tpmC), the associated price per transaction (\$/tpmC), and the availability date of the priced configuration.

TPC-E is an enterprise-class online transaction processing (OLTP) benchmark. It is more complex than previous OLTP benchmarks such as TPC-C because of its diverse transaction types, more complex database, and overall execution structure. TPC-E involves a mix of 12 concurrent transactions of different types and complexity, either executed online or triggered by price or time criteria. The database is comprised of 33 tables with a wide range of columns, cardinality, and scaling properties. TPC-E is measured in transactions per second (tpsE). While the benchmark portrays the activity of a stock brokerage firm, TPC-E is not limited to the activity of any particular business segment but rather represents any industry that must report upon and execute transactions of a financial nature.

TPC-H (Pöss and Floyd 2000) is an enterprise-class decision support benchmark. It consists of a suite of business-oriented ad hoc queries and concurrent data modifications. The queries and the data populating the database have been chosen to have broad industry-wide relevance. This benchmark illustrates decision support systems that examine large volumes of data, execute queries with a high degree of complexity, and give answers to critical business questions. The performance metric reported by TPC-H is called the TPC-H Composite Query-per-Hour Performance Metric (QphH@Size) and reflects multiple aspects of the capability of the system to process queries. These aspects include the selected database size against which the queries are executed, the query processing

power when queries are submitted by a single stream, and the query throughput when queries are submitted by multiple concurrent users. The TPC-H price/performance metric is expressed as \$/QphH@Size.

TPC-DS (Poess et al. 2002; Poess et al. 2007; Nambiar and Poess 2006; Poess et al. 2017) is an enterprise-class benchmark, published and maintained by the Transaction Processing Performance Council (TPC), to measure the performance of decision support systems running on SQL-based big data systems. TPC-DS models several generally applicable aspects of an SQL-based big data system, including queries and data maintenance. The benchmark provides a representative evaluation of performance as a general-purpose decision support system. A benchmark result measures query response time in single-user mode, query throughput in multiuser mode, and data maintenance performance for a given hardware, operating system, and data processing system configuration under a controlled, complex decision support workload. The purpose of TPC-DS benchmarks is to provide relevant, objective performance data to industry users.

TPC-DI (Poess et al. 2014) is an enterprise-class data integration benchmark, modeled after an online brokerage firm. Historically, the process of synchronizing a decision support system with data from operational systems has been referred to as extract, transform, load (ETL), and the tools supporting such process have been referred to as ETL tools. Recently, ETL was replaced by the more comprehensive acronym, data integration (DI). DI describes the process of extracting and combining data from a variety of data source formats, transforming that data into a unified data model representation and loading it into a data store. The TPC-DI benchmark combines and transforms data extracted from an online transaction processing (OTLP) system along with other sources of data and loads it into a data warehouse. The source and destination data models, data transformations, and implementation rules have been designed to be broadly representative of modern data integration requirements.

TPC-VMS is TPC's first benchmark to measure the performance of database workloads run in virtualized environments. Introduced in 2012, the TPC Virtual Measurement Single System Specification (TPC-VMS) leverages the TPC-C, TPC-E, TPC-H, and TPC-DS benchmarks by adding the methodology and requirements for running and reporting performance metrics for virtualized databases. The intent of TPC-VMS is to represent a virtualization environment where three database workloads are consolidated onto one server. Test sponsors choose one of the four benchmark workloads (TPC-C, TPC-E, TPC-H, or TPC-DS) and run one instance of that benchmark workload in each of the three virtual machines (VMs) on the system under test. The three virtualized databases must have the same attributes, e.g., the same number of TPC-C warehouses, the same number of TPC-E load units, or the same TPC-DS or TPC-H scale factors. The TPC-VMS Primary Performance Metric is the minimum value of the three TPC Benchmark Primary metrics for the TPC benchmarks run in the virtualization environment.

TPCx-V measures the performance of a virtualized server platform under a demanding database workload. It stresses CPU and memory hardware, storage, networking, hypervisor, and the guest operating system. TPCx-V workload is database-centric and models many properties of cloud services, such as multiple VMs running at different load demand levels, and large fluctuations in the load level of each VM. Unlike previous TPC benchmarks, TPCx-V has a publicly available, end-to-end benchmarking kit, which was developed specifically for this benchmark. It loads the databases, runs the benchmark, validates the results, and even performs many of the routine audit steps. Another unique characteristic of TPCx-V is an elastic workload that varies the load delivered to each of the VMs by as much as 16x while maintaining a constant load at the host level.

TPCx-BB measures the performance of Hadoop-based big data systems. It measures the performance of both hardware and software

components by executing 30 frequently performed analytical queries in the context of retailers with physical and online store presence. The queries are expressed in SQL for structured data and in machine learning algorithms for semi-structured and unstructured data. The SQL queries can use Hive or Spark, while the machine learning algorithms use machine learning libraries, user-defined functions, and procedural programs.

TPCx-HCI benchmark measures the performance of hyper-converged infrastructure clusters under a demanding database workload. It stresses the virtualized hardware and software of converged storage, networking, and compute resources of the HCI platform. The TPCx-HCI benchmark is based on the TPCx-V benchmark and uses the same kit as TPCx-V, but the results of these benchmarks are not comparable. The number of VMs is calculated differently for the two benchmarks, even on similar hardware. The TPCx-HCI workload is database-centric and models many properties of cloud services, such as multiple VMs running at different load demand levels, and large fluctuations in the load level of each VM. The TPCx-HCI benchmarking kit, which was developed from scratch, is a complete end-to-end kit that loads the databases, runs the benchmark, validates the results, and even performs many of the routine audit steps. Two unique characteristics of TPCx-HCI are:

1. It has an elastic workload that varies the load delivered to each of the VMs by as much as 16x while maintaining a constant load at the cluster level. Sustaining optimal throughput for this elastic workload on a multi-node HCI cluster would typically benefit from frequent migrations of VMs to rebalance the load across nodes. This property measures the efficiency of VM migration as well as the uniformity of access to data from all the nodes.
2. In the data accessibility test of TPCx-HCI, a node is powered down ungracefully, and the benchmark continues to run on the other nodes. The test sponsor has to include a

throughput graph for this test, demonstrating the impact on performance, as well as report the recovery time to regain resilience.

TPCx-IoT is the industry's first benchmark that enables direct comparison of different software and hardware solutions for gateway systems in the Internet of Things (IoT). Positioned between edge architecture and the back-end data center, gateway systems perform functions such as data aggregation, real-time analytics, and persistent storage. TPCx-IoT was specifically designed to provide verifiable performance, price/performance, and availability metrics for commercially available systems that typically ingest massive amounts of data from large numbers of devices while running real-time analytic queries. The workload is representative of activities typical in IoT gateway systems, running on commercially available hardware and software platforms. The TPCx-IoT can be used to assess a broad range of system topologies and implementation methodologies in a technically rigorous and directly comparable, vendor-neutral manner.

The TPC-Pricing Specification and TPC-Energy Specification are common across all the benchmark standards. **TPC Pricing** is a consistent set of pricing procedures and methodologies for all TPC benchmarks. TPC Pricing includes various pricing methodologies and models to allow benchmark sponsors to produce verifiable prices for benchmarks executed on both physically acquired hardware and licensed compute services (Cloud). **TPC-Energy** standard (TPC, 16) is designed to augment existing TPC benchmarks with energy metrics, so that end users can understand the energy costs associated with a specific benchmark result.

TPC Foundations

Before the release of any new benchmark standard, the TPC creates a lengthy and detailed definition of the new benchmark. The resulting specifications are dense documents with stringent

requirements. These very complete specifications help ensure that all published benchmark results are comparable. TPC members also constantly work to update and improve specifications to help them stay current and complete.

Unique to the TPC is the requirement that all published benchmarks be audited by an independent third party, which has been certified by the organization. This requirement ensures that published results adhere to all of the very specific benchmark requirements and that results are accurate so any comparison across vendors or systems is, in fact, comparing "apples to apples."

The end result is that the TPC creates benchmark standards that reflect typical database workloads. The process of producing a benchmark is highly structured and audited so that valid assessments can be made across systems and vendors for any given benchmark. Reported results include performance, price/performance, and energy/performance, which help customers identify systems that deliver the highest level of performance, using the least amount of energy.

Key Applications

TPC benchmarks are designed to measure the performance and price/performance of a broad range of application environments. TPC benchmarks use performance methodologies in a technically rigorous and directly comparable, vendor-neutral manner both on-premise and in the cloud.

TPC-DS is an enterprise-class benchmark, published and maintained by the Transaction Processing Performance Council (TPC), to measure the performance of decision support systems running on SQL-based big data systems. TPC-DS models several generally applicable aspects of an SQL-based big data system, including queries and data maintenance. The benchmark provides a representative evaluation of performance as a general-purpose decision support system. A benchmark result measures query response time in single-user mode, query throughput in multiuser mode, and data maintenance performance for a given hardware, operating system, and data processing system configuration under a controlled, complex decision support workload. The purpose of TPC-DS benchmarks is to provide relevant, objective performance data to industry users.

TPC Big Data Sort Benchmark

► [TPCx-HS](#)

TPC Express Benchmark HS

► [TPCx-HS](#)

Historical Background

TPC's decision to split the benchmark TPC-D into two new benchmarks, TPC-H and TPC-R, in February 26, 1999, was meant to be a temporary solution, until a more modern decision support benchmark was developed. It took the TPC 8 years to develop a new benchmark and 5 additional years to finally release the first version of TPC-DS on January 17, 2012. The second version of TPC-DS was published on August 28, 2015. The second version of TPC-DS was specifically designed to measure the performance of decision support systems (DSS) running on

SQL-based big data systems. The most recent version of TPC-DS can be accessed at [http://www\(tpc.org/%20TPC_Documents_Current_Versions/%20pdf/TPC-DS_v2.8.0.pdf](http://www(tpc.org/%20TPC_Documents_Current_Versions/%20pdf/TPC-DS_v2.8.0.pdf).

Foundations

Business Environment

TPC-DS models any industry that must manage, sell, and distribute products, for instance, food, electronics, furniture, music and toys, etc. It utilizes the business model of a large retail company having multiple stores located nationwide. Beyond its brick and mortar stores, the company also sells goods through catalogs and the Internet. Along with modeling a system to manage sales and returns, it models the data of a simple inventory system and a promotion system. The following are examples of business processes of this retail company:

- Record customer purchases and track customer returns from any of the three sales channels.
- Find revenue impact of price changes based on promotions.
- Maintain warehouse inventory.
- Create dynamic web pages.

TPC-DS does not benchmark the operational side of the business. It is assumed that the sales channel subsystems were designed at different times by diverse groups having dissimilar functional requirements. It is also recognized that they may be operating on significantly different hardware configurations, software configurations, and data model semantics. All three sales channel subsystems are autonomous and retain possibly redundant information regarding customer profiles and their addresses.

TPC-DS' modeling of the business environment falls into three broad categories:

- Data model
- Query and user model
- Data maintenance model

Data Model

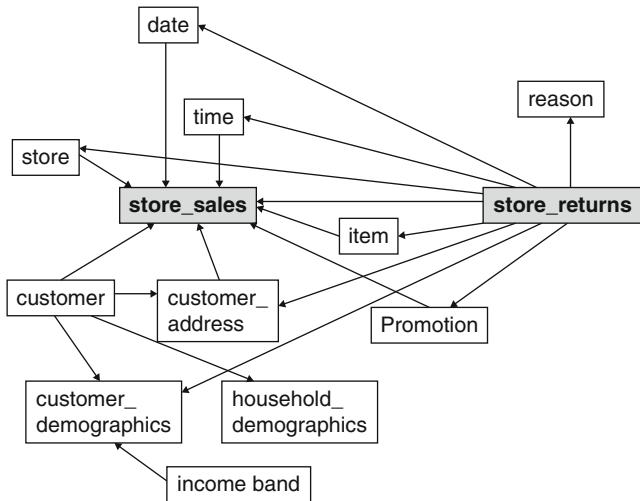

TPC-DS models a system that allows potentially long-running and multipart queries where the DBA can assume that the data processing system is quiescent for queries during any particular period. TPC-DS' data tracks, possibly with some delay, the state of an operational database through data maintenance functions, which include a number of modifications impacting some part of the decision support system. The schema is a snowflake schema consisting of multiple dimension and fact tables. Each dimension table has a single-column surrogate key. The fact tables join dimensions using each dimension table's surrogate key. The dimension tables can be classified into one of the following types:

- Static, which means that the contents of the dimension are loaded once during database load and do not change over time. The date dimension is an example of a static dimension.
- Historical, which means that the history of the changes made to the dimension data is maintained by creating multiple rows for a single business key value. Each row includes columns indicating the time period for which the row is valid. The fact tables are linked to the dimension values that were active at the time the fact was recorded, thus maintaining "historical truth." Item is an example of a historical dimension.
- Nonhistorical, which means that the history of the changes made to the dimension data is not maintained. As dimension rows are updated, the previous values are overwritten, and this information is lost. All fact data is associated with the most current value of the dimension. Customer is an example of a nonhistorical dimension.

Schema

The TPC-DS schema models the sales and returns for an organization that employs three primary sales channels: *stores*, *catalogs*, and the *web*. The relationship between tables of the store channel tables is given in Fig. 1. The schema, organized as a snowflake schema, includes seven fact tables,

TPC-DS, Fig. 1
Store_sales and
store_returns relationships

a pair of fact tables that models product sales and returns for each of the three channels, and one single fact table that models warehouse inventory for the catalog and Internet sales channels. In addition, the schema includes 17 dimension tables that are associated with all sales channels. As an extension to the pure star schema, the snowflake schema separates static data in the outlying dimension tables from the more dynamic data in the inner dimension tables and the fact tables. That is, in addition to their relation to the fact table, dimensions can have relations to other dimensions.

Dataset Scaling

TPC-DS deploys a data scaling approach that is a hybrid between domain and dataset scaling. Domain scaling keeps the number of tuples fixed but expands the domains used to generate them. For example, there could be a new type of store introduced in a retail dataset, or it could cover a longer historical period. Dataset scaling expands the number of tuples in a dataset but keeps the underlying value sets (the domains) static. The business analogy for dataset scaling would be a system where the number of items remains static but the volume of transactions per year increases. Most table columns in TPC-DS employ dataset scaling instead of domain scaling, especially fact table columns. Some columns in small tables employ domain scaling. The do-

mains have to be scaled down to adjust for the lower table cardinality. For instance, the domain for county is approximately 1800. At scale factor 100, there exist only about 200 stores. Hence, the county domain had to be scaled down for stores.

Fact tables scale linearly with the scale factor, while dimension tables scale sublinearly. Consequently, the unrealistic scaling issues that TPC-H is encountering are avoided. Even at larger-scale factors, the TPC-DS number of customers, items, etc. remains realistic. At scale factor 100, the database contains approximately 100GB of raw data. That is, 58 million items are sold per year by 2 million customers in 200 stores. On average each shopping card contains 10.5 items.

T

Workload

TPC-DS models user queries and data maintenance operations. The queries convert operational facts into business intelligence, while the data maintenance operations synchronize the operational side of a business with the data warehouse. Taken together, the combination of these two workloads constitutes the core competencies of any decision support system. The TPC has carefully evaluated the TPC-DS workload to provide a robust, rigorous, and complete means for the evaluation of systems meant to provide that

competency. The queries modeled by the benchmark exhibit the following characteristics:

- They address complex business problems.
- They use a variety of access patterns, query phrasings, operators, and answer set constraints.
- They employ query parameters that change across query executions.

In order to address the enormous range of query types and user behaviors encountered by a decision support system, TPC-DS utilizes a generalized query model to generate the queries. This model allows the benchmark to capture important aspects of the interactive, iterative nature of online analytical processing (OLAP) queries, the longer-running complex queries of data mining and knowledge discovery, and the more planned behavior of well-known report queries.

The size of the schema and its three sales channels allow for amalgamating the above query classes, especially ad hoc and reporting, into the same benchmark. An ad hoc querying workload simulates an environment in which users connected to the system send individual queries that are not known in advance. The system's administrator (DBA) cannot optimize the system specifically for this set of queries. Consequently, execution time for those queries can be very long. In contrast, queries in a reporting workload are very well known in advance. As a result, the DBA can optimize the system specifically for these queries to execute them very rapidly by using clever data placement methods (e.g., partitioning and clustering) and auxiliary data structures (e.g., materialized views and indexes). Amalgamating both types of queries has been traditionally difficult in benchmark environments since per the definition of a benchmark, all queries, apart from bind variables, are known in advance. TPC-DS accomplishes this fusion by dividing the schema into reporting and ad hoc parts. The catalog sales channel is dedicated for the reporting part, while the store and web channels are dedicated for the ad hoc part. The catalog sales channel was chosen as the reporting part because its data accounts for

40% of the entire dataset. The reporting and ad hoc parts of the schema differ in what kind of auxiliary data structures can be created. The idea behind this approach is that the queries accessing the ad hoc part constitute the ad hoc query set, while the queries accessing the reporting part are considered the reporting queries.

A sophisticated decision support system must support a diverse user population. While there are many ways to categorize those diverse users and the queries that they generate, TPC-DS has defined four broad classes of queries that characterize most decision support queries:

- Reporting queries
- Ad hoc queries
- Iterative OLAP queries
- Data mining queries

Reporting queries capture the “reporting” nature of a DSS system. They include queries that are executed periodically to answer well-known, predefined questions about the financial and operational health of a business. Although reporting queries tend to be static, minor changes are common. From one use of a given reporting query to the next, a user might choose to shift focus by varying a date range, a geographic location, or a brand name.

Ad hoc queries capture the dynamic nature of a DSS system in which impromptu queries are constructed to answer immediate and specific business questions. The central difference between ad hoc queries and reporting queries is the limited degree of foreknowledge that is available to the system administrator when planning for an ad hoc query.

Iterative OLAP queries allow for the exploration and analysis of business data to discover new and meaningful relationships and trends. While this class of queries is similar to the “ad hoc queries” class, it is distinguished by a scenario-based user session in which a sequence of queries is submitted. Such a sequence may include both complex and simple queries.

Data mining is the process of sifting through large amounts of data to produce data content

relationships. It can predict future trends and behaviors, allowing businesses to make proactive, knowledge-driven decisions. This class of queries typically consists of joins and large aggregations that return large data result sets for possible extraction.

Implementation Rules

A TPC-DS database must be implemented using commercially available data processing software, and its queries must be executed via an SQL interface. More generally, the implementation must be based on systems, products, technologies, and pricing that:

- Are generally available to users
- Are relevant to the market segment that the individual TPC benchmark models or represents (e.g., TPC-DS models and represents complex, high data volume, decision support environments)
- Would plausibly be implemented by a significant number of users in the market segment modeled or represented by the benchmark

The use of new systems, products, technologies (hardware or software), and pricing is encouraged so long as they meet the requirements above. Specifically prohibited are benchmark systems, products, technologies, or pricing (hereafter referred to as “implementations”) whose primary purpose is performance optimization of TPC benchmark results without any corresponding applicability to real-world applications and environments. In other words, all “benchmark special” implementations, which improve benchmark results, but are not real-world performance or pricing, are prohibited.

The use of explicitly created auxiliary data structures (EADS) is highly regulated in TPC-DS. In case their use is allowed, all replicated data must be managed by the system used for the benchmark implementation, all replications must be transparent to all data manipulation operations, their creation must be included in the database load test, and they may not be created or deleted during the performance test.

Auxiliary data structures that do not include data materialized from Catalog_Sales or Catalog_Returns are subject to the following limitations:

- They may materialize data from no more than one base table.
- They may materialize all or some of the following three items:
 1. The primary key or any subset of PK columns if the PK is a compound key
 2. Pointers or references to corresponding base table rows (e.g., “row IDs”)
 3. At most one of the following:
 - A foreign key or any subset of the FK columns if the FK is a compound key
 - A column having a date data type
 - A column that is a business key

Auxiliary data structures that include data materialized from Catalog_Sales or Catalog_Returns may not include any data materialized from Store_Sales, Store_Returns, Web_Sales, Web_Returns, or Inventory. Auxiliary data structures that materialize data from both fact and dimension tables must be the result of joins between FK- and PK-related columns. Auxiliary data structures that materialize data from one or more dimension tables without simultaneously materializing data from the primary key or any subset of PK columns if the PK is a compound key. Auxiliary data structures that materialize data from one or more dimension tables must materialize at least one dimension row for every fact table row, unless the foreign key value for a dimension row is null.

T

Partitioning Schemas

Horizontal partitioning of base tables or EADS is allowed. If the partitioning is a function of data in the table or EADS, the assignment of data to partitions must be based on the values in the partitioning column(s). Only primary keys, foreign keys, date columns, and date surrogate keys may be used as partitioning columns. If partitioning DDL uses directives that specify explicit partition

values for the partitioning columns, they must satisfy the following conditions:

- They may not rely on any knowledge of the data stored in the partitioning column(s) except the minimum and maximum values for those columns and the definition of data types for those columns.
- Within the limitations of integer division, they shall define each partition to accept an equal portion of the range between the minimum and maximum values of the partitioning column(s).
- For date-based partitions, it is permissible to partition into equally sized domains based upon an integer granularity of days, weeks, months, or years, all using the Gregorian calendar (e.g., 30 days, 4 weeks, 1 month, 1 year, etc.). For date-based partition granularities other than days, a partition boundary may extend beyond the minimum or maximum boundaries as established in that table's data characteristics.
- The directives shall allow the insertion of values of the partitioning column(s) outside the range covered by the minimum and maximum values.
- Multilevel partitioning of base tables or auxiliary data structures is allowed only if each level of partitioning satisfies the general partition conditions as stated above.
- Vertical partitioning of base tables or EADS is allowed when meeting all of the following requirements:
 - SQL DDL that explicitly partitions data vertically is prohibited.
 - SQL DDL must not contain partitioning directives which influence the physical placement of data on durable media.
 - The row must be logically presented as an atomic set of columns.

Constraints

The use of both enforced and unenforced constraints is permitted. If constraints are used, they must satisfy the following requirements:

- Enforced constraints shall be enforced either at the statement level or at the transaction level.
- Unenforced constraints must be validated after all data is loaded during the load test and before the start of the performance test.
- They are limited to primary key, foreign key, and NOT NULL constraints.

NOT NULL constraints are allowed on EADS and tables. Only columns that are marked “N” in their logical table definition (or columns in EADS derived from such columns) can be constrained with NOT NULL. If foreign key constraints are defined and enforced, there is no specific requirement for a particular delete/update action when enforcing a constraint (e.g., ANSI SQL RESTRICT, CASCADE, and NO ACTION are all acceptable).

The Data Accessibility Properties

The system under test (SUT) must be configured to satisfy the requirements for data accessibility. Data accessibility is demonstrated by the SUT being able to maintain operations with full data access during and after the permanent irrecoverable failure of any single durable medium containing tables, EADS, or metadata. Data accessibility tests are conducted by inducing failure of a durable medium within the SUT. The medium to be failed is to be chosen at random by the auditor.

The data accessibility test is performed by causing the failure of a single durable medium during the execution of the first data maintenance test. The data accessibility test is successful if all in-flight and subsequent queries and data maintenance functions complete successfully. The data accessibility test must be performed as part of the performance test that is used as the basis for reporting the performance metric and results while running against the test database at the full reported scale factor.

Execution Rules

A full run of TPC-DS consists of the following tests:

1. Database Load Test – the database load test is the process of building the test database.
2. Power Test – the power test is executed immediately following the load test. It measures the ability of the system to process a sequence of queries in the least amount of time in a single-user fashion. The queries in the power test shall be executed in the order assigned to its stream identification number:
3. Throughput Test 1 – the throughput tests measure the ability of the system to process the most queries in the least amount of time with multiple users. It immediately follows the power test.
4. Data Maintenance Test 1 – the data maintenance tests measure the ability to perform desired data changes to the TPC-DS dataset. Each data maintenance test executes $S_q/2$ refresh runs, with S_q being the number of query streams. Each refresh run uses its own dataset as generated by dsdgen. Refresh runs must be executed in the order generated by dsdgen. Refresh runs do not overlap; at most one refresh run is running at any time. All data maintenance functions need to have finished in refresh run n before any data maintenance function can commence on refresh run $n + 1$.
5. Throughput Test 2 – repeat of the first throughput test.
6. Data Maintenance Test 2 – repeat of the first data maintenance test.

Primary Performance Metric

TPC-DS defines three primary metrics:

1. Performance metric, QphDS@SF, reflecting the TPC-DS query throughput, defined as follows:

$$QphDS@SF = \left\lfloor \frac{SF * Q}{\sqrt[4]{T_{PT} * T_{TT} * T_{LD}}} \right\rfloor$$

where:

- SF is defined in Clause 3.1.3 and is based on the scale factor used in the benchmark.

- Q is the total number of weighted queries: $Q = S_q * 99$, with S_q being the number of streams executed in a throughput test.
- $T_{PT} = T_{Power} * S_q$, where T_{Power} is the total elapsed time to complete the power test and S_q is the number of streams executed in a throughput test.
- $T_{TT} = T_{TT1} + T_{TT2}$, where T_{TT1} is the total elapsed time of throughput test 1 and T_{TT2} is the total elapsed time of throughput test 2.
- $T_{DM} = T_{DM1} + T_{DM2}$, where T_{DM1} is the total elapsed time of data maintenance test 1 and T_{DM2} is the total elapsed time of data maintenance test 2.
- T_{LD} is the load factor computed as $T_{LD} = 0.01 * S_q * T_{Load}$, where S_q is the number of streams executed in a throughput test and T_{Load} is the time to finish the load.
- T_{PT} , T_{TT} , T_{DM} , and T_{LD} quantities are in units of decimal hours with a resolution of at least 1/3600th of an hour (i.e., 1 s).
- 2. Price-performance metric, $$/QphDS@SF$, as defined as follows:

$$$/QphDS@SF = \frac{P}{QphDS@SF}$$

where:

- P is the price of the priced system.
- QphDS@SF is the reported performance metric.
- 3. System availability date.

Synonyms

[Ad hoc benchmark](#); [Data warehouse benchmark](#)

Definitions

An enterprise class decision support benchmark by the Transaction Processing Performance Council examines large volumes of data to answer critical ad hoc business questions. It executes a suite of complex ad hoc SQL queries

in single- and multiuser modes together with concurrent data modifications. The queries and the data populating the database have broad industry-wide relevance while maintaining a sufficient degree of ease of implementation.

Historical Background

The first decision support benchmark, TPC-D, was released to the public by the Transaction Processing Performance Council (TPC) on May 5, 1995. For the technology available at that time, TPC-D imposed many challenges both on hardware and on DBMS systems. It implemented a data warehouse using a 3rd normal form (3NF) schema consisting of eight tables. Anticipating the data explosion of data warehouses in the industry, TPC-D was developed to scale from 1 GB to 3 TB of raw data pushing IO subsystems to their limit.

Toward the end of the 1990s, DBMS vendors developed aggregate/summary structures, commonly referred to as join indices, summary tables, and materialized views that are automatically maintained and transparently used by the query optimizer via query rewrite. These types of auxiliary data structures are typically used in reporting benchmarks to speed up queries that are well known in advance. As the cost of creating and maintaining these auxiliary data structures was not accounted for in the metric of TPC-D, this technology decreased query elapsed times considerably, resulting in an over proportional increase in the main performance metric. As a result, the TPC recognized that TPC-D was effectively broken.

Unable to integrate two workloads typical for decision support systems, ad hoc and reporting, the TPC constituted two separate benchmarks, TPC-R for a reporting workload and TPC-H for an ad hoc querying workload. An ad hoc querying workload simulates an environment in which users connected to the database system send individual queries that are not known in advance. Hence, the system's database administrator (DBA) cannot optimize the database system specifically for these queries. Consequently, exe-

cution time for these queries can be very long. On the other hand, queries in a reporting workload are very well known in advance, because they are executed periodically, for example, daily sales reports. As a result, the DBA can optimize the database system specifically for these queries to execute them very rapidly.

TPC-R was never adopted by the industry and was decommissioned by the TPC in the late 2002. TPC-H, on the other hand, continued to thrive. As of November 2017, there have been 329 TPC-H benchmark results published.

Foundations

Business Environment

The use case of TPC-H is built on any industry that has to manage, sell, and distribute products or services worldwide, similar to a car rental company, food distributor, and parts manufacturer. The use case is divided into two large areas, a *business operation* area and a *decision support* area. The *business operation* models the operational end of the business environment where transactions are executed on a real-time basis. Performance of systems managing this part is represented in other TPC benchmarks such as TPC-C and TPC-E and is not modeled in TPC-H. TPC-H focuses on executing the queries of the *decision support* part of a business where trends are computed and refined data are produced to support the making of sound business decisions. These queries:

- Give answers to real-world business questions
- Simulate ad hoc queries, for instance, issued via a point and click GUI interface
- Are far more complex than most OLTP transactions
- Include a rich breadth of operators and selectivity constraints
- Generate intensive activity on the part of the database server component of the system under test
- Are executed against a database complying to specific population and scaling requirements

- Are implemented with constraints derived from staying closely synchronized with an online production database

The TPC-H operations are modeled as follows:

- The database is continuously available 24 h a day, 7 days a week, for ad hoc queries from multiple end users and data modifications against all tables, except possibly during infrequent, for instance, once a month, maintenance sessions.
- The TPC-H database tracks, possibly with some delay, the state of the OLTP database through ongoing refresh functions, which batch together a number of modifications impacting some part of the decision support database.
- Due to the worldwide nature of the business data stored in the TPC-H database, the queries and the refresh functions may be executed against the database at any time, especially in relation to each other. In addition, this mix of queries and refresh functions is subject to specific ACID requirements, since queries and refresh functions may execute concurrently.
- To achieve the optimal compromise between performance and operational requirements, the database administrator can set, once and for all, the locking levels and the concurrent scheduling rules for queries and refresh functions.

T

Business Environment

TPC-H uses the same 3rd normal form schema as its predecessor TPC-D did. It consists of eight base tables, *lineitem*, *orders*, *part*, *partsupp*, *customer*, *supplier*, *nation*, and *region*. TPC supplies a data generator (dbgen) that generates data for all base tables depending on a scale factor (SF). The scale factor determines the size of the raw as generated by dbgen, for instance, SF = 100 means that the sum of all base tables equals about 100 GB. While dbgen accepts any integer between 1 and 100,000, scale factors that are valid for publication are

limited to 10, 30, 100, 300, 1000, 3000, 10,000, 30,000, and 100,000. Scale factor 1 is not valid for publication but is used to generate a small database that is used for demonstrating ACID and answer set correctness. The number of rows in all tables, except for nation and region, scales proportionally with the scale factor. *Lineitem* and *orders* are the two largest tables. They contain about 83% of the data.

Workload

The workloads in TPC-H consist of a database load, the execution of 22 queries in both single and multiuser mode, and two refresh operations. The process of building the test database is known as “database load.” The database load time includes all of the elapsed time to create the tables, load data, create optional indices, define and validate optional constraints, gather statistics configure the system, and ensure that the test database meets the ACID requirements including syncing loaded data on RAID devices and the taking of a backup of the database, when necessary.

Two refresh operations (RF1, RF2) model the loading of new sales information (RF1) and the purging of stale or obsolete sales information (RF2) from the database. RF1 inserts new rows into the tables *lineitem* and *orders*, while RF2 removes the same amount of rows from those tables.

Four components, a business question, a functional query definition, substitution parameters, and a query validation, characterize the 22 queries. The business question illustrates the business context in which the query is used. The functional query definition defines the function to be performed by the query in SQL-92 language (ISO/IEC 9075:1992). Each query is defined as a query template. Before a query can be executed against a database, parameters are substituted with values generated by the supplied program *qgen* in such way that the performance for different queries is comparable. The query validation describes how to validate each query by executing them against a 1 GB database and comparing their results against a predefined result set.

The 22 queries are run in single-user mode, which is in one database session, to demonstrate the ability of the test system to use all of the resources for a single-user and in multiuser mode, which is in multiple concurrent database sessions, to demonstrate the ability of the systems to use all of the resources to satisfy concurrent users. The queries are intended to test most query capabilities in respect to a typical decision support system. They:

Implementation Rules

The database must be implemented using a commercially available database management system (DBMS). Physical clustering of records within the database is allowed as long as this clustering does not alter the logical independence of each table. The intent of this clause is to permit flexibility in the physical design of a database while preserving a strict logical view of all the tables.

Partitioning Schemes

Horizontal partitioning of base tables or auxiliary structures created by database directives is allowed. If this assignment is a function of data in the table or auxiliary structure, the assignment must be based on the value of a partitioning field. A partitioning field must be one and only one of the following:

- A primary key of the table, whether or not it is defined as a primary key constraint
- A foreign key of the table, whether or not it is defined as a foreign key constraint
- A column having a date datatype

If directives are used that specify explicit values for the partitioning field, they must satisfy the following conditions:

- They may not rely on any knowledge of the data stored in the table except the minimum and maximum values of columns used for the partitioning field as defined in the specification.
- Within the limitations of integer division, they must define each partition to accept an equal

portion of their range between the minimum and maximum values of the partitioning column(s). For date-based partitions, it is permissible to partition into equally sized domains based upon an integer granularity of days, weeks, months, or years (e.g., 30 days, 4 weeks, 1 month, 1 year, etc.). For date-based partition granularities other than days, a partition boundary may extend beyond the minimum or maximum boundaries.

- The directives must allow the insertion of values of the partitioning column(s) outside the range covered by the minimum and maximum values.
- Multiple-level partitioning of base tables or auxiliary structures is allowed only if each level of partitioning satisfies the conditions stated above and each level references only one partitioning field as defined above.

Auxiliary Structures

The only type of auxiliary structure allowed in TPC-H is an index. Indexes can refer to only one base table. They can refer to a primary or foreign key as defined in the TPC-H specification, a compound primary or foreign key as defined in the TPC-H specification or any single date datatype column.

Primary Performance Metric

The primary performance metric in TPC-H is the *composite* performance metric (QphH). It equally weights the contribution of the single-user power metric and the multiuser throughput metric. It expresses the number of queries the system can perform per hour.

In order to compute the composite metric for a test system at a given scale factor, one needs to run a *power test* (single-user) followed by a *throughput test* (multiuser). The results of the power and the throughput tests are then combined to calculate the composite metric.

A power test consists of the execution of the refresh operation RF1, followed by the execution of all 22 queries in single-user mode and concluded by the execution of the refresh operation RF2. During a throughput test, multiple

concurrent sessions execute all 22 queries in a predefined order. One sequence of queries in a session is also called a “query-stream” (S_1, \dots, S_n). One pair of update functions (RF1, RF2) is executed for each query-stream. All update-pairs are executed sequentially in a separate session. The sequence of update functions is also called the “update-stream.” TPC-H requires a multi-stream run with a minimum number of streams. The minimum number of streams depends on the scale factor.

Scale factor	S (Streams)
1	2
10	3
100	4
300	6
1000	7
3000	8
10,000	9

The power metric (Power@Size) is computed as the geometric mean of the elapsed times for all queries and both refresh functions obtained from the power run. The unit is queries per hour. For a given scale factor (SF), it is computed as:

Power@Size

$$= \sqrt[24]{\prod_{i=1}^{22} QI(i, 0) * \prod_{j=1}^2 RI(j, 0)} \frac{3600 * SF}{3600}$$

with:

- **QI(i,0):** elapsed time of query Q_i obtained in the power run in seconds
- **RI(j,0):** elapsed time of the refresh function RF_j obtained in the power run in seconds
- **3600:** seconds

The throughput metric (Throughput@Size) is computed as the ratio of the total number of queries executed over the length of the measurement interval of the multi-stream run. The unit is queries per hour. For a given scale factor (SF), it

is computed as:

$$\text{Throughput@Size} = \frac{S * 22 * 3600}{T_s} * SF$$

with:

- T_s : elapsed time of the multistream run
- S: stream count
- 3600: seconds
- 22: number of queries per stream

The Composite Query-Per-Hour Performance Metric (QphH) is calculated as the geometric mean of the power and throughput metrics:

$$\begin{aligned} \text{QphH@Size, QphR@Size} \\ = \sqrt{\text{Power@Size} * \text{Throughput@Size}} \end{aligned}$$

Lastly, TPC-H defines a price/performance metric as the ratio of the total system price divided by the composite metric and an availability metric, which indicates the date the system is available for purchase by the general public.

TPCx-HS

Tariq Magdon-Ismail
VMware Inc., Palo Alto, CA, USA

Synonyms

[TPC Big Data sort benchmark](#); [TPC Express Benchmark HS](#)

Definitions

TPCx-HS is the first industry standard Big Data benchmark for objectively measuring the performance and price/performance of Apache Hadoop and Apache Spark compatible software distributions. It stresses both the hardware and software stacks including the operating system, execution engine (MapReduce or Spark), and Hadoop Filesystem API compatible layers. TPCx-HS can be used to assess a broad range of system topologies and implementation methodologies in a technically rigorous and directly comparable, vendor-neutral manner.

Historical Background

Up until 2007, Jim Gray defined, sponsored, and administered a number of sort benchmarks (Anon et al. 1985) available to the general community. These include Minute Sort, Gray Sort, Penny Sort, Joule Sort, Datamation Sort, and TeraByte Sort. TeraByte Sort measures the amount of time

taken (in minutes) to sort 1 TB (10^{12} bytes) of data.

In 2009, Owen O’Malley and others of Yahoo! Inc. published the results of a Hadoop MapReduce implementation of TeraByte Sort called TeraSort. It was capable of sorting 100 TB of data in 173 min using 3452 nodes, each running two quad-core Intel Xeon processors with 8 GB memory and four SATA disks, breaking previously held records. Today, Big Data processing has reached mainstream status, and since its release in 2009, many companies have been making performance claims based on TeraSort that are not easily verifiable or comparable. While TeraSort nicely defines the dataset and tasks needed to measure Big Data Hadoop systems, it lacks a formal specification and enforcement of rules that enable the comparison of results across systems and vendors.

In February 2014, the *Transaction Processing Performance Council (TPC)* formed a committee to develop an industry standard benchmark based on the already popular TeraSort workload and in July that same year formally approved TPCx-HS as a standard.

Foundation

Sizing and Scale Factors

TPCx-HS follows a stepped benchmark sizing model. Unlike TeraSort, which can be scaled using an arbitrary number of rows in the dataset, TPCx-HS limits the choices to one of the following: 10 B, 30 B, 100 B, 300 B, 1000 B, 3000 B, 10000 B, 30000 B, and 100,000 B, where each row/record is 100 bytes. (There is no inherent scale limitation in the benchmark. Larger datasets can be added (and smaller ones retired) based on industry trends over time.) In TPCx-HS, these dataset sizes are referred to in terms of *scale factors*, which are defined as follows: 1 TB, 3 TB, 10 TB, 30 TB, 100 TB, 300 TB, 1000 TB, 3000 TB, and 10,000 TB, respectively. For example, a 3-terabyte scale factor corresponds to a dataset with 30-byte rows.

The primary motivation for choosing a stepped design in benchmark sizing is to ease the comparison of results across different systems. However, it should be noted that results at different scale factors are not comparable to each other due to the substantially different computational challenges found at different data volumes. Similarly, the system price/performance may not scale down linearly with a decrease in dataset size due to configuration changes required by changes in dataset size.

Data Replication

The benchmarked system, or *system under test (SUT)*, must provide data redundancy equivalent to or better than that of local JBOD storage with a replication factor of three. The alternative hardware or service must prevent data loss in the event of a permanent, irrecoverable failure of any storage device containing data generated by the benchmark modules HSGen or HSSort.

Benchmark Execution

The TPCx-HS benchmark workload consists of four modules:

- **HSGen** generates the input dataset at a particular scale factor.
- **HSSort** sorts the input dataset in total order.
- **HSValidate** validates that the output dataset is globally sorted.
- **HSDataCheck** verifies the cardinality, size, and replication factor of the dataset.

HSGen, HSSort, and HSValidate are based on TeraGen, TeraSort, and TeraValidate, respectively. The TPCx-HS kit also includes HSDataCheck, which verifies that the dataset generated by HSGen and the output produced by HSSort match the specified scale factor.

A valid benchmark run consists of five separate and non-overlapping phases that are executed sequentially. The phases are listed below:

1. Generation of input data via HSGen
2. Verification (cardinality, size, and replication) of the input data via HSDataCheck
3. Sorting the input data using HSSort

4. Verification (cardinality, size, and replication) of the sorted dataset via HSDataCheck
5. Validation of the sorted output data via HSVValidate

If any of the verification or validation phases fail, the run is considered invalid. The TPCx-HS *performance metric* for a run is based on the end-to-end run time of all five phases as illustrated in Fig. 1. To account for variance, a benchmark test consists of two identical runs – Run 1 and Run 2 – with the reported result being for the run with the lower performance metric.

No part of the SUT may be rebooted or restarted during or between the runs or any of the phases. If there is a non-recoverable error reported by any of the applications, operating system, or hardware in any of the five phases, the run is considered invalid. If a recoverable error is detected in any of the phases and is automatically dealt with or corrected by the applications, operating system, or hardware, then the run is considered valid. However, manual user intervention is not allowed. If the recoverable error requires manual intervention to deal with or correct, then the run is considered invalid. A minimum of three-way data replication must be maintained throughout the run.

The SUT cannot be reconfigured, changed, or retuned by the user during or between any of the five phases or between Run 1 and Run 2. Any manual tunings to the SUT must be performed

before the beginning of Phase 1 of Run 1 and must be fully disclosed. Any automated changes or tuning performed by the OS or commercially available product between any of the phases is allowed. Any changes to default tunings or parameters of the applications, operating systems, or hardware of the SUT must be disclosed as well.

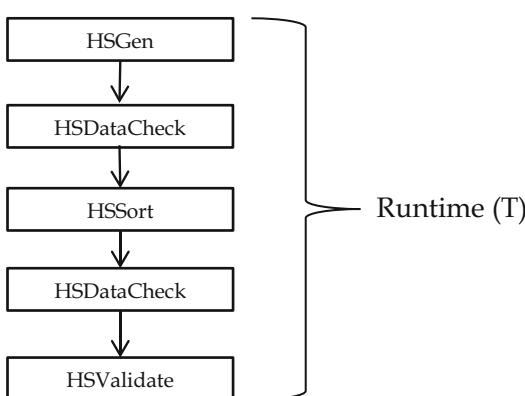

Metric

While the execution rules define the way in which a benchmark is run, the metric emphasizes the pieces that are measured (Nambiar et al. 2011). This is the most visible part of the performance data and one of the most controversial when trying to reach an agreement between different parties.

In general, a performance metric needs to be simple such that easy system comparisons are possible. If there are multiple performance metrics (e.g., A, B, C), system comparisons are difficult because vendors can claim they perform well on some of the metrics (e.g., A and C). This might still be acceptable if all components are equally important, but without this determination, there would be much debate on this issue. In order to unambiguously rank results, the TPC benchmarks focus on a single primary performance metric, which encompass all aspects of a system's performance, weighting the individual components. Taking the example from above, the performance metric M is calculated as a function of the three components A, B, and C; that is, $M = f(A, B, C)$. Consequently, TPC's performance metrics measure system and overall workload performance rather than individual component performance. In addition to the performance metric, the TPC also includes other metrics, such as price/performance metrics.

The TPC distinguishes between *primary* and *secondary* metrics. Each TPC Express Benchmark Standard (Huppler and Johnson (2013)) must define primary metrics selected to represent the workload being measured. The primary metrics must include both performance and price/performance metrics.

TPCx-HS defines three primary metrics:

TPCx-HS, Fig. 1 TPCx-HS execution phases

- HSph@SF: Composite performance metric, reflecting the TPCx-HS throughput, where SF is the scale factor
- \$/HSph@SF: Price/performance metric
- System availability date

TPCx-HS also reports the following numerical quantities:

- T_G , data generation phase completion time with HSGen reported in hh:mm:ss format
- T_S , data sort phase completion time with HSSort reported in hh:mm:ss format
- T_V , data validation phase completion time reported in hh:mm:ss format

When the TPC Energy option is chosen for reporting, the TPCx-HS energy metric reports the power/performance and is expressed as Watts/HSph@SF (see the TPCx-HS (TPCx-HS Benchmark 2018) and TPCx Energy specifications (TPC Energy 2018) for additional details and requirements).

Each secondary metric shall be referenced in conjunction with the scale factor at which it was achieved. For example, TPCx-HS TG references shall take the form of TPCx-HS TG @ SF, or “TPCx-HS TG = 2 hours @ 1.”

The primary performance metric of the benchmark is HSph@SF, the effective sort throughput of the benchmarked configuration. We use a summation method as an illustrative example:

$$\text{HSph@SF} = \left[\frac{SF}{T/3600} \right]$$

where SF is the scale factor and T is the total elapsed time for the run, in seconds.

The price/performance metric for the benchmark is defined as:

$$\$/\text{HSph@SF} = \frac{P}{\text{HSph@SF}}$$

where P is the total cost of ownership of the SUT.

The system availability date is defined in the TPC Pricing Specification (TPC Pricing 2018).

A TPCx-HS result is only comparable with other TPCx-HS results of the same scale factor. As noted before, results at the different scale factors are not comparable due to the substantially different computational challenges found at different data volumes. Similarly, the system price/performance may not scale down linearly with a decrease in dataset size due to configuration changes required by changes in dataset size.

Key Applications

TPCx-HS is designed to measure the performance and price/performance of a broad range of Hadoop and Spark system topologies and implementation methodologies, in a technically rigorous and directly comparable, vendor-neutral manner both on premise and in the cloud.

Trace Clustering

Jochen De Weerdt
KU Leuven, Leuven, Belgium

Synonyms

Clustering of process instances; Process variant discovery

Definitions

Given an event log being a bag of process instances, with each process instance or trace consisting of a sequence of events, trace clustering refers to grouping these process instances so as to maximize the similarity between them and maximize the dissimilarity between the groups. While trace clustering might be described as discovering process variants, usually, the term process variant is already used for a collection of process instances with exactly the same event sequence. As such, trace clustering usually refers to the grouping of those variants into logically coherent groups, which can be, confusingly, referred to as variants of the process.

Overview

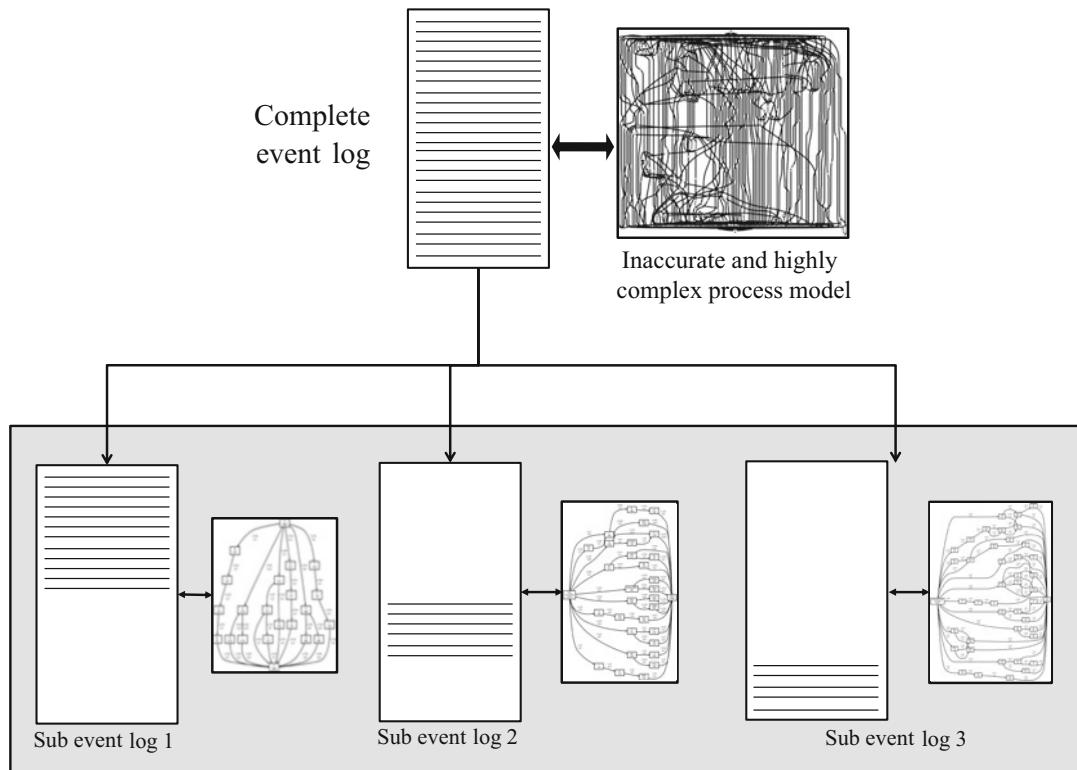

This entry discusses trace clustering in the context of process mining. The technique is

explained in general, followed by a dense yet informative typology of techniques. This entry is concluded by an overview of related topics.

Introduction

Despite the demonstrated usefulness of *automated process discovery* in flexible environments, it has been shown that its application is usually also most challenging in these contexts. More specifically, a multitude of studies illustrates that process discovery techniques experience difficulties to produce accurate and interpretable process models out of *event logs* stemming from highly flexible environments (Günther 2009; Goedertier et al. 2011; Jagadeesh Chandra Bose and van der Aalst 2009b; Veiga and Ferreira 2010). This problem is largely due to the high variety of behavior that is captured in certain event logs.

Accordingly, different approaches have been proposed to cope with this issue. Event log filtering, event log transformation (Jagadeesh Chandra Bose and van der Aalst 2009a), and tailor-made discovery techniques such as Fuzzy Mining (Günther and van der Aalst 2007) are noteworthy solutions. *Trace clustering* can be considered as another solution for reducing the complexity of the learning task at hand. This is because one can rely on multiple process models to represent the variety in behavior of a certain event log by separating execution traces into different groups. The purpose of clustering process executions is detailed in Fig. 1. By dividing traces into different groups, process discovery techniques can be applied on subsets of behavior and thus improve the accuracy and comprehensibility of discovered models. Partitioning event logs into multiple groups is a convenient approach for addressing the challenge of discovering accurate and understandable process models from logs presenting a large amount of distinct process behavior. Observe that distinct process behavior refers to the presence of a large variety of different event sequences or process variants in which the process is executed. Note that trace

Trace Clustering, Fig. 1 Creating three clusters of process instances in order to alleviate the resulting complexity of a single discovered process model

clustering does not include decomposed process discovery where traces are being split into sub-traces (e.g., corresponding to stages). As such, the difference is that in decomposed process discovery, the event log is decomposed vertically, whereas in trace clustering, it is decomposed horizontally (the traces are not split but rather grouped together).

Partitioning algorithms operating at the trace (or process instance) level are usually referred to as trace clustering techniques within the process mining domain. Observe that in some cases, there might be a natural combination of several processes into one event log. Typically, one would be able to separate out the cases pertaining to these processes based on activity names, resources, etc. However, in some cases, it might be difficult to decouple multiple processes logged into one event log, which might necessitate the use of a trace clustering technique. However, the latter can be considered as an unlikely situation, thus

not often considered as a starting point for trace clustering.

Trace Clustering Techniques

Accordingly, trace clustering is most interesting as an approach to deal with the problem that many event logs contain an extensive amount of distinct behavior (i.e., process variants), because it allows the user to split up a log so that multiple distinct models can be learnt to describe the underlying business process. Observe that, intrinsically, grouping by process variant can also be considered as trace clustering. Nevertheless, this task is trivial (and should not be subject to the use of an algorithm). As such, trace clustering techniques should operate at the level of grouping distinct process instances or process variants. Please also note that trace clustering refers to horizontal log splitting. Vertical log splitting entails

the discovery of hierarchical subprocesses, which is considered as an orthogonal learning task.

A variety of trace clustering techniques exist within the process mining field. For a recent comparative assessment, see, for instance, Thaler et al. (2015). Table 1 presents a basic overview. Trace clustering techniques often translate the problem to a propositional setting, by featurizing the process instances and subsequently applying a traditional data clustering technique. In Table 1, these techniques are referred to as “propositional.” Given that they employ distance-based data clustering algorithms, they are also considered as “distance-based.” Nevertheless, some techniques derive distances between process variants but avoid the featurization step. These techniques only have a check mark in the corresponding “distance-based” column. Finally, an entirely different set of trace clustering techniques are model-driven, i.e., they rely either on some temporal probabilistic model like a hidden Markov model, or on actual process models (in the form of Petri nets, dependency graphs, or other representations).

Propositional Trace Clustering

The simplest idea for clustering traces relies on the use of traditional data clustering techniques,

most importantly hierarchical or partitional algorithms (Jain and Dubes 1988). In order to apply these traditional data clustering techniques, one should convert an event log, i.e., a set of traces, into an attribute-value data set (i.e., the typical input format expected by data clustering techniques). As such, one should “featurize” the traces.

The first study proposing such a “featurization” approach is the pioneering study by Greco et al. (2006), who proposed a projection of the traces onto a set of suitable features, in this case a set of frequent k-grams of activity sequences. The projection of an event log onto a feature set was further explored by Song et al. (2008). Their trace clustering implementation allows for a multitude of so-called profiles to determine the vector associated with each process instance. As such, they define activity, transition, performance, case attribute profiles, etc. Furthermore, whereas Greco et al. (2006) relied on k-means, Song et al. (2008) provide an implementation that offers a full range of distance metrics and data clustering algorithms. Later, the same authors investigated the use of dimensionality reduction techniques in the context of profile-based trace clustering (Song et al. 2013). Along the same line of reasoning, Bose and van der Aalst

(2010) proposed a refinement of the technique of Greco et al. (2006) by making use of so-called conserved patterns (e.g., maximal, super maximal, and near-super-maximal repeats) as projection features. The implementation applies hierarchical clustering instead of k-means.

Other Distance-Based Trace Clustering Techniques

In Jagadeesh Chandra Bose and van der Aalst (2009b), Bose and van der Aalst turn away from the use of an attribute-value feature space but instead regard log traces as strings over the alphabet of task labels and as such calculate the distance between traces directly by exploiting the idea of a string edit distance. However, in contrast to contemporary approaches such as the Levenshtein distance (Levenshtein 1966), specific substitution, insertion, and deletion costs are derived so as to take into account characteristic features of an event log, such as concurrency of tasks. A similar, alignment-based technique is proposed in Evermann et al. (2016). Furthermore, Delias et al. (2015) have developed a more robust spectral learning approach, where the similarity metric is adjusted in the face of significant deviating behavior. Finally, Appice and Malerba (2015) deploy a co-training strategy based on multiple views: separate clusterings are created using instance similarity based on the activities, resources, sequences, and timing aspects of the process instances and then combined to create a single multiple-view clustering.

Model-Driven Trace Clustering

A third class of trace clustering techniques can be best described as *model-driven*. Inspired by the work of Cadez et al. (2003) in the area of web usage mining, Ferreira et al. (2007) propose to cluster sequences by learning a mixture of first-order Markov models using the Expectation-Maximization (EM) algorithm. This technique has been applied in Veiga and Ferreira (2010) to server logs. Also in Folino et al. (2011), Markov chain clustering is used. Furthermore, De Weerdt et al. (2013) propose the *ActiTraC*-algorithm,

which is an active learning-inspired trace clustering technique that strives to optimize the combined fitness of the underlying process models. Finally, Chatain et al. (2017) also propose a process model-driven trace clustering technique but rely on the concept of alignments to construct models that serve as the centroids of the trace clusters.

Multi-objective Trace Clustering

Trace clustering techniques often strike a balance between multiple objectives. Typical objectives are to maximize intra-cluster trace similarity; intercluster trace dissimilarity; fitness, precision, generalization, and simplicity of the underlying process models; stability of the clustering solution; understandability by experts; and justifiability by experts (solutions need to be in line with expert knowledge). Oftentimes, trace clustering techniques inherently consider only a single optimization, e.g., propositional techniques optimize in terms of trace similarity, while only few techniques directly incorporate multiple objectives in the learning phase. In De Koninck and De Weerdt (2016b), a multi-objective trace clustering technique was presented, built on top of the active trace clustering paradigm proposed in De Weerdt et al. (2013).

Furthermore, García-Bañuelos et al. (2014) address complexity-aware trace clustering by proposing the SMD-technique, a kind of meta-level trace clustering technique which, based on a two-way divide-and-conquer discovery technique, wherein discovered process models are split, are both based on process variants and hierarchically using subprocess extraction. Observe that, because the technique can basically work on top of any other trace clustering technique, the check marks in Table 1 are put between brackets. Finally, also expert-driven trace clustering has received attention recently. In De Koninck et al. (2017b), a constraint clustering-inspired trace clustering algorithm was developed that takes both expert information (in the form of a preexisting expert clustering) and process model quality into account while grouping the traces.

Further Topics in Trace Clustering

Next to the development of trace clustering techniques, research on the topic has also addressed related problems such as the understandability of a trace clustering solution, the use of trace clustering for concept drift detection, and the determination of an appropriate number of clusters. E.g., in De Weerdt and Vanden Broucke (2014) and De Koninck et al. (2017a), a method is proposed to learn instance-level explanations of trace clusterings. Hompes et al. (2015) apply trace clustering for concept drift detection and explanation based on statistical and visual comparisons of case clusters. Finally, in De Koninck and De Weerdt (2016a, 2017), tailor-made techniques for determining the appropriate number of trace clusters have been proposed based on the concepts of stability and separation.

ACID properties in MMOGs; Consistency models in MMOGs

Definitions

Massively Multiplayer Online Games (MMOGs) are large virtual worlds replicated across player machines. Clients interact with the world by sending game actions, which must be executed over the world state according to specified game-aware ACID semantics.

Overview

Massively Multiplayer Online Games (MMOGs) are a popular genre of online games. These games revolve around large virtual worlds where players control their avatar to interact with others and the environment. The appeal of MMOGs lies in the persistence of data: the state of the game is constantly evolving and shared by the players. Personal data has value: most of the time spent in the game involves collecting items.

Another important aspect of MMOGs is their size. The millions of players which constitute the user base of commercial games are divided into shards, each with a limited capacity measured in thousands of clients. The focus is put on expanding the scale of games which must be supported by the underlying system.

The typical structure of MMOGs has clients each controlling a single character, or avatar, in the world through a graphical user interface. This game world is populated by various types of

objects: characters that are either controlled by players or artificial intelligence, noninteractive objects (e.g., trees, buildings) which form the environment, and mutable items which can be used or interacted with by characters. Players also take *actions*, which constitute the basic mean of interaction in MMOGs. This includes moving in the world, picking up items, dropping them from the character's inventory, and trading with other players. Since the game world is common to all players, the actions executed by one should be observable by others.

MMOGs can be treated as a database application (Gupta et al. 2009). The world objects are the data, and actions are logical sequences of read and write operations on the attributes of one or more objects. Ideally, these actions run as transactions with ACID properties. Actions require atomicity, executing in their entirety or not at all. Durability is essential as these game worlds run for long periods of time and need to survive various system failures. Different players can request actions on the same objects concurrently, requiring concurrency control to provide isolation.

However, several reasons exist as to why MMOGs cannot be implemented simply as a set of transactions using a traditional database system. First, most actions are update transactions, and the high rate of requests to be processed often cannot be handled by a single database server using traditional database techniques (Dalton 2007). Secondly, the system is, by nature, highly replicated. Each player sees part of the game world and the characters residing in that area. This is usually achieved by giving each client copies of the relevant game objects which are updated whenever changes occur (Kienzle et al. 2009).

Since these games can have thousands of players playing simultaneously, the update rate and the degree of replication are considerable. Propagating every change to every copy in an eager fashion (within transaction boundaries) in order to provide a consistent view to every player is simply not possible (Bharambe et al. 2006). In many cases, existing game engines restrict the number of players that can populate

a game region or instantiate the game to reduce the number of updates (Glinka et al. 2008). Furthermore, they commonly allow many inconsistencies to occur which the players are forced to accept (Henderson 2001). Durability is mostly handled in a very optimistic fashion: any gameplay shortly before an outage can be lost (Gupta et al. 2009).

Key Research Findings

Due to the unique replicated nature and workload properties of MMOGs, a set of consistency models are proposed which take into account game action semantics (Zhang and Kemme 2011). Consistency requirements can differ widely between actions due to their variation in complexity. An action's complexity is influenced by some of the following factors:

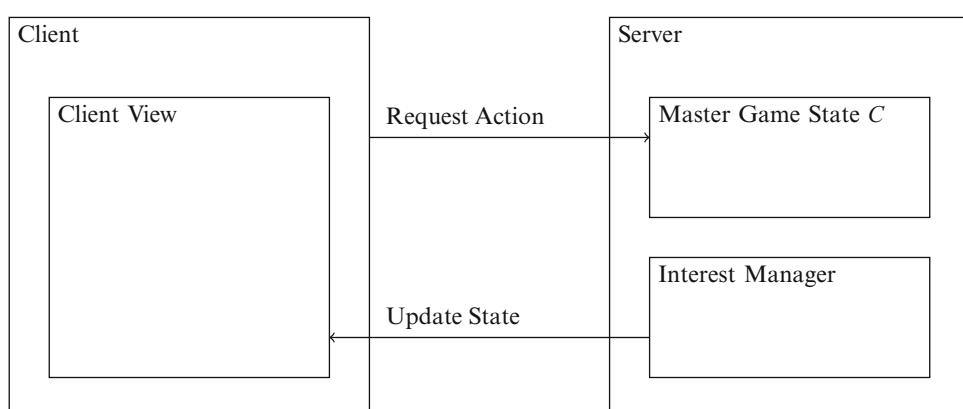

1. Repeatability: if an action is frequently executed, it might not require a high level of consistency as it can tolerate transient faults;
2. Number of objects: Atomicity becomes a greater issue when an action involves more than one object;
3. Number of reads: The effects of certain actions depend on the value of read attributes. Isolation is more difficult to maintain as the number of reads increases;

4. Importance: Crucial events with a significant impact on the game, actions that take a long time to be accomplished, or ones using real currency necessitate a high level of consistency.

Transactions in MMOGs have similarities with the various degrees of isolation, such as read committed and serializability, that are offered by traditional database systems (Berenson et al. 1995). In both cases, the developer is presented with a trade-off between performance and consistency. The approach in MMOGs goes further as it considers staleness of replicated objects.

Replication Model

The typical architecture of an MMOG system is depicted in Fig. 1. Each player hosts the client software of the game. It is able to render the game world and to receive input from the player. Clients control their avatar and can submit actions. The client software sends them to the server who serializes them, adjusts the game state, and notifies all players that are affected by the game change. This can be supported using a primary copy replication mechanism with master/replica proxy objects (Kienzle et al. 2009; Bharambe et al. 2006). Using this replication model, the game world consists of a set of objects, each of them being a collection of attributes. The server holds a *master proxy* (shortened to master) of

Transactions in Massively Multiplayer Online Games, Fig. 1 Simplified architecture

each object. The attribute values of the master proxy contain the latest and correct state of the corresponding object. The game state C , as maintained by the server, is defined as the union of the states of the master proxies of all objects.

Each client can then hold a read-only *replica proxy* (also called *replica*) for an object (white shapes in the Figure). At any given time, the state of a replica proxy might be lagging behind that of the corresponding master proxy, missing some of the changes that have already been installed at the latter. A client holds replica proxies only for objects that it is interested in. The composition of a client's *replication space* is determined dynamically by a process called *interest management*. Various methods exist for determining a player's interest (Boulanger et al. 2006). For example, one can define a circle around a player: all objects within this range are considered interesting and must be included in the replication space. The perceived state of all replicas held by a client is called the *client view*.

Action Definition and Processing

An action is a sequence of read and write operations performed on attributes of objects found in the world. The write set $WS(A)$ is defined as the set of all objects updated by action A . Without loss of generality, actions contain at least one write and do not create new objects.

As part of an action A , the client reads the state of some of its replicas before submitting the action to the server. The server then performs a sequence of read and write operations on some of the masters. As a result of the action, the master proxies of the objects in $WS(A)$ now possess a new state which must be disseminated to the replica proxies.

Figure 1 illustrates action execution. The client submits the action to the server, which executes it and disseminates the changes to all replicas, including the original client who submitted the action.

Read Operations

Understanding what objects are actually read and how the reads are performed is crucial to recognizing the required levels of consistency.

Action reads. Consider the following actions. Moving an avatar first reads the current position of the character. Drinking a bottle checks its content attribute: the action succeeds only if there is water remaining.

Action reads operations are inside the action code. Some are first performed on the client replicas. In particular, *validation reads* are used to verify whether an action is possible. For example, when a player tries to pick up an item, the local client software first checks the local replica state of the item. If it is on the ground, it forwards the action to the master. Otherwise, it rejects it immediately. The server repeats the validation reads on the master state, as it can differ from the client view. Client reads are considered preliminary, used to prevent sending unnecessary actions to the server. However, a valid action at the client might fail at the server. For instance, although a player saw an item on the ground, the pickup request might not succeed because the state at the server indicates that the item is already in the inventory of another avatar. In general, it is important to note that action reads performed on replicas usually always have the potential of being stale.

Client reads. A player continuously observes the state of all its replicas, whether they are stale or not. The player uses this information to decide what action to perform. The player is reading certain semantically relevant attributes before initiating an action on its client software. The key aspect is that any value from any object visible to the player can potentially be read and affect the judgment of the player. These reads are implicitly outside of the action code. Thus, each action has a *client read set*, determined by the player, which is read before the action is submitted. For instance, consider a player who decides to move to a location to pick up an item. Clearly, the move action does not read or update the item, only the position attribute of the player. Yet, the decision to move the player is directly dependent on the position of the item, as established by the player. The action read set contains the current position of the player's avatar, and the client read set contains the location of the item.

Transactions

In principle, a transaction for an action can be split into three parts. Clients first perform action reads and client reads on its replicas. The server then executes read and write operations on the master proxies. Finally, clients apply the changes from the server.

If possible, the entire transaction should be executed under full transactional properties: atomicity, isolation, and durability. Unfortunately, this would be costly, requiring distributed locking, eager propagation of updates, and a distributed commit protocol. No game architecture uses such approach. Instead, consistency is relaxed by considering correctness criteria for the server transaction and those for the client transactions separately.

Server Transactions

To begin, assume that actions are designed in a consistent manner: given a consistent game state C , the full execution of an action at the server under isolation transitions C to a new consistent state C' .

Moreover, the traditional definition of isolation is used for server transactions. A concurrency control mechanism is put in place to regulate parallel action execution. For instance, two-phase locking can be used to guarantee serializability (Lupei et al. 2010). Assume one action breaks a bottle and a concurrent action picks it up. If the break is serialized before the pickup, then a broken bottle is picked up. If the pickup gets the lock and executes before the break, then the break will not succeed as a bottle that is in the inventory of another avatar cannot be broken.

Formally, *master isolation* is provided if the execution at the server is serializable. That is, the concurrent execution of a set of actions at the server is equivalent to serial execution of these actions.

Master atomicity is said to be maintained if all or none of the action succeeds at the server. This can be implemented easily via a standard rollback functionality. Atomicity is more challenging in a distributed setting.

Durability is also a property maintained at the server and is dependent upon the aforementioned properties.

Providing transactional properties at the server guarantees that the game world as a whole remains consistent.

Client Transactions

The atomicity and isolation properties of client transactions reflect the player's gameplay experience.

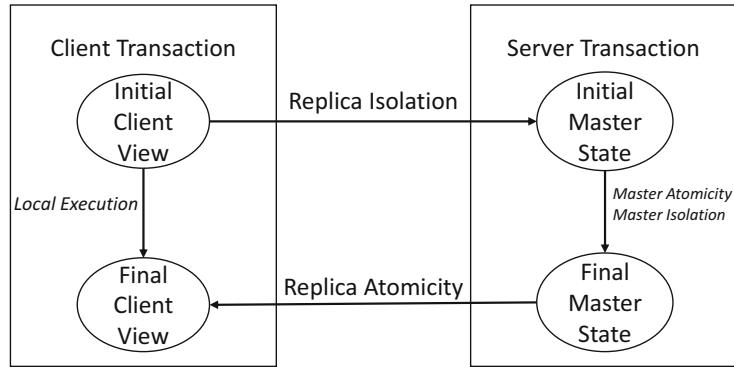

Replica atomicity is given if every update performed at a master is also applied at the related replicas. For performance reasons, this happens after the action commits at the server and not within the boundaries of the server transaction. Note that this does not require that the updates are applied within the boundaries of the server transaction. That is, the definition of atomicity is more relaxed than the traditional definition.

Replica isolation refers to the notion that if a client initiates an action based on its local action and client reads, then the updates triggered by the action from the server which are applied to the local replicas of the client are updates that conform to said reads. That is, if the client transaction had acted in isolation (performing only local reads and changing the local replicas), the outcome would be the same as the updates triggered by the server transaction.

For example, suppose a player wants to purchase an item at a given price. The client reads the price from the item replica as value P . If replica isolation is maintained, the price read at the master should also be value P . Suppose not and the master value is actually $P + 1$. Assuming the player has enough funds to purchase the item at the higher price, the update triggered from this action notifies the client that the item was bought at $P + 1$ and not P . Since the outcome is different from an execution using the locally read price value, replica isolation is violated.

Looking at this formally, replica isolation does not provide serializability at the global level. The state of the master might be different to the state read at a replica, leading to something similar to non-repeatable reads. However, if the difference does not have an effect on the write operations,

Transactions in Massively Multiplayer Online Games, Fig. 2
Client and server ACID properties

then it does not violate replica isolation. This means that the definition of replica isolation considers the game semantics.

Figure 2 illustrates the relationship between client and server transactions. When the server receives an action request, master atomicity and isolation enables the game state to move from one consistent state to the next. The view perceived at the client depends on whether replica isolation and atomicity are supported or not.

Examples of Application

Given the variety of actions, a multilevel approach to game consistency provides the best trade-off between consistency and performance. Lower categories are more efficient and scalable, while higher levels offer more consistency guarantees which are clearly defined. Thus, application developers can choose for each of their actions the proper consistency level, making them aware of the consistency properties that are achieved. In total, there exist five categories, each with an action handling protocol that can satisfy the requirements of each category while maximizing its performance and scalability.

All of the categories defined for a single server system offer master isolation and atomicity. Master isolation is achieved through a standard strict two-phase locking protocol. The three lowest category levels do not offer replica isolation and differ on replica atomicity. The three highest levels all offer replica atomicity but contrast in the way they handle replica isolation.

The granularity for read and write operations are object attributes and not entire objects to allow for fine-grained concurrency. Attributes are categorized by the way they are updated. An attribute x is said to be of category c if c is the *lowest* category level for which there exists an action which writes to x .

No Consistency

The lowest consistency category provides no guarantee and follows a “best-effort” *maybe* semantic model. Replica atomicity and isolation are not guaranteed. The server is not required to inform clients about any state changes incurred by no consistency actions.

This consistency category can be used for minor actions whose effects others do not necessarily need to be aware of. These actions are usually easily repeatable to compensate failures. For instance, graphical effects such as rotating a character or showing an emote (such as dancing or smiling) fall in this category as they do not have any real importance on gameplay.

Actions can be sent using an unreliable message channel (e.g., UDP).

Low Consistency

Like no consistency, low consistency does not require every update to be propagated to every replica, but it does provide a bound on the staleness of the data. Replica atomicity is therefore provided to some degree. This is useful for large volume actions that need to provide some guarantee in regard to their visibility.

The most common action type that fits into this category is the progressive movement of an avatar leading to a target destination. The idea here is that while clients might not perceive the exact position of a player at any time, they always know its approximate location, possibly defined through a specific error bound. For instance, the position seen at any replica should not be off by more than x movements or a distance of y units from the current position at the server. Another possibility is to support eventual convergence to the real position value.

Medium Consistency

The medium consistency category reflects the way current game middleware handles most of the actions. Replica atomicity is provided and requires exact updates to be sent. According to the definition, it is enough to send these updates after the action committed at the server. The bound on replica staleness is therefore the maximum latency for delivering an update from the server to a client.

Actions at this level still do not require replica isolation. Since clients can perform stale reads, the outcome at the server may be different to what the client expects.

This consistency level is appropriate for actions which are important enough to require exact updates. The inconsistencies which arise from the lack of replica isolation must be tolerable or predictable. For example, two nearby players send a request to pick up an item. At the server, one action is serialized before the other. The second action will be rejected because the item will already be picked up. Upon receiving this result, the client of the second action can justify the outcome due to the close proximity of the other player, as it can deduce that other player must have picked up the object.

High Consistency

Unexpected outcomes are sometimes undesirable. This is the case if critical attributes are affected by an action. For example, price is a critical attribute when buying an item. Normally, one does not want to buy an item for more than the locally visible price, but it is acceptable if

the item is cheaper. With medium consistency however, the item will be bought independently of the exact price at the server as long as the client has enough funds.

Thus, the high-consistency category introduces the concept of *critical attributes* and guarantees a limited form of replica isolation on such attributes. The isolation property is relaxed along two dimensions.

First, strict repeatable reads are not required; *comparable reads* are sufficient: the difference between the value at the master and the value at the replica must be *acceptable* for the action. What is acceptable depends on the game semantics. For instance, if a client submits a buy operation based on a certain price of an item, then a negative price difference (client price – server price) is not acceptable, and the action should fail as a repeatable read is violated. However, the action should succeed with a positive price difference.

Second, only replica isolation *safety* is provided. If the difference is unacceptable, the action must be rejected. High consistency essentially reduces any inadmissible executions into a rejection, which does not generate any inconsistencies since no changes are made to the game state.

Exact Consistency

For high consistency, stale critical attributes can lead to frequent aborts at the server. Reading stale values at the client and making decisions on behalf of this data can be considered an optimistic approach, where the final validation at the server may fail.

Exact consistency is the level where full replica isolation is provided. Guaranteed fresh data is possible only when client confirmation is integrated into the action itself. This category is designed specifically for those complex actions with multiple client input steps. An example is trading where items and money are exchanged between two avatars. Given the complexity and the importance of this type of action for gameplay, performance is not that crucial. In contrast, all players need to have the accurate state for decision-making and want to be assured

that the action succeeds properly at all involved parties.

This model enforces a stronger condition than replica atomicity. In all lower categories, changes are sent asynchronously to all replicas. In contrast, with exact consistency, all involved players receive the updates within the boundaries of the transaction, i.e., eagerly. Thus, atomic execution on all replicas of involved players is provided.

Other ACID Properties

For the sake of brevity, this chapter only covers consistency for MMOGs transactions. For more details on atomicity, which is nontrivial in a distributed (multi-server) setting, and durability, please refer to the following paper (Zhang and Kemme 2011).

Future Directions for Research

Future works include extended ACID model for MMOGs, adaptive transaction models, and optimized protocols for each consistency level.

Trip Context Inference

► Using Big Spatial Data for Planning User Mobility

Truth Discovery

Laure Berti-Équille

Aix-Marseille University, CNRS, LIS, Marseille, France

Introduction

In the era of Big Data, *volume*, *velocity*, and *variety* are commonly used to characterize the salient features of Big Data. However, the importance of *veracity*, the fourth “V” of Big Data, is now well-recognized as a critical dimension that needs to be assessed by joint solutions coming from various research communities such as natural language processing (NLP), database (DB), and machine learning (ML), as well as from data science practitioners and journalists (Cohen et al. 2011; Berti-Équille 2016). The problem of estimating veracity of online information in presence of multiple conflicting data is very challenging: information extraction suffers from uncertainties and errors; information sources may be dependent or colluded; and misinformation is evolving and spreading fast in complex social networks. All these aspects have to be well-understood to be properly modeled in order to detect and combat effectively fake news and misinformation campaigns.

Rumor detection, misinformation spreading truth discovery, and fact checking have been the subjects of much attention recently (see recent surveys (Berti-Équille and Borge-Holthoefer 2015; Li et al. 2015; Berti-Équille 2016) and comparative studies (Waguilh and Berti-Equille 2014)). Typically, the main goal of truth finding is to infer the veracity of online (conflicting) information being claimed and/or (repeatedly) amplified by some sources on the Web, the blogosphere, and the social media.

More and more sophisticated truth discovery model algorithms have been designed to capture the richness and complexity of real-world fact-checking scenarios, both for generic and specific cases. Monitoring and tracking systems have been developed and tested in operational contexts e.g., “Fact Check” in Google News for fact checking (e.g., ClaimBuster Hassan et al. 2017), or tracking the social dynamics of online news sharing (e.g., Hoaxy (Shao et al. 2016)).

In this chapter, we will review these lines of work and also touch upon some cutting-edge problems for discovering truth in settings where information from multiple sources is conflicting and rapidly evolving. We discuss how close we are to meeting these challenges and identify many open problems for future research.

Definitions

Reputation, trust, and trustworthiness are concepts closely related to truth discovery.

Trustworthiness was originally measured by checking whether the contributor (i.e., the source) was contained in a list of trusted providers, since there exists an interdependency between the source (as data provider) and the data itself. On the one hand, data is likely to be accepted as true if it is provided by a trustworthy provider. On the other hand, the source is trustworthy if it provides true data. Thus, both data and data source can be checked to measure their trustworthiness (Dong et al. 2016). However, the assumption that the value confidence can be measured using only its source trustworthiness has some limitations: for example, non-authoritative sources may provide

some true and relevant information, whereas reputable sources may provide false or erroneous information. Therefore the users have to make decisions based on factors such as some prior knowledge about the subject, the reputation of the source.

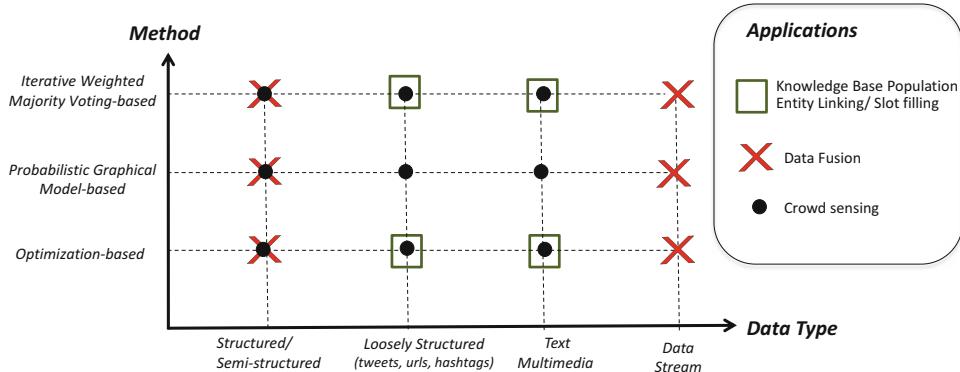

As we will see in the next section, the conjecture of SourceRank (Balakrishnan and Kambampati 2011) has influenced many research work in truth discovery: typically, in SourceRank, the more true relevant tuples a source returns, the more likely that other independent sources agree with its results. Inversely, independent sources are not very likely to agree on the same false tuples. Various methods have been then proposed to compute:

- Source trustworthiness as a score that quantifies how reliable the source is: It is a function of the confidence of its claims (also referred as source accuracy, quality, or reliability)
- value confidence as a score that quantifies the veracity of the claim. It is a function of the trustworthiness of the sources claiming it.

Current approaches for evaluating the veracity of data are iterative methods that compute and update each source trustworthiness score and then update the belief score of their claimed values.

Classification and Evolution of Truth Discovery Methods

We propose a classification of existing approaches across a two-dimensional space as illustrated in Fig. 1. Figure 1 presents a high-level view of the coverage of current methods in terms of applications such as data fusion, knowledge base population, and social sensing with crowd sourced data. The X-axis presents the considered data types in four categories based on the data structure: structured and semi-structured data, loosely structured and microtexts, free text or multimedia content, and data streams. The Y-axis defines the main principle of the underlying truth discovery methods such as weighted majority voting, probabilistic methods, or optimization-based methods as we will detail as follows.

Truth Discovery, Fig. 1 Classification of the main approaches for truth discovery with typical application contexts, underlying computation model and data type

- **Weighted voting-based methods** compute the value labels (i.e., true or false) and confidence scores using some variant of majority voting (MV) (Galland et al. 2010; Pasternack and Roth 2010; Yin and Han 2007). Traditional MV regards the value claimed by the majority of sources as the true value and randomly selects a value in case of tie with $1/|V_{o_a}|$ chance to infer the truth wrongly (with $|V_{o_a}|$, the number of distinct, conflicting values for the considered attribute a of object o). The reason is that MV assumes that each source has the same quality, but in reality, sources have different qualities, coverage, and scope. Various methods have adapted MV such that truths can be inferred through weighted voting to follow the principle that the information from reliable sources will be counted more in the aggregation.
- **Bayesian and graphical probabilistic model-based methods** were proposed to precisely address the issues of MV mainly related to the latent (unknown) properties of the sources and of the claims. TRUTHFINDER (Yin and Han 2007) was the first method that applies Bayesian analysis to estimate source trustworthiness and identify true claims with taking value similarity into consideration. DEPEN AND ACCU models (Dong et al. 2009, 2010) were also the first Bayesian models that incorporate source copying detection techniques, highlighting the importance of

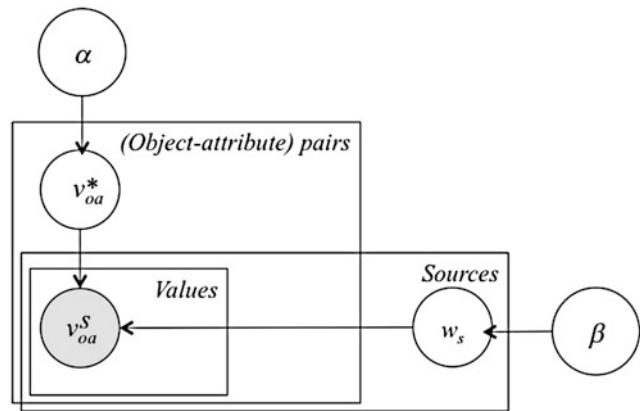

source dependence in truth discovery. Other methods (Zhao et al. 2012; Wang et al. 2012; Pasternack and Roth 2013) modeled a truth discovery scenario as a probabilistic graphical model (PGM) which expresses the conditional dependency structure (represented by edges) between random variables (represented by nodes). Figure 2 shows the generic PGM for truth discovery. In these approaches, the unknown identified truth noted $\{v_{o_a}^*\}$ and weights of the sources $\{w_s\}$ are the latent variables with a prior about the truth, denoted by α and a prior about the source reliability, denoted by β . The main principle is the following: if claimed values are close to the identified truth, the sources supporting them will gain weights. The goal is to maximize the likelihood and estimate high source weights when claims are close to the ground truth. To infer the two latent variables, techniques such as expectation maximization (EM) are adopted (Wang et al. 2012; Pasternack and Roth 2013), and the corresponding likelihood of a value being true is defined as:

$$\prod_{s \in S} p(w_s | \beta) \prod_{o \in O} \left(p(v_{o_a}^* | \alpha) \prod_{s \in S} p(v_{o_a}^s | v_{o_a}^*, w_s) \right). \quad (1)$$

- **Optimization-based methods** rely on setting an optimization function that can capture

Truth Discovery, Fig. 2

Generic plate diagram for GPM-based truth discovery methods

the relations between sources' qualities and claims' truth with an iterative method for computing these two sets of parameters jointly. The optimization function is generally formulated as:

$$\arg \min_{\{w_s\}, \{v_{oa}^*\}} \sum_{o \in O} \sum_{s \in S} w_s d(v_{oa}^s, v_{oa}^*) \quad (2)$$

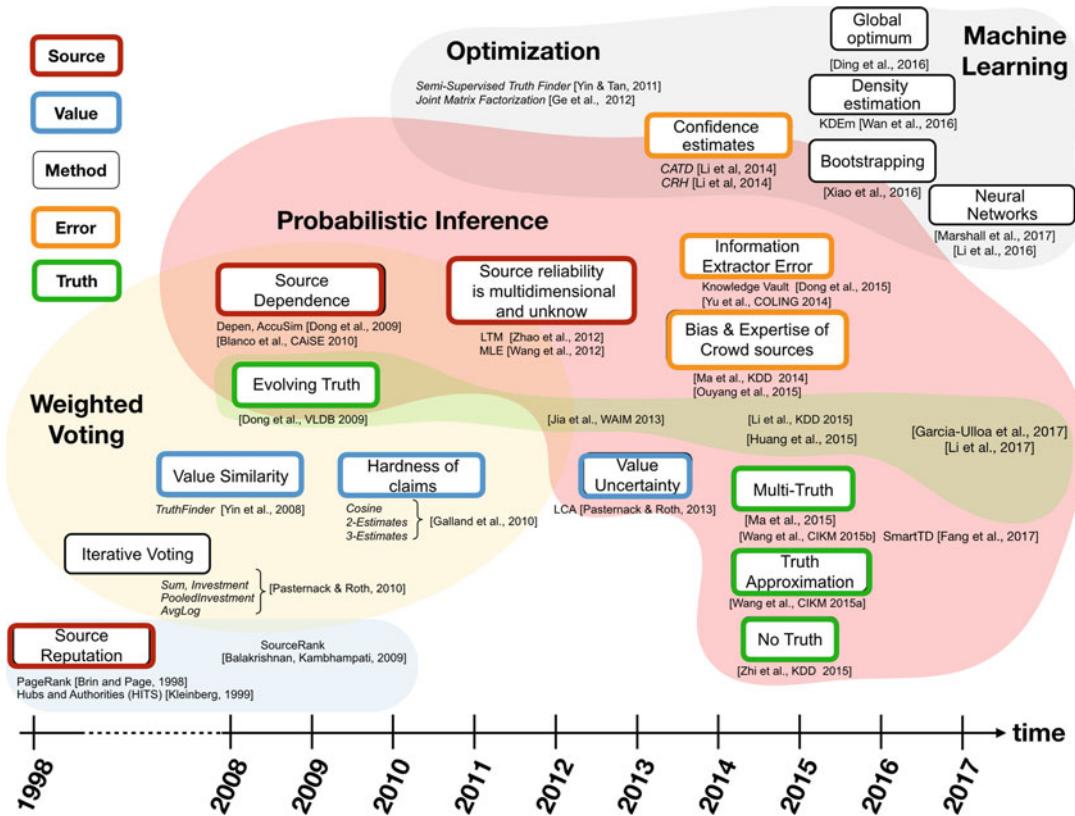

where $d(\cdot)$ is a distance function that measures the difference between the information provided by source s and the identified truth (e.g., 0–1 loss function for categorical data or L_2 -norm for continuous data). The objective function measures the weighted distance between the value for an object-attribute pair denoted $\{v_{oa}^s\}$ claimed by source s and the identified truth $\{v_{oa}^*\}$. By minimizing this function, the aggregated results will be closer to the information from the sources with high weights.

As illustrated in Fig. 3, the methods have significantly evolved in the last decade. The main trigger of this evolution is to overcome some of the limitations of previous approaches and to relax some modeling assumptions related to the sources (red boxes in the figure), their claimed values (blue boxes), the truth characteristics (green boxes), and the uncertainty or error associated (orange boxes) as we will mention in section “Modeling Considerations”.

Key Research Findings

We will now present the main principle and core algorithm of truth discovery and review the modeling assumptions underlying the key research findings in this domain. Truth discovery methods applied to structured data take as input some conflicting quadruplets in the form of $\{\text{source}, \text{object}, \text{attribute}, \text{value}\}$, where $\text{source} (s \in S)$ denotes the location where the data originates, $\text{object} (o \in O)$ is an entity, attribute is an attribute of the object, and $\text{value} (v \in V_{oa}^s \subset V)$ is the value of an attribute of an object claimed by a source. For example, a quadruplet: (imdb.com, director of Star Wars: Episode VIII - The Last Jedi, Rian Johnson) indicates that the website “IMDb” claims that the director of the movie “Star Wars: Episode VIII - The Last Jedi” is “Rian Johnson.” If a is a single-valued attribute for object o , $|V_{oa}^s| = 1$. In case of a multi-valued attribute, e.g., “the list of actors” or “full cast and crew”, $|V_{oa}^s|$ is bigger than 1.

For each input quadruplet, the methods infer a Boolean truth label (i.e., true or false) as the output. Formally, we name the factual value of an attribute a of an object o as the ground truth, denoted by v_{oa}^* . We note $(v)_m$ the label output given by a truth discovery method m for value v as the identified truth. Each method outputs the identified truth for each object and its set of attributes. We denote the identified truth labels of all objects' attributes in O output by method m as (V_{oam}) and the ground truth of v_{oa}^* . The

Truth Discovery, Fig. 3 Evolution of truth discovery research

closer (v_{o_a})_m is to $v_{o_a}^*$ for each attribute of each object, the better the method m performs. In most cases, the ground truth provided with real-world datasets is only a subset of the complete ground truth due to the prohibitive cost of collecting ground truth data.

Core Iterative Algorithm

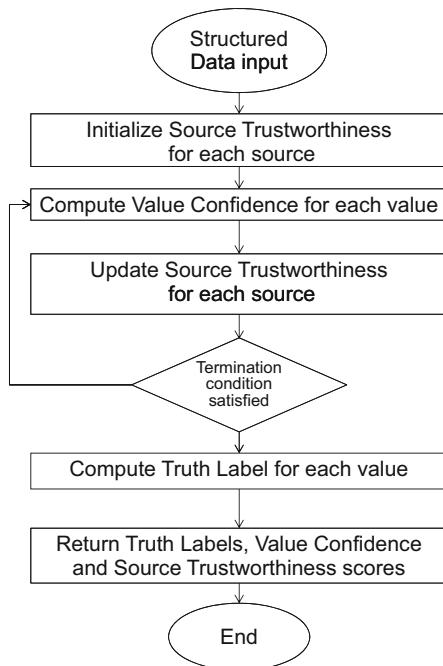

As illustrated in Fig. 4, the core algorithm of a fact finder is an iterative, transitive voting algorithm. First, the trustworthiness of each source is initialized. For each object and each attribute value, the method calculates the confidence from the reliability of its sources. Then, it updates the trustworthiness of each source from the confidence of the claims it makes. The procedure is repeated until the stopping condition is satisfied. Usually, the stopping criterion is defined either as a maximum number of iterations or a threshold under which the results (i.e., value confidence or

source trustworthiness scores) are considered to be stable from one iteration to the next. Some methods start with initializing the confidence scores of the values instead of the source trustworthiness, then compute source trustworthiness and update value confidence scores in a similar way. The methods differ in the way they compute and update the two scores as presented in section “Classification and Evolution of Truth Discovery Methods”.

Modeling Considerations

Every truth discovery method relies on several modeling assumptions related to the sources, the input claims, the truth, and the output result.

- **Modeling the sources.** Three main modeling assumptions concern the sources: (1) Sources are assumed to be self-consistent and nonredundant. This means that a source

Truth Discovery, Fig. 4 Basic iterative algorithm for truth discovery

should neither claim conflicting values for the same object-attribute pair nor provide duplicate claims; (2) current methods rely on trusting the majority, and they are adapted only when the sources are assumed to be predominantly honest and the number of sources providing true claims is assumed to be significantly larger than the number of sources providing false claims. This assumption referred in Waguilh and Bertie-Equille (2014) as the “optimistic scenario” is an important limitation for nowadays truth discovery scenarios.

- **Modeling the input claims.** Several considerations are important: (1) The cardinality (e.g., single or multi-valued attributes) and type of input claims (e.g., nominal vs numeric data) will determine the methods that can be applied and if data formatting is required; (2) the hardness of evaluating certain claims veracity can be considered in the model (see Galland et al. 2010); (3) the extraction of structured claims is generally assumed to have no error, but

information extractors can generate uncertainties to be considered in truth discovery computation (see Dong et al. 2014); (4) only claims with a direct source attribution are considered in the current methods. This requires that each claim has its source explicitly identified with a direct correspondence; (5) claims are usually assumed to be positive (except in Galland et al. 2010): e.g., *S claims that A is false* or *S does not claim A is true* are not considered by current methods; (6) regarding claim uncertainty, few methods (e.g., LCA Pasternack and Roth 2013) can handle cases such as *S claims that A is true with 15% uncertainty*. They use a weight matrix to express the confidence of each source in its assertions.

- **Modeling the relationship between source reliability and claim truthfulness.** (1) A potential limitation of current approaches is that the relationships between source reliability and claim truthfulness are often represented by simplified functions (e.g., linear, quadratic, or binomial). This assumption may lead to suboptimal truth discovery results because the exact relational dependency between sources and claims is usually unknown *a priori*; (2) another important related assumption is that the probability a source asserts a claim is independent of the truth of the claim. For example, some sources may choose to stay silent except for trivial or “easy” truths. This will lead to a very high trustworthiness score for these sources, although they may not deserve it. Penalties in these cases can be applied to refine some existing model in order to address the “long-tail phenomenon” (Li et al. 2014).
- **Modeling choices for the truth and output results.** (1) Each claim is assumed to be either true or false. Although value confidence score is generally returned as output by every method, truth labeling is usually Boolean with no contextual information or additional evidence (except in Waguilh et al. 2015 where a posteriori explanations of the truth discovery results are provided in the form of decision trees and the robustness of a true claim is tested with the generation of allegations); (2) single-truth assumption: Claims related to the

attribute of an object are organized into disjoint mutual exclusion sets where only one of the claims in each set is generally assumed to be true. However, some methods can handle multi-truth scenarios (e.g., LTM Zhao et al. 2012) and situations where none of the values claimed by the sources is actually true (Zhi et al. 2015).

- **Evaluation limits.** To evaluate efficiency and effectiveness performance of truth discovery methods, various metrics are traditionally used. Memory cost and running time can be used to evaluate the efficiency. Recall, precision, F1-measure, accuracy (or error rate) for categorical data, mean of absolute error (MAE), and root of mean square error (RMSE) for continuous data are computed for quality performance when ground truth is available. However, the labor cost of collecting ground truth is usually prohibitive. As a consequence, ground truth is often very limited or even impossible to obtain in a reasonable amount. Methods that show the same accuracy on sparse ground truth may have different performance in reality. Under these circumstances, it is hard to conclude which method performs better as we cannot trust the comparison results due to its low statistical significance over sparse ground truth (Berti-Équille and Borge-Holthoefer 2015; Waguilh and Berti-Equille 2014).

Relaxing these modeling assumptions, enlarging the range of real-world scenarios captured by the models, evaluating and benchmarking truth discovery methods, and estimating the significance of the evaluation results based on sparse ground truth are the next challenging milestones in the truth discovery research agenda.

Novel Research Directions

Novel approaches leveraging machine learning have been recently proposed. They are promising research directions for addressing the great diversity of real-world misinformation scenarios.

ETCIBoot (Estimating truth and confidence interval via bootstrapping) (Xiao et al. 2016). Existing truth discovery methods focus on providing a point estimator for each object’s truth, but in many real-world applications, confidence interval estimation of truths is more desirable because it contains richer information. ETCIBoot constructs confidence interval estimates as well as identifies truths with integrating bootstrapping techniques into the truth discovery procedure. Due to the properties of bootstrapping, the estimators obtained by ETCIBoot are more accurate and robust compared with the state-of-the-art truth discovery approaches. The authors of Xiao et al. (2016) theoretically prove the asymptotic consistency of the confidence interval obtained by ETCIBoot.

Neural networks. A novel neural network-based approach has been recently proposed by Marshall et al. (2018). This method can learn complex relational dependency between source reliability and claim truthfulness. A multi-layer neural network model has been developed to solve the truth discovery problem in social sensing without any assumption on the prior knowledge of the source-claim relational dependency distribution. In particular, a neural network for truth discovery is defined by a set of input neurons which are activated by social sensing data (i.e., sources and the claims they make). After being weighted and transformed by a learning function, the activation of these neurons are then passed on to other neurons inside the neural networks. This process is repeated until the output neuron that determines the truthfulness of a claim is activated. The complex source-claim relational dependency is learned by the neural network model through the above training process.

Conclusions

This chapter presented an overview of recent advances of truth discovery research emphasizing on the main methods and their underlying modeling assumptions.

We have observed that none of the methods constantly outperforms the others in terms of precision/recall, and a “one-fits-all” approach does not seem to be achievable. Most of the current methods have been designed for excelling in *optimistic* scenarios with a reasonable number of honest and reliable sources. However, experiments (e.g.) in Waguih and Berti-Équille (2014) revealed that, for *pessimistic* or adversarial scenarios when most of sources are not reliable, most of the methods have relatively low precision and some expose prohibitive runtime and may suffer from scalability or fluctuating results. Ensembling (Berti-Équille 2015) and bootstrapping (Xiao et al. 2016) truth discovery methods seems to be very promising research directions.

Another challenge is related to the usability of the methods. The assumptions made by current truth discovery models and their complex parameter settings make most methods still difficult to apply to the wide diversity of on-line information and existing scenarios on the Web. Since limited and generally sparse ground truth is available, performance evaluation and comparative studies may not be reliable and have low statistical significance; to this matter, benchmarks and repeatability experiments are critically needed.

Types of Stream Processing Algorithms

Lukasz Golab
University of Waterloo, Waterloo, ON, Canada

Synonyms

[One-pass algorithms](#); [Online Algorithms](#)

Definitions

A stream processing algorithm operates over a continuous and potentially unbounded stream of data, arriving at a possibly very high speed, one item or one batch of items at a time, and does so in limited time per item and using limited working storage. At any point in time, a stream algorithm can produce an answer over the prefix of the stream observed so far or over a sliding

window of recent data. Stream processing algorithms are used to answer *continuous* queries, also known as *standing* queries.

Stream processing algorithms can be categorized according to (1) what output they compute (e.g., what function is being computed, is the answer exact or approximate) and (2) how they compute the output (e.g., sampling vs. hashing, single-threaded vs. distributed, one-pass vs. several passes).

Overview

Stream processing algorithms operate sequentially over unbounded input streams and produce output streams. The input stream is assumed to consist of *items* which may be key-value pairs or structured tuples. Stream algorithms face the following common challenges.

- In contrast to offline algorithms, the input is not provided in advance, and instead it arrives continuously and sequentially, possibly at a very high speed, one item or one batch of items at a time. The data arrival order cannot be controlled by the algorithm as it is determined by the source (and perhaps also by the communication channel which may reorder the data).
- In order to keep up with the input, the algorithm must process items in limited time and using limited (and fast) working storage. Latency must be low as late results rapidly lose value. For example, in network and infrastructure monitoring, anomalies and attacks must be detected as quickly as possible.

Although they share the above characteristics, there is a wide variety of stream processing algorithms. They can be classified based on semantics (what is computed) and methodologies (how it is computed).

Semantic Classification

From the point of view of semantics, one can classify stream processing algorithms into the following types:

- What function or query is computed? Examples include identifying frequently occurring items and counting the number of distinct items.
 - Is the output exact or approximate? Many stream processing algorithms produce approximate answers as a consequence of using limited time and memory. However, some simple functions may be computed exactly. For example, to output the maximum value seen so far in a stream of numbers, it suffices to keep track of the current maximum value and compare it to every incoming value.
 - Is the output computed over the entire stream observed so far or over a sliding window?
- any parallel algorithm, load balancing is critical (Nasir et al. 2015). Additionally, some algorithms may be distributed by moving some computation to sources of the data (e.g., sensors or network interface cards).
- How many passes over the stream are allowed? In many applications, only one pass is allowed, so an algorithm only gets one look at the data. However, multi-pass algorithms have also been studied. These are useful in applications where a data stream has already been collected and can be played back several times or when a static dataset is processed sequentially offline.

Technical Classification

From a technical point of view, stream processing algorithm may be classified as follows:

- How is an unbounded stream “compressed” to fit in limited working storage? In high-volume stream processing, even sliding windows may be too large to store and process. Furthermore, the space of possible distinct items (*keys*) may be too large to fit in memory (e.g., all possible IP addresses). Stream processing algorithms may use *sampling* to decide which items to retain in working storage and *hashing* or *sketching* (Cormode 2017) to map the key space to a smaller domain. Of course, the use of sampling, hashing, or other lossy summarization techniques means that results will not be exact.
- Parallelism and distribution. Classical stream algorithms assume a single processing thread, but modern distributed stream processing infrastructures support inter- and intra-operator parallelism. In inter-operator parallelism, different operators are executed by different nodes in a computing cluster. In intra-operator parallelism, multiple instances of the same operator are running and are responsible for different parts of the input. For example, frequency counts may be computed in parallel by dividing the key space among threads. As is the case in

Key Research Findings

The three Vs of big data are volume, velocity, and variety. “Big streams” are characterized by high volume, fast arrival rates, and a wide variety of distinct items or keys (e.g., the number of distinct IP addresses in an Internet traffic stream). What follows is a summary of key research findings on algorithms for large-scale stream processing.

Stream Processing Algorithms

This section discusses fundamental algorithms for popular stream processing tasks: sampling from a stream, counting the number of distinct items (also known as *cardinality estimation*), and identifying frequently occurring items. Let d be the number of distinct items or keys in the stream and let n be the total number of items in the stream (of course n is not known in advance).

One of the earliest stream processing algorithms produced a random sample of r items from the stream (Vitter 1985). Random sampling is an important operation as it can be used to estimate various statistical properties of the stream. Note that if n is known, the sampling from the stream is easy: each item should be sampled with probability $\frac{r}{n}$. However, in an online setting where the stream arrives one item at a time, n is not known a priori.

The algorithm, called *reservoir sampling*, works as follows. The first r items that arrive are included in the sample. When the $r + 1$ st

item arrives, with probability $\frac{r}{r+1}$, the new item replaces a randomly selected item from the current sample (and with probability $1 - \frac{r}{r+1}$, the new item is ignored). More details about stream sampling may be found in Haas (2016).

Note that some data stream engines employ *load shedding* (Babcock et al. 2004; Tatbul et al. 2003) by randomly dropping some stream items during periods of overload and processing all items during steady state. However, this type of random load shedding does not produce a random sample of the stream.

Another early work on stream processing considered (approximately) counting the number of distinct items in the stream (Flajolet and Martin 1983) and then is improved in Durand and Flajolet (2003) and Flajolet et al. (2007). It is assumed that there are more distinct items than can fit in memory, and therefore it is not possible to compute the distinct count exactly by indexing the items.

The Flajolet-Martin algorithm requires only $\log(d)$ space. The main idea is to use a random hash function that maps stream items to bit vectors of length $\log(d)$. On average, one would expect half the items to hash to bit vectors that end with a zero and the other half to hash to bit vectors that end with a one. Similarly, on average, a quarter of the items should hash to bit vectors that end with two zeros and so on. In general, $\frac{1}{2^k}$ items should have to bit vectors that end with k zeros. To exploit this observation, the algorithm hashes each item and records the number of zeros the hash ends with. Let ℓ be largest number of such trailing zeros seen so far. It turns out that a reliable estimate for the number of distinct items is $\frac{2^\ell}{0.77351}$. To improve accuracy, multiple hash functions can be used, and the resulting estimates can be averaged.

Streaming algorithms for identifying frequently occurring items must also resort to approximation – in large-scale data streams, there may not be enough fast memory or enough per-item processing time to maintain frequency counters for all items. The challenge is to decide which item frequencies to track at a given point in time. Note that initially infrequent items may become frequent over the lifetime of stream. A

survey and an experimental comparison of well-known frequent item algorithms may be found in Cormode and Hadjieleftheriou (2010).

Two approaches for identifying frequent items have appeared in the literature:

- Counter-based approaches: allocate some number of counters to maintain the frequencies of selected items.
- Sketch-based approaches: maintain a small summary of the stream and use it to identify frequent items.

One of the earliest frequent item algorithms used a counter-based approach (Misra and Gries 1982). It uses k counters, each labeled with the item it represents, and identifies items that appear at least $\frac{n}{k}$ times. Initially, all counters are set to zero and their labels are blank. When a new item arrives with value v and there already exists a counter for v , that counter is incremented. Otherwise, if there is at least one counter with a count of zero, this counter now becomes allocated to v and is incremented. Otherwise, if all k counters are non-zero, then *all* k counters are decremented. A similar algorithm called *Space Saving* was proposed subsequently. It differs in how it handles the case when all k counters are non-zero: *Space Saving* selects the counter with the smallest count, gives it to v , and increments it (Metwally et al. 2005). Other examples of counter-based algorithms for finding frequent items (and quantiles) include Greenwald and Khanna (2001) and Manku and Motwani (2002).

On the other hand, the Count-Min sketch (Cormode and Muthukrishnan 2005) and earlier related sketches (such as Charikar et al. 2002) are examples of a stream summaries that can approximate the frequency distributions of items and therefore identify frequent items. These techniques use a set of independent hash functions to map newly arrived items onto a smaller space.

Sliding Window Algorithms

Let w be the sliding window size, either in the number of items or time units. Let s be the slide

interval of a window; e.g., a *time-based* window may have a size of 10 minutes, and it may slide forward every minute, whereas a *count-based* window may store the most recent 1000 items and may slide every ten items.

The stream processing algorithms described earlier had to deal with inserting new items. The additional technical challenge in sliding window processing is removing items that *expire* from the window. Notice that every item eventually expires, which happens w time units after its insertion or after w new items have arrived.

The remainder of this section discusses algorithms for sampling from sliding windows, computing approximate statistics using limited space, computing simple aggregates exactly using limited space, and joining multiple streams using sliding windows.

Sliding window sampling algorithms were presented in Babcock et al. (2002). For count-based windows, the idea is to reuse reservoir sampling. However, whenever an item is included in the sample, the index, or position within the stream, of its *successor* is preselected by randomly choosing an index from the next window (the w items that will arrive after the original item expires). For time-based windows, the idea is to assign a priority to each element, corresponding to a random number between zero and one. The sample then includes k non-expired items with the highest priority. Importantly, it is not sufficient to store just those k items. Additionally, the algorithm stores items for which there is no item with both a later timestamp and a higher priority. This ensures that any sampled item that expires can be replaced with another stored item. The sampling algorithms were later improved by Braverman et al. (2012).

There exist many algorithms for approximately computing various statistics over count-based sliding windows using sublinear space, including counts, sums, quantiles, and frequent items (Arasu and Manku 2004; Datar et al. 2002; Lee and Ting 2006). The idea is to partition a window into blocks or sub-windows and precompute some statistic for each block. When the window slides forward, new blocks are opened and old blocks are expired.

Approximation is due to the fact that the oldest block may contain some items that have already expired.

A special case has also been studied of computing simple group-by aggregates such as sum and average over count- or time-based windows. This can be done without storing all the items in the window. Again, the idea is to partition a window into buckets whose sizes are equal to the slide interval and pre-aggregate the items within each bucket. The final result is computed by merging the partial aggregates from each bucket, and old buckets are replaced with new buckets as the window slides. For example, to compute the sum of the values for each key, it suffices to add up the partial sums pre-aggregated in each bucket. Examples of this method, and related methods that maintain a hierarchical structure of buckets, can be found in, e.g., (Arasu and Widom 2004; Bulut and Singh 2005; Krishnamurthy et al. 2006; Li et al. 2005).

Since data streams are unbounded, joining two (or more) streams is usually done using sliding windows. When a new item arrives on one stream, it can only join with a window of items from the other stream. A simple pipelined hash join implementation maintains hash tables for both windows, and when a new item arrives on one stream, it is inserted into its window and the other window is probed for matching items. Hash tables can be partitioned into buckets to make data expiration easier. Examples of sliding window join algorithms may be found in, e.g., (Golab and Özsu 2003; Kang et al. 2003). A parallel implementation was proposed in Teubner and Müller (2011).

T

Distributed Algorithms

In data stream processing, distributed computation can refer to one of the following two scenarios:

1. Data streams continuously arrive, potentially from multiple distributed sources, to a stream processing system, which consists of multiple compute nodes. Each node may be responsible for processing different parts of the stream

- (e.g., different subsets of keys) or different query operators.
2. Data streams are continuously generated and partially processed by distributed sources. Pre-processed streams arrive to a stream processing system for final processing.

In the first scenario, distributed systems such as Spark Streaming have recently been proposed (Zaharia et al. 2013). These systems execute MapReduce-style jobs over (small) batches of data. Furthermore, many of the counter-based and sketch-based algorithms discussed earlier have a useful property that the underlying data structures are *mergeable* while preserving their error guarantees (Agarwal et al. 2013). That is, different processing nodes can work on different subsets of the stream and produce local summaries, and the final answer can be computed from the merged summary.

In the second scenario, some computation (and data volume reduction) can be done by the sources (sensors, network interface cards, etc.). This approach is useful when it is infeasible to send all the data for processing due to insufficient processing resource and/or insufficient bandwidth. There are two ways to realize this approach: pull-based and push-based. In pull-based methods, the system periodically requests new data from the sources to recompute the result or a function of interest. In push-based methods, the sources decide when to push updates to the system. The challenge is to determine a trade-off between push frequency (and therefore communication bandwidth) and data freshness. Push-based methods have been studied for computing statistics such as sums over distributed streams (Olston et al. 2003) and maintaining the k largest values in distributed streams (Babcock and Olston 2003). Furthermore, sampling over distributed streams has been studied by Cormode et al. (2012).

Examples of Applications

Internet traffic monitoring was an early motivating application: identifying source or destination

IP addresses that consume significant bandwidth, detecting attacks and malfunctions, etc. (Cranor et al. 2003). Sensor networks (Madden and Franklin 2002) and electronic financial trading (Stonebraker et al. 2005) were also mentioned. Recently, large-scale distributed stream processing systems have been built to analyze social media streams (e.g., Twitter's Heron Kulkarni et al. 2015) and Web search logs (e.g., Google's MillWheel Akidau et al. 2013), and there is recent interest in stream processing for energy analytics (Liu et al. 2017).

Future Directions for Research

A majority of existing work on stream processing algorithms focuses on computing functions and aggregates over numeric streams. Recently, there has been work on complex tasks such as online machine learning models. Another area for future research involves streaming graph processing, where the input consists of edges and nodes of a time-evolving graph.

Uncertain Data Integration

- ▶ Probabilistic Data Integration

Definitions

A set of methods to support a matching process among elements of multiple data sources, using uncertainty management tools to quantify the inherent uncertainty in the process.

Uncertain Ontology Alignment

- ▶ Uncertain Schema Matching

Overview

Data integration has been the focus of research for many years now, motivated by data heterogeneity (arriving from multiple sources), the lack of sufficient semantics to fully understand the meaning of data, and errors that may stem from incorrect data insertion and modifications (e.g., typos and eliminations).

At the heart of the data integration process is a schema matching problem (Bellahsene 2011) whose outcome is a collection of correspondences between different representations of the same real-world construct. Schema matching research has been going on for more than 25 years now, first as part of schema integration and then as a stand-alone research field (see surveys Batini et al. 1986; Rahm and Bernstein 2001; Shvaiko and Euzenat 2005). Over the years, a significant body of work has been devoted to the identification of *schema matchers*, heuristics for schema matching. The main objective of schema matchers is to provide correspondences. Examples of algorithmic tools used for schema matching include COMA (Do and Rahm 2002),

Cupid (Madhavan et al. 2001), OntoBuilder (Modica et al. 2001), Autoplex (Berlin and Motro 2001), Similarity Flooding (Melnik et al. 2003), Clio (Miller et al. 2001), Glue (Doan et al. 2002), and others (Bergamaschi et al. 2001; Saleem et al. 2007). These have come out of a variety of different research communities, including database management, information retrieval, the information sciences, data semantics and the semantic Web, and others. Research papers from different communities have yielded overlapping, similar, and sometimes identical results. Meanwhile, benchmarks, such as the OAEI ([Ontology alignment evaluation initiative](#)), indicate that the performance of schema matchers still leaves something to be desired.

In recent years, data integration has been facing new challenges as a result of the evolution of data accumulation, management, analytics, and visualization (a phenomenon known as *big data*). Big data is mainly about collecting *volumes* of data in an increased *velocity* from a *variety* of sources, each with its own level of *veracity*. Big data encompasses technological advancements such as the Internet of things (accumulation), cloud computing (management), and deep learning (analytics), packaging it all together while providing an exciting arena for new and challenging research agenda. The veracity of data puts aspects of uncertainty as a forefront challenge in any big data integration task. In particular, a matcher may consider several possible correspondences as possible, and when it needs to choose, it may choose wrong (Gal 2006). For example, when two companies merge, the companies' employee databases need to be consolidated. The schemata may be different, and in such a case, there may be many different ways of mapping one schema to another. As another example, a Web search engine performing a product search over databases of multiple vendors needs to find correspondences between the product databases of different vendors. Multiple ways of representing the data might lead to multiple possible correspondences.

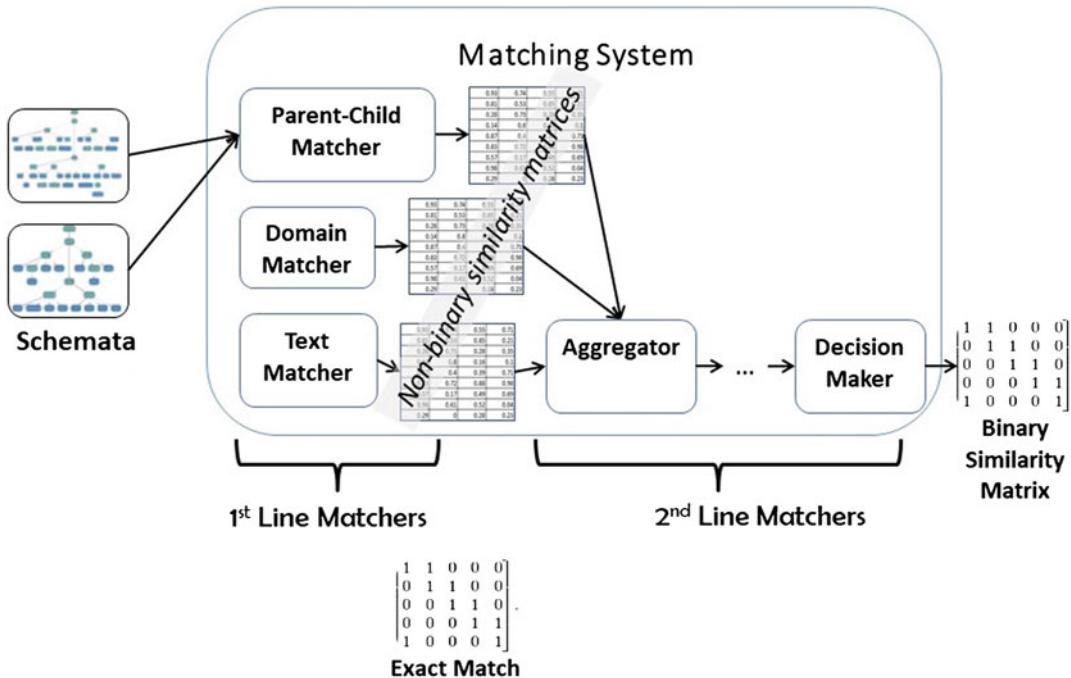

The realization that schema matchers are inherently uncertain has emerged even before the age of big data. A prime reason for the

uncertainty of the matching process is the enormous ambiguity and heterogeneity of data description concepts: it is unrealistic to expect a single matcher to identify the correct mapping for any possible concept in a set. Madhavan et al. (2002) argued for the need “to incorporate *inaccurate* mappings and handle *uncertainty* about mappings. Inaccuracy arises because in many contexts there is no precise mapping... mappings may be inaccurate [since] the mappings language is too restricted to express more accurate mappings.” Since 2003, work on the uncertainty in schema matching has picked up (along with research on uncertainty in other areas of data management) (Dong et al. 2009; Gal et al. 2009).

Key Research Findings

A matching process matches two schemata by aligning their attributes. Many matching techniques exist, see surveys (e.g., Bernstein et al. 2011) and books (e.g., Gal 2011), using matching cues such as attribute names, instance data, schema structure, etc. The result of a matching problem is a collection of correspondences between attributes. This collection is often formalized as a similarity matrix between the corresponding schemata. Each row and column in the matrix correspond to one of the matched attribute sets. Therefore, each entry in the matrix represents the degree of confidence that the two attributes correspond. Confidence is usually expressed as a real value in $[0, 1]$. Binary similarity matrices are constrained to allow entries in $\{0, 1\}$ only (match/non-match).

Matching is often a stepped process (see Fig. 1) in which different algorithms, rules, and constraints are applied. Several classifications of matching steps have been proposed over the years. Matchers can be separated into those that are applied directly to the problem (*first-line matchers* – 1LMs) and those that are applied to the outcome of other matchers (*second-line matchers* – 2LMs). 1LMs receive two schemata and return a similarity matrix. Table 1 provides an example of the outcome of a 1LM, matching two

Uncertain Schema Matching, Fig. 1 A matching system illustrated

schemata in a reservation system. Such a matcher gives high scores to attributes with similar names. 2LMs receive one or more similarity matrices and return a similarity matrix. Among the 2LMs, we term *decision-makers* those that return a binary matrix as an output, also known as *alignments as solutions* (Shvaiko and Euzenat 2005). For example, Table 2 represents the outcome of

a decision-making 2LM that enforces a 1 : 1 matching over the similarity matrix of Table 1.

ILMs are bound to provide uncertain results. Similarity functions return an uncertain value, typically between 0 and 1. Most data integration evaluation methods to date use a binary (match/no match) approach, while the variety and veracity of big data require to broaden evaluation to a full scope in between. As a concrete example, consider the evaluation measures of precision and recall, common in the area of information retrieval. These measures test the completeness and soundness of a matcher outcome with respect to some reference match. Precision and recall are based on a binary correspondence comparison, which requires binary decision-making from the matcher side and a binary reference match. With big data integration, matchers may not be able to provide a crisp decision regarding a correspondence and may prefer to provide an uncertain one (in terms, e.g., of a probability). On the other hand, research shows (Sagi and Gal 2014) that experts may fail to agree on a reference match and instead multiple opinions can be gathered regarding the correctness of a correspondence.

Utilizing existing measures requires us to binarize both algorithmic and human aggregate responses and implicitly assume that the human’s result is to be preferred over the algorithmic response. Since we do not assume humans to be inherently better at matching, especially if they are given partial context as part of a pay-as-you-go scheme (e.g., Zhang et al. 2013), information regarding both parties’ uncertainty should be retained and used in disagreement resolution. An initial work on non-binary evaluation, using finite real vector space representation, extends traditional measures and suggests a fresh approach toward quality measures in an uncertain setting (Sagi and Gal 2018).

Many of the 2LMs are decision-makers, which is modeled as a binary similarity matrix. When it comes to uncertain schema matching, one may take advantage of an explicit modeling of uncertainty as part of the schema matching process; see, for example, the use of Bayesian probabilistic models for matching (Assoudi and Lounis 2015).

Madhavan et al. (2002) argue that “when no accurate mapping exists, the issue becomes one of choosing the *best* mapping from the viable ones.” The latter approach was later extended to handle Top- K multiple schema matches in parallel (Gal 2006; Domshlak et al. 2007). Top- K schema matches are intuitively defined as a ranked list of the best K schema matches a matcher can generate. The formal definition is recursive, providing interesting insights into the behavior patterns of matchers. Top- K schema matches play a pivotal role in managing uncertain schema matching. The effectively unlimited heterogeneity and ambiguity of data description suggest that in many cases an exact match will not be identified as a best match by any schema matcher. Therefore, top- K schema matches serve to create a search space in uncertain settings (Bernstein et al. 2006) and can also help improve the precision of matching results (Gal 2006). All in all, empirical results have shown the top- K list to be a quality set of candidates for schema matching.

Extended solutions, which consist of multiple possible matches, lead naturally to *probabilistic schema matching*, methods that quantify the rela-

tive confidence in multiple match results and use this quantification for query answering. Probabilistic schema matching studies two semantics for answering queries over multiple databases using probabilistic schema matches – a *by-table* semantics and a *by-tuple* semantics (Dong et al. 2009). The former semantics represents a situation where a single match should be applied to the entire set of tuples in the source relation. As for the latter, a choice of a match should be made for each of these tuples independently. The *by-tuple* semantics represents a situation in which data is gathered from multiple sources, each with a potentially different interpretation of a schema. An extension to the basic SPJ query answering under probabilistic schema matching into aggregations was presented by Gal et al. (2009).

An interesting aspect of uncertain schema matching is the possible lack of a reference match. Reference matches, the outcome of a manual validation, are rare, hard to come by and generate. In the absence of a reference match, schema matchers perform a “best effort” matching without any indication of the prospective success of their efforts. These observations led to research of *schema matching prediction* (Tu and Yu 2005; Sagi and Gal 2013), an assessment mechanism to support schema matchers in the absence of a reference match. A predictor measures the success of a matcher in identifying correct correspondences based on the matcher’s pair-wise similarity measures. For a predictor to be useful, its predictions should correlate well with the quality of the matcher’s decision-making.

Examples of Application

Over the years, schema matching research has expanded and specialized to answer research and application questions in a variety of domains. In its origin, schema matching was conceived to be a preliminary process to schema mapping to serve applications such as query rewriting and database integration. An underlying basic assumption of this original thinking was that schema matching

provides a set of definite (true or false) correspondences to be then validated by some human expert before mapping expressions are generated. This is no longer a valid assumption when it comes to uncertain schema matching. For example, consider an enterprise that is interested in investigating a new market, seeking partners with sufficient common interests to its own while providing sufficient added value to its capabilities. Matching here can ensure just the right amount of commonality between prospective business partners, judging what part of one schema can be covered (Saha et al. 2010) by attributes of another schema and vice versa. Also, effective reuse of previous matching results requires the accumulation of many attributes from which useful schemata for a specific need can be created. To ensure efficient processing, attribute repositories can be used to filter that only attributes of good quality are retrieved.

Prediction offers a promise for a whole new set of applications by presenting a designer with a quality assessment of a match as a first step toward decision-making under uncertainty. Prediction can serve in directing the flow of the integration process. For example, it can serve as a decision factor on whether the integration of two databases should be preferred over the design from scratch of a new database application. Prediction can also serve other schema matching tasks such as matcher self-configuration, matcher selection, user involvement optimization, etc. One example that illustrates the usefulness of prediction involves schema matcher ensemble construction. Contemporary ensemble tools, e.g., LSD (Doan et al. 2001), perform offline learning of matcher weights in an ensemble. Dynamically assigning weights can be done based on the matching outcome of individual matchers and their success prediction.

Future Directions for Research

The research area of schema matching is always in need of new heuristics, ILMs, to be added to ensembles of matchers and enable a better auto-

matic matching. Uncertainty management should be part of any such new heuristic to allow a better control over the quality of the matching outcome.

The ability to tap into crowdsourced and expert opinions in a piecemeal fashion has allowed pay-as-you-go frameworks for data integration (e.g., Hung et al. 2013; Zhang et al. 2013), to make flexible use of human input in integration processes. Such methods of evaluation should be carefully monitored from a perspective of uncertainty management.

Uncertainty in Streams

Avigdor Gal and Nicoló Rivetti
Faculty of Industrial Engineering and Management, Technion – Israel Institute of Technology, Haifa, Israel

Definitions

Models and algorithms that support a stream of events that may demonstrate uncertainty in event occurrence, as well as in values assigned to events in a stream.

Overview

Many contemporary applications depend on the ability to monitor efficiently streams of events (e.g., application messages or business events) to detect and react in a timely manner to situations. Some events are generated exogenously by devices such as sensors and flow across distributed systems. Other events (and their content) are inferred by complex event processing (CEP) systems. The first generation of CEP systems was built as stand-alone prototypes or as extensions of existing database engines. These systems were diversified into products with various approaches toward event processing, including stream-oriented, rule-oriented, imperative, and publish-subscribe paradigms. Common to all of these approaches is the assumption that received events have occurred and that the CEP system is complete. In other words the system captures all events and the values carried by events are deterministic and correct as the processing of the event itself. Second-generation CEP systems were extended to handle fault tolerance, adaptive query processing, and enhanced expressiveness. This chapter focuses on a specific functional aspect, namely, the ability to deal with uncertainty in event streams.

There are four basic approaches to handle uncertainty in event streams. First, in applications where uncertain situation are infrequent, simply

ignoring uncertainty turns out to be cost-effective since it may induce only negligible harm to the overall analysis. Alternatively, a deterministic approach may require absolute evidence to detect the situation. A third way to handle uncertainty is to get assistance from additional sources in case a situation detection is unreliable. A common solution (e.g., fraud detection) is to introduce a human observer in the loop, which monitors the detected situations and filters out false positives. Finally, a fourth approach is to quantify uncertainty (e.g., using probability theory) and then use tools such as utility theory to assist in decision-making.

Use-cases for second generation CEP engines include applications where the rate of false positives and negatives is non negligible, and simplistic approach to uncertainty may induce relevant, if not critical, damage. While the motivation exists, in general the handling of uncertainty in CEP is still a challenge. A few solutions have been presented, some being application dependent. Wasserkrug et al. (2012a,b) have presented the first model that deals with uncertainty in CEP. The model assumes independence of simple event occurrence, as in Zhang et al. (2013). Cugola et al. (2015) extended it also to complex events, while Ré et al. (2008) apply the Markovian hypothesis. It is worth noting that of all these works, only in Zhang et al. (2013) temporal uncertainty, is considered. These works leverage probability theory and Bayesian networks to build a probabilistic model, which in turn propagates the uncertainty from simple to complex events. In particular, Cugola et al. (2015) also take into account uncertainty at the rule level (i.e., incomplete or wrong assumptions about the environment).

Event Processing — An *event* is an occurrence within a particular system or domain (Etzion and Niblett 2010). It also represents the programming entity of the occurrence itself in a CEP engine. An event can either be *raw* or *derived*. A raw event is an event that is produced by an event producer (source), while a derived event is an event that is generated through the processing performed by the CEP engine. A derived event made of the composition of multiple events is said to

be composite. An event *pattern* is a template, specifying one or more relevant combinations of events. The matching of the pattern against the stream generates a *pattern matching set*, i.e., the set of sequences of events satisfying the pattern conditions. The pattern matching set can, in turn, become a derived event, either as a composite event or as an event resulting from some transformation applied to the set. A *situation* identifies an event occurrence (either raw or derived) that has to be handled.

Uncertainty Models

This section briefly describes three of the main alternatives for modeling uncertainty: *probability theory*, *fuzzy sets* (Zadeh 1965), and *possibility theory* (Halpern 2003). The three models differ in the way uncertainty is conceived and measured.

The **Probability theory** assumes that imperfect knowledge can be encoded as probabilities about sets of possible worlds. An intuitive way to define a probability space involves possible world semantics (Green and Tannen 2006). A probability space is a measure space with total measure one and is defined by a triple (W, F, μ) such that:

- W is the set of possible worlds, with each corresponding to a specific set of event occurrences that is considered possible.
- $F \subset 2^{|W|}$ is an algebra over W and F is a non-empty collection of sets of possible worlds that is closed under countable union and complementation.
- $\mu : F \rightarrow [0, 1]$ is a probability measure over F .

U

As an example, consider an unbiased coin single flip which can either be head or tail. We then have, i.e., $W = \{h, t\}$ while the algebra is $F = \{\emptyset, \{h\}, \{t\}, \{h, t\}\}$, where \emptyset is neither head nor tail and $\{h, t\}$ is head or tail. Finally, the probability measure μ is such that $\mu(\emptyset) = 0$, $\mu(\{h\}) = 0.5$, $\mu(\{t\}) = 0.5$, $\mu(\{h, t\}) = 1$

Bayesian (or belief) networks (Pearl 1988) are the most widely accepted paradigm for inference under uncertainty. Probability theory is used to capture the uncertainty by representing each

conjecture with a random variable. The random variables are modeled as nodes in a graph, where edges represent conditional dependencies. Such a graph, augmented by conditional probability tables, is a qualitative representation of the dependencies between nodes. Each node is assigned with the probability of each of its values, given the values of its parents. Several inference algorithms exist based upon this augmented graphical structure. To model temporal aspects, multiple extensions of Bayesian networks have been defined including Time Nets (Kanazawa 1991) and Temporal Nodes Bayesian Networks (Arroyo-Figueroa and Sucar 1999).

Probabilistic logics (Bacchus 1990; Halpern 1990) are general formal models suitable for the representation of probabilistic rules and may therefore be used to provide a formal setting for the representation of probabilistic knowledge in any particular domain. However, such logics are less suitable than Bayesian networks for the inference of probabilities given evidence.

A third alternative is the knowledge-based model construction (KBMC) paradigm. KBMC contains any probabilistic system in which the representation and inference models are separated. However, in most existing applications and specializations of this approach, knowledge is represented in a probabilistic logic, and inference is carried out by transforming the logical statements into a Bayesian network.

Fuzzy set theory defines a membership of an element x in a fuzzy set M on a universe U using a membership measure $\mu_M : U \rightarrow [0, 1]$, indicating the extent in which it is associated with the set (Zadeh 1965; Gal et al. 2005; Liu and Jacobsen 2004). Unlike probability theory, the degree of membership of an element over all fuzzy sets M does not necessarily sum to 1. Fuzzy logics are methods for reasoning with logical expressions describing membership in fuzzy sets. These logics define operators, such as triangular norms and fuzzy aggregates, to compute the membership measure of complex events.

Possibility theory associate a confidence measure π to an event (Dubois and Prade 1988). The possibility measure Π expresses the likelihood of event e occurrence, while the necessity measure N represents the unlikelihood

of the complement of e (Liu and Jacobsen 2004). These two measures satisfy the following equations:

$$N(e) = 1 - \Pi(\bar{e}) \quad (1)$$

$$\forall e, \Pi(e) \geq N(e) \quad (2)$$

If an event certainly occurs, then $\Pi(e) = 1$, and if it cannot occur, then $\Pi(e) = 0$. The intermediate values in $[0, 1]$ express different degrees of confidence in the event occurrence. Notice that, if $\Pi(e)$ is a probability distribution, then $\Pi(e) = N(e)$.

Discussion — Probabilistic and fuzzy set theory are competing methods for modeling uncertainty. A probabilistic approach assumes that there is no complete knowledge on what is modeled. However, this knowledge can be encoded as probabilities on events. The fuzzy approach aims at modeling the intrinsic imprecision of attributes of the modeled reality. Probabilistic reasoning relies on event independence assumptions, making event correlation hard or even impossible to evaluate. A study (Drakopoulos 1994) shows that probabilistic analysis is more expressive than fuzzy sets; however fuzzy sets are computationally more efficient.

Both fuzzy set theory and possibility theory use a numerical measure; however the former is more suited to represent uncertain description of an event (e.g., temperature value), while the latter defines the confidence in the occurrence of the event.

Element and Origin Uncertainty

Events uncertainty can be classified according to two orthogonal dimensions, namely, *element uncertainty* and *origin uncertainty*. The first dimension, element uncertainty, either refers to the uncertainty of the event occurrence or its attribute values. Uncertainty regarding event occurrence comes from the fact that the system does not know whether or not this event has in fact occurred. The uncertainty concerning the event attributes stems from inaccuracies in reported values, e.g., granularity, skew, or drift in clocks.

The second dimension, origin uncertainty, relates to both raw and derived events. The uncer-

tainty can thus originate at the source itself or can be traced to the uncertain inference performed by the systems on other events.

Due to the orthogonality of these dimensions, four types of event uncertainty can be identified:

- Uncertainty regarding event occurrence originating at an event source
- Uncertainty regarding event occurrence resulting from inference
- Uncertainty regarding event attributes originating at an event source
- Uncertainty regarding event attributes resulting from event inference

Causes of Source and Inference Uncertainty

Source uncertainty — Uncertainty regarding event occurrence at the source is caused by one of the following:

- An event source may malfunction and indicate that an event has occurred even if it has not or the converse.
- An event source may fail to signal the occurrence of events due to limited precision or may signal events that did not occur.
- The communication medium between the source and the CEP system may drop or intrude spurious events.
- In some cases, the source itself may produce estimations as events.

Uncertainty regarding the attributes originating at the event source can also be caused by any of the above reasons. Considering distributed systems, the skew and drift among the clocks of the involved entities introduce an additional source of uncertainty.

Note that in both of the above cases, uncertainty regarding a specific event may be caused by a combination of factors. For example, it is possible that both the event source itself and the communication medium simultaneously corrupt the same event.

Inference uncertainty — The uncertainty regarding event occurrence resulting from inference has the two possible causes: *propagation of uncertainty* or *uncertain rules*. While an inferred event can be a result of a deterministic rule, if the inference is made over uncertain events, then their uncertainty propagates to the inferred events. On the other hand, the rules may not be deterministic themselves. For instance, deterministic methods to identify malicious behavior may induce false negatives as well as false positives.

Source and inference uncertainty may be combined. That is, it may happen that not only is the inference of an event based on an uncertain rule, but also uncertainty exists regarding the occurrence (or attribute values) of one of the events which serves as evidence for this inference.

Considering uncertainty of inferred event attributes, the possible causes depend on how these attributes are calculated from the attributes of the evidence events. The most intuitive way to calculate such inferred attributes is by using deterministic functions defined over the attributes of the evidence events. In such a case, the only cause of uncertainty in the inferred attributes is rooted in the uncertainty of attribute values of the evidence events. Therefore, the rule cannot induce uncertainty regarding the attribute values of the inferred events. However, if the inference system makes it possible to define the attribute values of the inferred events in a nondeterministic manner, uncertain rules may also be a cause of inferred attribute uncertainty.

Key Research Findings

Handling Uncertainty through Probability Theory

Modeling uncertain raw events — The first model represents the uncertainty associated with event through probability theory. Such choice is supported by the following reasons:

- Probability theory has widespread acceptance, is well-understood, and is supported by powerful tools.

- Its use is facilitated by many technical results supported by formal justification.
- Under certain assumptions, probability is the only “rational” way to represent uncertainty (Halpern 2003).
- There are well-known and accepted methodologies for carrying out inferences based on probability theory, involving structures known as Bayesian networks (Pearl 1988).
- Probability theory can be used together with utility theory (Raiffa 1997) for automatic decision-making. Such automatic decision-making would facilitate the implementation of automatic actions by CEP engines.

The CEP engine maintains for each event a data structure dubbed Event Instance Data (EID). An EID incorporates all relevant information about an event, such as its type and time of occurrence. An event with n attributes (e.g., type, timestamp, etc) can be represented as a tuple of values $t = \langle v_1, \dots, v_n \rangle$, one value for each attribute. To capture the uncertainty on an event instance, the EID is a random variable with domain $\mathcal{V} = V \cup \{\perp\}$, where V is a set of tuples $\langle v_1, \dots, v_n \rangle$, each representing a possible combination of the event attributes values. A probability can then be attached to any subset of $S \subset \mathcal{V}$, expressing the probability that the event attribute values match one of the possible tuples in S , while associated with \perp is the probability of nonoccurrence of event e . This representation captures both the uncertainty regarding the attributes and occurrence. An additional concept, relevant in the context of event composition systems, is that of event history (EH). An event history $EH_{\tau_1}^{\tau_2}$ is the set of all events, as well as their associated data, whose occurrence time falls between τ_1 and τ_2 .

Complex event patterns — Deterministic CEP engines use pattern matching for situation detection. In such systems, a situation is said to have occurred if the stream of incoming events match some pattern. The event pattern notion can be extended to represent the uncertainty associated with event derivation (Wasserkrug et al. 2012a). This extension is based on

probability theory; however the framework can also be applied to fuzzy set theory or possibility theory.

At each point in time τ , the existence of relevant patterns can be checked in the event histories that are known at that time. A pattern p is defined as a tuple $\langle sel_p^n, pred_p^n, type_p, mapping_p, prob_p \rangle$ where:

- sel_p^n is a deterministic predicate returning a subset of an event history of size less than or equal to n (for some integer n). If the returned subset has strictly less than n elements, no further evaluation of the rule is carried out.
- $pred_p^n$ is a (possibly complex temporal) predicate of arity n over event instances (this is the same n appearing in sel_p^n). This predicate is applied to the n event instances selected by sel_p^n .
- $type_p$ is the type of event inferred by this pattern.
- $mapping_p$ is a set of functions mapping the attribute values of the events that matched this pattern to the attribute values of the inferred event.
- $prob_p \in [0, 1]$ is the probability of inferring the event by the pattern.

The quantity $prob_p$ is the only uncertainty associated with the pattern.

Inference over uncertain events — Pattern reasoning engines must be able to compute at any time τ the probability that an event has occurred at time $\tau' \leq \tau$, based only on the knowledge available to the engine at time τ . Therefore, a (possibly different) probability space (cf., section “[Uncertainty Models](#)”) is defined for each τ , as a tuple $P_\tau = (W_\tau, F_\tau, \mu_\tau)$. W_τ is a set of possible worlds, with each possible world corresponding to a specific finite event history that is considered possible at time τ . The event history, as well as the overall number of events, is assumed to be finite since a system cannot consider an infinite number of events.

A computationally more efficient, while less intuitive, probability space definition is the following. Let E_1, E_2, \dots be the set of EIDs repre-

senting the information about all events of interest. Each finite event history can be represented by a finite number of values e_1, \dots, e_n , such that there is a finite number of EIDs E_1, \dots, E_n where e_i is a possible value of E_i . Then, each possible world $w_\tau \in W_\tau$ can be represented by such a finite number of values. Moreover, since the overall number of events is finite, there is a finite number of events E_1, \dots, E_m such that E_i has occurred in some $w_\tau \in W_\tau$. Finally, if $|W_\tau|$ is finite, each E_i can only have a finite number of associated values (one for each world in W_τ) in which it appears. Note that in such a case, each possible world w_τ can be represented by a finite number of values t_1, \dots, t_m , where the values t_1, \dots, t_n for some $n \leq m$ represent the values of one of the n events that occurred in w_τ , and t_{n+1}, \dots, t_m are all $\{\perp\}$. It follows that if the probability space P_τ represents the knowledge of the composite event system at time τ , this knowledge can be represented by a set of m EIDs - E_1, \dots, E_m .

Therefore, when $|W_\tau|$ is finite, it is possible to define the probability space P_τ as $(\Omega_\tau, F_\tau, \mu'_\tau)$ where:

- $\Omega_\tau = \{t_1, \dots, t_m\}$ such that the tuple t_1, \dots, t_m is the set of values corresponding to an event history, where this event history is a possible world $w_\tau \in W_\tau$ as described above. Obviously, $|\Omega_\tau|$ is finite.
- $F_\tau = 2^{|\Omega_\tau|}$
- $\mu'_\tau(\{t_1, \dots, t_m\}) = \mu_\tau(w_\tau)$ such that w_τ is the world represented by $\{t_1, \dots, t_m\}$

This representation is called the *EID representation*.

Intuitively, the semantics of each pattern p is as follows: Let $EH_{\tau_1}^{\tau_2}$ be an event history. If the pattern p is applied at some time $\tau \geq \tau_2$ and the set of events selected by sel_p^n from $EH_{\tau_1}^{\tau_2}$ is of size n and is such that $pred_p^n$ on this event is true, then the event inferred by rule p occurred with probability $prob_p$. The value of its corresponding attributes is the value defined by $mapping_p$. Otherwise, the event cannot be inferred.

Formally, let $sel_p^n(EH_{\tau_1}^{\tau_2})$ denote the set of events selected by sel_p^n from $EH_{\tau_1}^{\tau_2}$, and let $pred_p^n(sel_p^n(EH_{\tau_1}^{\tau_2}))$ denote the value of the predicate $pred_p^n$ on $sel_p^n(EH_{\tau_1}^{\tau_2})$ (recall that if $|sel_p^n(EH_{\tau_1}^{\tau_2})| < n$ then the rule is not applied). In addition, let v_1, \dots, v_n denote the value of the attributes of the inferred event e_p as defined by $mappingExpressions_p$. Then, if the specific event history is known and denoting by E_p the EID corresponding to e_p , we have the following:

$$\begin{aligned} \mathbb{P}(E_p = \{v_1, \dots, v_n\} | EH_{\tau_1}^{\tau_2}) &= prob_p \\ \text{if } pred_p^n(sel_p^n(EH_{\tau_1}^{\tau_2})) &= true \end{aligned}$$

$$\begin{aligned} \mathbb{P}(E_p = \{\perp\} | EH_{\tau_1}^{\tau_2}) &= (1 - prob_p) \\ \text{if } pred_p^n(sel_p^n(EH_{\tau_1}^{\tau_2})) &= true \end{aligned}$$

$$\begin{aligned} \mathbb{P}(E_p = \{\perp\} | EH_{\tau_1}^{\tau_2}) &= 1 \\ \text{if } pred_p^n(sel_p^n(EH_{\tau_1}^{\tau_2})) &= false \end{aligned}$$

For a finite W_τ , the probability space can be represented by a finite set of finite random variables. In addition, note that the rule semantics defined above specify that the probability of the inferred event does not depend on the entire event history but rather on the events selected by sel_p^n . Let us denote by E_1, \dots, E_m the set of EIDs that describe knowledge regarding the event history and let $\{E_{i_1}, \dots, E_{i_l}\}$ describe the subset of $\{E_1, \dots, E_m\}$ that are candidates for selection by sel_p^n (note that $l \geq n$, as sel_p^n must choose the first n events that have **actually occurred**). An EID E is a candidate for selection if there is a possible event history in the probability space P_τ such that there is a set of n events, chosen by sel_p^n from this event history, and the event e corresponding to E is in this set. Then, for all sets of values $\{t_1, \dots, t_m\}$ such that $E_i = t_i$, we have that:

$$\mathbb{P}(E_p | E_{i_1}, \dots, E_{i_l}) = \mathbb{P}(E_p | E_1, \dots, E_m) \quad (3)$$

i.e., E_p is conditionally independent of $\{E_1, \dots, E_m\} \setminus \{E_{i_1}, \dots, E_{i_l}\}$ given $\{E_{i_1}, \dots, E_{i_l}\}$. Now let t_{i_1}, \dots, t_{i_m} denote a specific set of values of

E_{i_1}, \dots, E_{i_l} . Given such a set of specific values, the subset $\{e'_{j_1}, \dots, e'_{j_n}\}$ selected by sel_p^n is well

defined. Therefore, we have from the above equations that:

$$\mathbb{P}(E_p = \{v_1, \dots, v_n\} | t_{i_1}, \dots, t_{i_m}) = prob_p \text{ if } pred_p^n(e'_{j_1}, \dots, e'_{j_n}) = true \quad (4)$$

$$\mathbb{P}(E_p = \{\perp\} | t_{i_1}, \dots, t_{i_m}) = (1 - prob_p) \text{ if } pred_p^n(e'_{j_1}, \dots, e'_{j_n}) = true \quad (5)$$

$$\mathbb{P}(E_p = \{\perp\} | e_{i_1}, \dots, e_{i_m}) = 1 \text{ if } pred_p^n(e'_{j_1}, \dots, e'_{j_n}) = false \quad (6)$$

Inference algorithm — We now detail an algorithm for uncertain inferencing of events (Wasserkrug et al. 2008). In a nutshell, the algorithm works as follows: Given a set of patterns and a set of EIDs at time τ , a Bayesian network is automatically constructed, representing the probability space at τ according to the semantics previously defined. Probabilities of new events are then computed using standard Bayesian network methods.

Any algorithm for event derivation must support both termination and determinism (Widom and Ceri 1994). The former guarantees that the algorithm will terminate. Determinism ensures that for the same input (i.e., set of explicit EIDs), the derivation result will be always the same. The Bayesian network construction algorithm should provide two additional features, namely, efficiency and dynamic updates. The latter determines that the network represents the probability space P_τ at all times. Event derivation algorithms are likely to store some additional meta data to support efficiency.

Patterns are assumed to be acyclic, and, to enforce determinism in the activation order, each is assigned a priority. By definition, the occurrence time of each inferred event is the time in which the pattern was applied. Therefore, the single possible occurrence time $E.\sigma\tau$ of each EID defines a full order on the EIDs. According to Eq. 3, each EID is independent of all preceding EIDs, given the EIDs that may be selected by the selection expression. Therefore, we construct a Bayesian network such that the nodes of the network consist of the set of random variables in the system event history, and an edge exists between EID E_1 and EID E_2 iff $E_1.\sigma\tau \leq E_2.\sigma\tau$

and E_2 is an EID corresponding to an event that may be inferred by pattern p , where the event corresponding to E_1 may be selected by sel_p^n . A network constructed by these principles encodes the probabilistic independence required (Pearl 1988) by Eq. 3. This structure is now augmented with values based on Eqs. 4, 5, and 6.

Based on the above principles, a Bayesian network is constructed and dynamically updated as events enter the system. At each point in time, nodes and edges may be added to the Bayesian network. The algorithm below describes this dynamic construction. The information regarding the new event is represented by some EID E , the system event history is represented by EH , and the constructed Bayesian network by BN .

1. $EH \leftarrow EH \cup \{E\}$
2. Add a node for E to BN .
3. For each such pattern p in a decreasing priority order:
 - a. Denote by $sel_p^n(EH)$ the subset of EIDs in EH that may be selected by sel_p^n (these are all EIDs whose *type* attribute is of one of the types specified by sel_p^n).
 - b. If there is a subset of events in $sel_p^n(EH)$ that may be selected by sel_p^n such that $pred_p^n$ is true, add a vertex for the inferred event's EID E_p . In addition, add edges from all events in $sel_p^n(EH)$ to the event E_p .
 - c. For E_p , fill in the quantities for the conditional probabilities according to Eqs. 4, 5, and 6.
4. Calculate the required occurrence probabilities in the probability space defined by the constructed Bayesian network.

The above algorithm describes at a high level the calculation of the required probabilities, omitting the details of several steps. The omitted details include the mechanism for selection of events as indicated by sel_p^n , the evaluation of the predicates defined by $pred_p^n$, and the exact algorithm used to infer the required probabilities from the Bayesian network. In all of these cases, standard algorithms from the domains of deterministic event composition and Bayesian networks may be used and extended. The specific algorithms used for these tasks will determine the complexity of our algorithm. However, the dominant factor will be the calculation of the required probabilities from the Bayesian network, which is known to be computationally expensive.

Handling Uncertainty through Fuzzy Set Theory

Modeling uncertain raw events — An event attribute x is represented (Liu and Jacobsen 2004) in the form “ x is \tilde{A} ,” where \tilde{A} is a fuzzy value with an attached membership function μ . With fuzzy set theory, the event “sensor s temperature reading x is in acceptable range” could be modeled with the following membership function:

$$\mu_{\text{acceptable}}(x) = \begin{cases} 0.15 & \text{if } 37.3 \leq x < 37.4 \\ 0.50 & \text{if } 37.4 \leq x \leq 37.6 \\ 0.15 & \text{if } 37.6 < x \leq 37.7 \\ 0.0 & \text{otherwise} \end{cases}$$

Inference over uncertain events — The membership function of a complex event \hat{e} over n events e_1, \dots, e_n is defined as follows: $M(e_1, \dots, e_n) = R(\mu_A(e_1), \dots, \mu_A(e_n))$, where the relation R determines the method according to which membership values of different fuzzy sets can be combined. Consider once more the event “temperature of sensor s is acceptable” and an additional event “day d is cold” with the following membership function μ_{cold} :

$$\mu_{\text{cold}}(x) = \begin{cases} 0.0 & \text{if } x < 10.0 \\ 0.1 & \text{if } 10.0 \leq x < 15.0 \\ 0.2 & \text{if } 15.0 \leq x < 20.0 \\ 0.7 & \text{otherwise} \end{cases}$$

The complex event “temperature of sensor s is acceptable and day d is cold” can be defined through the following membership function $M(e_1, e_2) = \min(\mu_{\text{cold}}(e_1), \mu_{\text{acceptable}}(e_2))$.

The min operator is the most well-known representative of a large family of operators called t-norms (i.e., triangular norms), routinely deployed as interpretations of fuzzy conjunctions (Hajek 1998; Klir and Yuan 1995). A t-norm $T : [0, 1]^2 \rightarrow [0, 1]$ is a binary operator satisfying the following axioms $\forall x, y, z \in [0, 1]$:

Boundary condition: $T(x, 1) = x$

Monotonicity: $x \leq y \implies T(x, y) \leq T(y, z)$

Commutativity: $T(x, y) = T(y, x)$

Associativity: $T(x, T(y, z)) = T(x, T(y, z))$

A fuzzy aggregate (Klir and Yuan 1995) is an operator $H : [0, 1]^n \rightarrow [0, 1]$ satisfies the following axioms $\forall x_1, \dots, x_n, y_1, \dots, y_n \in [0, 1]$ such that $\forall i \in [1, n], x_i \leq y_i$:

Idempotency: $H(x_1, \dots, x_1) = x_1$

Increasing monotonicity: $H(x_1, \dots, x_n) \leq H(y_1, \dots, y_n)$

H is continuous

The average operator $Ha(\bar{x}) = \frac{1}{n} \sum_1^n x_i$ is an example of fuzzy aggregate operator.

The space of possible computation method is large and additional research is needed to identify the best fuzzy operator for a given complex event.

U

Research Directions

Uncertainty in event streams involves three classes of challenges, namely, modeling, usability, and implementation.

Considering modeling, a single model does not fit all cases. The challenge is to define a flexible generalized model that can accommodate the model best suited for a specific implementation.

A major difficulty with respect to usability is to obtain required patterns and probabilities. As for many other scenarios, specifying correct cases and their associated probabilities is a daunting task even for domain experts. Patterns and probabilities may be automatically generated through machine learning techniques (Turchin et al. 2009); however state-of-the-art in this area supports only mining of simple patterns.

In the implementation area, stream processing engines have reached high levels of scalability and performances (Heinze et al. 2014), a trend that CEP engines must abide to. Therefore, there is a need to develop algorithmic performance improvements (Wasserkrug et al. 2012b) to the current models such as Bayesian networks, which are known to be computationally intensive. Possible additional directions for future work include performance improvements of existing derivation algorithms, either by general algorithmic improvements or by developing domain- and application-specific efficient algorithms.

Context-aware user mobility; Trip context inference; User mobility planning

Definitions

User mobility is the movement of individuals from one place to another. *Trip* is a segment of user mobility. A *context* is any information that can be used to characterize the situation of an entity (i.e., any user), according to Dey and Abowd (2000). *Trip contexts* provide trip-related information to any person planning to make a trip. Further, *route planner* is a system designed to help user mobility which consists of a number of trips. Usually, the route planners present some predefined contexts to a user and provide a route plan between two locations on the basis of user-selected contexts. The *big spatial data* can facilitate diverse sets of trip contexts with their respective geographic location information on the earth's surface which can aid the effective planning of user mobility.

Overview

The study of user mobility is to deal with understanding, analyzing, and modeling the movement

of individuals in the spatial and temporal domains. A meaningful movement (i.e., movement between two meaningful places) of a user is considered user mobility. For example, home and office are two meaningful places. Therefore, the “home to office” and “office to home” movements of a user are called user mobility. In fact, these two types of mobility are very common in our day-to-day life. User mobility can be divided into small segments called “trips.” Essentially, a set of trips connecting two arbitrary places is required to define the user mobility between two meaningful places. Each trip is accomplished using a mode of transport such as bike, car, public transport, or walking. An example of user mobility is illustrated in Fig. 1. We can see that the user mobility between two places p_1 and p_5 consists of a sequence of interconnected trips using different modes of transport. A user can choose his/her preferred mode of transport from the list of available modes. This results in different routes being selected for traveling between p_1 and p_5 . Figure 1 shows three different routes from p_1 to p_5 marked with three different colors (i.e., black, brick red, and blue). Each of these routes has a different combination of transport modes.

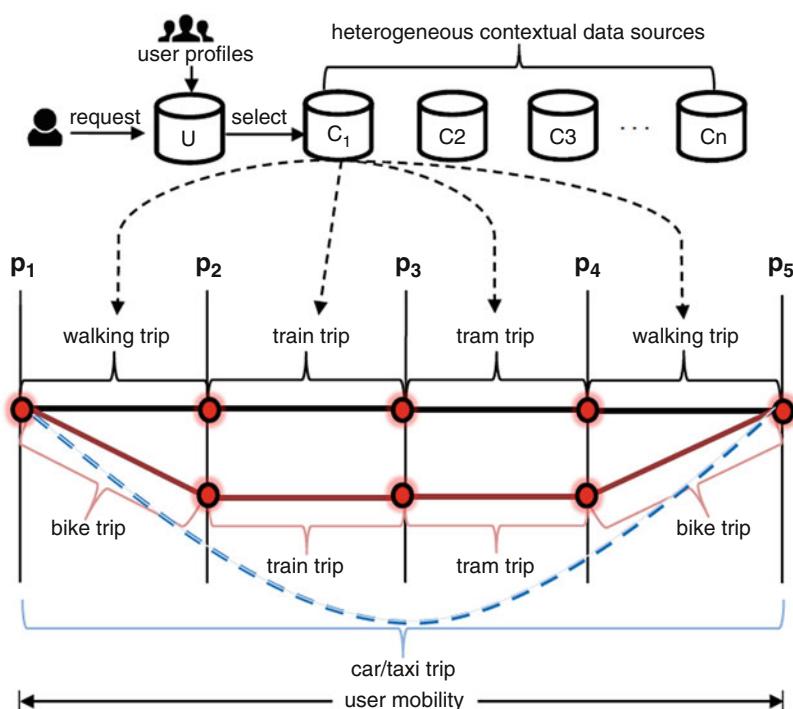

The first two routes (i.e., black and brick red) are for public transport users, and the corresponding sequence of transport modes from p_1 to p_5 is (walk, train, tram, walk) and (bike, train, tram, bike), respectively. Note that these two routes have some common parts in terms of the preferred mode of transport, as seen between p_2 and p_4 . The third route contains only car or taxicab as the preferred mode of transport to travel between p_1 and p_5 .

Route planner systems allow users to plan their mobility between two places. Usually, a route planner integrates trips on the basis of certain predefined user preferences chosen from a list of options and includes the shortest time, shortest distance, minimum number of transport mode changes, and the preferred mode of transport. However, many other situations, if considered, can significantly improve the mobility planning. For instance, an effective mobility plan should include traveler-specific situational

factors (i.e., trip contexts) for each trip selected for integration into the trip plan. These trip contexts can be related to the trip origin location, trip destination location and the route itself. Sometimes, external contexts such as weather can have a notable influence on the trip selection for planning user mobility.

Let us consider two different users and their respective trip contexts. The first user is a person with a wheel chair, and the second is a taxicab driver. While planning a mobility along an arbitrary mobility segment (i.e., trip), the person with a wheel chair needs to consider contexts such as steepness, weather, and road crossing. This user may also consider information about ramps and lifts at the trip end location to ensure comfortable mobility. In contrast, a taxicab driver would consider traffic congestion while determining the preferred mobility segment. The spatial and temporal changes in lucrativeness of mobility segments can also be considered since some mobility segments are more lucrative for a passenger pickup job during weekdays,

while others are so on weekends. The weather can have a direct effect on the state of congestion along a mobility segment. This driver may also prefer a trip with a high likelihood of getting a passenger pickup job at the trip end location. The preference may also include the waiting time before a passenger pickup job with the job likelihood. Therefore, these contexts are very important as they have a considerable effect on these users' choice of trips. Therefore, mobility planning is a challenging issue, as the contexts are diverse among users and user-specific contexts must be taken into consideration for effective planning. An example of context awareness in mobility planning is illustrated in Fig. 1. Here, different user profiles are stored in the user profile database (U). The heterogeneous contexts are stored in separate databases (C_1, C_2, \dots, C_n). Based on a user's request, the appropriate user profile is selected which includes the user-specific context(s). These user-specific contexts are then used to retrieve appropriate contextual information from heterogeneous contextual databases. The

Using Big Spatial Data for Planning User Mobility, Fig. 1 Example of trip contexts in user mobility planning

retrieved information is used for user mobility planning.

For providing effective mobility plans, all of these trip contexts need to be collected, stored, and analyzed. The collection of these context data was not this easy even a decade ago. However, the current era of *big spatial data* enables us to collect and analyze vast amounts of relevant information about many natural or constructed trip contexts with respect to space and time.

Key Research Findings

The big spatial data can provide many important contextual information for user mobility planning and decision making. The availability of various types of contextual information and given the fact that these contexts originate from heterogeneous spatial data sources, various research problems have emerged. Some key research issues include contextual data collection, contextual data fusion and analysis, and context-aware planning using this vast amount of spatial data and taking into account the context information.

Contextual Data Collection

It is important and challenging to collect various contextual data to address diverse sets of user needs for effective mobility planning. The collection of contextual big spatial data is leveraged by the ubiquitousness of sensing devices (i.e., GPS, ticketing systems, and passenger and pedestrian counting systems). This large volume of data related to trip contexts can be used for traveler-specific mobility planning. In recent years, user mobility have been studied using large publicly available datasets such as the Geolife trajectory dataset (Zheng et al. 2008) and the NYC taxi trip dataset (TLC 2016). These datasets include traces of pedestrians, public transport, and taxi trips with timestamps (Zhao et al. 2015). Many research projects have been conducted using these publicly available datasets to develop real-world mobility solutions.

The Geolife GPS trajectory dataset (Zheng et al. 2008) was built using the GPS traces of 182 users between April 2007 and August 2012. A

GPS trace is represented by a sequence of timestamped latitude/longitude points. This dataset contains a total of 17,621 user traces covering a total distance of approximately 1200,000 km. These user traces were recorded at a variety of sampling rates. Approximately 91% of the traces were recorded every 15 s, which was equivalent to 510 m per spatial point. The GPS traces recorded in this dataset represent different types of outdoor movements of users, such as “go to work,” “go home,” “shopping,” “dining,” “sightseeing,” “bicycling,” and “hiking.” This trajectory dataset is used in many research fields ranging from user mobility pattern mining, activity recognition and mobility planning to urban planning, and location recommendation.

The NYC taxi trip dataset (TLC 2016) is a real-world taxi trip dataset built by the New York City’s Taxi & Limousine Commission (TLC). In New York City, 0.5 million taxi trips are generated on an average per day, totaling 175 million trips per year by 13,000 operating taxis. Each trip record in this dataset describes a trip by its timestamped start and end locations, the trip distance, total number of passengers on board during the trip, fare type, fare and tip amount, and the taxi’s unique identification number called medallion.

Contextual Data Fusion and Analysis

A fusion of trip contexts is required after the collection of the context information from various sources. This fusion is required to better represent the effects of other trip contexts for planning the user mobility between two places. Thus far, a number of data fusion methodologies have been developed for cross-domain data fusion (Zheng 2015). Further, a context representation framework can be used to deal with this issue (Rahaman et al. 2018). Context representation techniques for trip planning can leverage the existing data modeling techniques.

Sometimes, predictive analytics is used for an inference-based representation of trip contexts for user mobility. The predictive analytics provides a detailed analysis and prediction of future trip contexts. To provide efficient prediction outcomes, different machine learning techniques are used. These machine learning

techniques are trained with historical data to gain appropriate knowledge for a prediction task. However, the predictive analytics need to deal with various issues such as data sparsity and imbalance problems. Some of the trip contexts can be imbalanced (i.e., very infrequently occurring contexts as compared to the others) which makes the predictive analytics more complex. Many researchers have addressed this issue. Various sampling techniques can be used to deal with this issue (He and Garcia 2009). Some researchers have also investigated how expert knowledge can be collected and incorporated into the problem domain. A new strategy to incorporate expert knowledge for enhanced trip context prediction was proposed by Rahaman et al. (2017b).

Context-Aware Planning

For providing effective mobility plans, user-specific trip contexts need to be considered in such a way that the wide range of user-specific trip contexts can be addressed. However, this is a challenging issue to deal with. Thus far, several algorithmic approaches have been proposed to handle user-defined contextual preferences while providing plans for user mobility. Most of these approaches provide mobility plans considering only the context selected by the user. Some route planner systems consider more than one trip context at a time while providing mobility plans. Some researchers also consider user-specific trip-special contexts for recommending mobility plans.

Examples of Application

Big spatial user mobility data have been used in many real-world applications. The applications related to user mobility planning can be categorized as follows: trip context inference, contextual predictive analytics, and contextual modeling.

- In context inference, various trip contexts are retrieved from the different big spatial

datasets, which may include the fusion of various heterogeneous datasets.

- The predictive analytics of trip contexts provides predictions about future trip contexts by using different statistical, machine learning, and data mining techniques to analyze the current and historical trip events from big spatial user mobility datasets.
- In contextual modeling, the trip context(s) are taken into consideration to provide mobility plans for different users. Usually, the context information is represented in a graph or matrix form before applying the route planning techniques.

In many cities such as Singapore and New York, taxicabs are regarded as the preferred mode of transport for user mobility. Here, big spatial data have been utilized to predict user-specific taxi trip contexts including taxi drivers and passengers. For instance, it is important for a taxi driver to predict the queue context information at the trip end location before making a trip. A queue context prediction framework was proposed by Rahaman et al. (2017a) which leveraged the big spatial data generated by the taxi trip logs in New York City. Some other research projects aimed at providing information about trip contexts. For instance, techniques for finding the lucrativeness of passenger pickup locations were developed by Hwang et al. (2015) and Yuan et al. (2011). By analyzing the historical mobility data of taxicabs, techniques to find profitable routes for cruising before passenger pickup were proposed by Ge et al. (2010) and Dong et al. (2014). By considering the passengers' trip contexts, an on-demand trip context information system was developed by Balan et al. (2011) whose aim was to provide trip contexts such as approximated fare and trip time prior to the trip. Another research proposed a model for passenger wait time prediction before a taxi ride (Qi et al. 2013) which utilized a large number of historical taxi GPS traces.

Contextual modeling is used for providing effective mobility planning and recommendations to the users. Many studies were conducted to rec-

ommend routes considering two of the most common user preferences: distance and time. Many other research works focused on route planning and recommendation (Sasaki and Takama 2013; Völkel and Weber 2008; Rahaman et al. 2017c) by considering other user-specific contexts leveraging the big spatial data sources. A route recommendation system was developed by Sasaki and Takama (2013) which considered three criteria to recommend a route, namely, safety, amenity, and walkability of the route. A client/server system to annotate multimodal geographical data and to provide mobility service to mobility impaired pedestrians was proposed by Völkel and Weber (2008). Multi-criteria route planning for people with special needs was proposed by Rahaman et al. (2017b). Route recommendation considering the scenic beauty of the route was proposed by Quercia et al. (2014), while relative safety was considered by Elsmore et al. (2014) for mobility planning. Table 1 summarizes the use of contexts in different applications using public user mobility datasets.

formation is collected through direct crowd participation such as safety or scenic beauty ratings of a mobility segment. This information is a good data source for making context-aware mobility plans, as the information contains actual user perceptions. However, it is challenging to ensure the data quality of such crowd-generated context information. Future research can address this issue.

Another research direction is related to the diversity of spatial contextual data sources. These contextual data are heterogeneous, i.e., sourced from different domains and locations. These data have different sampling rates and representations. Advanced techniques for heterogeneous data fusion are required for the effective user mobility planning.

Many trip contexts require efficient predictive analytics with big spatial data for user mobility. However, predictive analytics techniques are usually domain specific. Therefore, appropriate domain adaptation is required for the analytics techniques adopted from other domains.

Future Directions for Research

There are several directions for future research on user mobility planning using big spatial. The three most important aspects are data quality, data fusion, and effective predictive analytics.

In the era of big data, the spatial contextual information is mainly collected through autonomous loggers. However, some contextual in-

Virtual Distributed File System: Alluxio

Calvin Jia and Haoyuan Li
Alluxio Inc., San Mateo, CA, USA

Synonyms

[Tachyon](#)

Definitions

Alluxio (2018) is the world’s first memory speed virtual distributed storage. Alluxio is an open source project with a community of over 700 contributors from over 150 organizations. In the big data stack, it is a layer between applications such as Apache Spark (2018) and Apache MapReduce (Apache Hadoop 2018a) and data stores such as Amazon S3 (Amazon 2018) (Simple Storage System) and Apache HDFS (Apache Hadoop 2018b) (Hadoop Distributed File System).

Alluxio presents a set of disparate data stores as a single file system, greatly reducing the

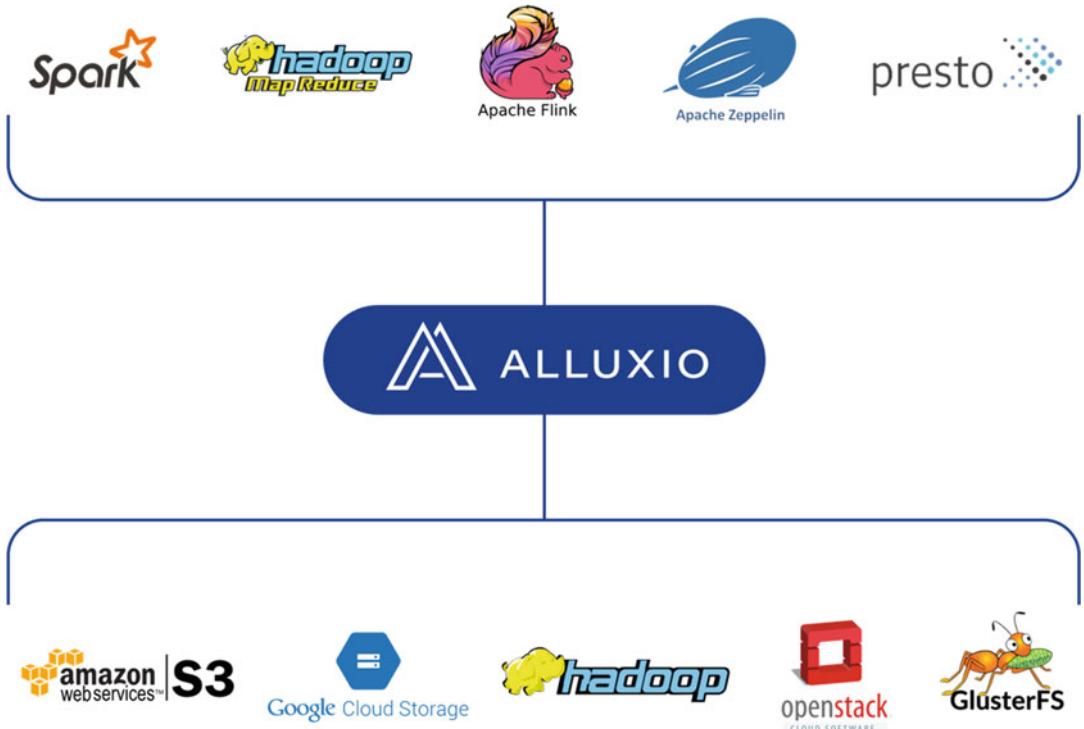

complexity of storage APIs (Application Programming Interface), locations, and semantics exposed to applications. For example, an object storage in the cloud and an on-premise distributed file system both appear to applications as subtrees in the Alluxio file system namespace.

Alluxio is designed with a memory centric architecture, enabling applications to leverage memory speed I/O by simply using Alluxio. Because Alluxio is between compute and storage, it serves as a transparent cache that enables applications to benefit from data sharing and locality.

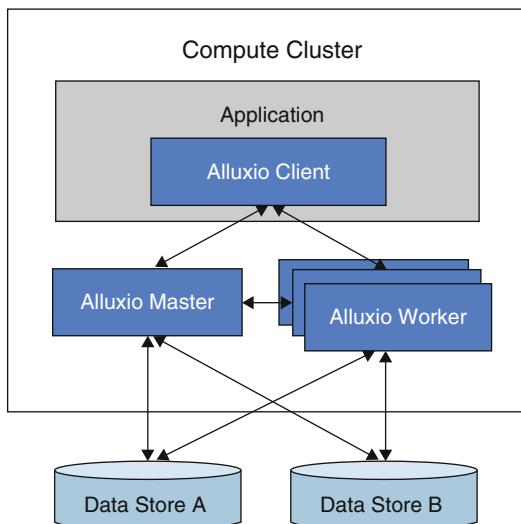

By being a layer between applications and data stores, Alluxio enables rapid innovation in both compute and storage by abstracting basic functionality and compatibility.

Overview

Alluxio is a Java-based distributed system with a master–worker architecture. Master nodes are responsible for handling metadata requests and cluster registration. Workers are responsible for handling data requests and transferring data from Alluxio storage or data stores to clients. Clients are part of applications that use Alluxio. Finally, the under storage is comprised of different data stores which house the persistent copies of the data. Figure 1 above shows the general interaction pattern between Alluxio and other projects in the big data ecosystem, and Fig. 2 below shows the communication and deployment pattern of Alluxio with respect to its internal components.

Virtual Distributed File System: Alluxio, Fig. 1 Alluxio and the ecosystem

Virtual Distributed File System: Alluxio, Fig. 2
Alluxio system components

Clients

The Alluxio client is a library that is used by applications to interface with the servers. Client

applications have several interfaces available to them – an Alluxio Java interface, a Hadoop compatible file system interface, a S3 compatible object store interface, a FUSE (Filesystem in Userspace) interface, and a REST (Representational State Transfer) interface. Alluxio supports many interfaces to give application developers the most flexibility when working with Alluxio.

The Alluxio Java interface is preferred for the best performance and functionality. The newest features will always be available in the Java interface first, and it will have the smallest overhead of all the clients.

Because Alluxio supports a Hadoop-compatible file system interface, existing applications in the ecosystem can leverage Alluxio by providing the client binary and switching input paths to an “alluxio://” scheme. This is desirable, as no code changes are needed for Alluxio to be used with applications that were already using a Hadoop-compatible file system interface.

Similarly, the S3 interface allows applications that previously used S3 as storage to switch to Alluxio with minimal code changes. An object storage interface can be attractive for applications dealing with media data. While Alluxio provides the same interface, it provides characteristics such as strong consistency and memory speed I/O that are not commonly provided by object stores.

The FUSE interface allows applications previously working with local storage to seamlessly migrate to using Alluxio. This is even more transparent than the Hadoop integration, and no binary or path changes are required. A separate Alluxio FUSE process is responsible for redirecting requests to the mounted path to Alluxio. The FUSE interface allows applications previously working with only local data to expand to all the data repositories available in an organization.

Finally, the REST interface is a convenient and ubiquitous interface for applications that may only need to do simple operations with Alluxio. This interface can be used by any application that can send HTTP requests.

Masters

The Alluxio master is a quorum of nodes (possibly only one) that record the state of the Alluxio file system and cluster. Only one master node is actively serving requests at a time, the other nodes participate in keeping the journal up-to-date as well as act as hot failovers if the active master crashes. Quorum membership and leader election are managed through Apache Zookeeper (2018).

The Alluxio master manages worker membership, registering a unique id for each worker. Each Alluxio worker is expected to only associate with one Alluxio master. Alluxio masters also assign unique ids to workers and keep track of the data available on each worker.

Alluxio master records the metadata for data blocks which make up files. Blocks are the smallest unit of data in Alluxio, usually ranging from tens to hundreds of megabytes. Each block has a unique id but can be stored on zero, one, or many worker nodes.

One or more blocks comprise the data portion of a file. The master also keeps track of the file system tree information required to map a human readable path to a specific file. Along with path information, the Alluxio master also keeps various file level metadata such as permissions and modification time.

The Alluxio master is designed to accept incoming requests but not make any outgoing requests, aside from responses. This allows clients and workers to freely join or leave the cluster. Clients typically communicate with the master to make logical updates to the metadata tree or create new files. These requests are independent and stateless, enabling the master to scale up to thousands of concurrent clients. Workers have a periodic heartbeat with the master for as long as they are part of the cluster. The heartbeat is low cost, and Alluxio clusters have scaled to a thousand nodes in production environments.

The master is also responsible for keeping a journal of events. This is for fault tolerance guarantees; whenever the master restarts, it recovers the previous metadata state including the file system tree and block list from the journal. The journal is typically stored on distributed storage to avoid a single point of failure, for example, if a disk were lost. Protobufs (Google 2018) are used to serialize journal entries with the added benefit of being easily extended to support future use cases.

Typical deployments have two or more master nodes for fault tolerance. The number of files the Alluxio master supports is proportional to the memory allocated to it. A single master node can scale up to hundreds of millions of files. Similarly, allocating more CPUs to the master allows for lower response latency in highly concurrent environments.

Workers

Worker nodes make up the bulk of an Alluxio cluster. These nodes are responsible for managing local storage (Alluxio storage) and providing data access to the data stores Alluxio abstracts to applications. The Alluxio worker process is lightweight and does not rely on persistent data; the system is designed to tolerate the complete

loss of a worker and its local storage. Because of the worker's small footprint, worker processes run colocated with applications.

Deploying the worker process colocated with applications greatly improves the maximum possible read/write throughput to Alluxio. Alluxio has optimizations to allow clients to read and write at memory speed if the client is running on the same node. In workloads that require a large amount of I/O, reducing the network traffic and serving data locally significantly improve performance.

Alluxio workers can be deployed on dedicated nodes as well. This has the benefit of isolating workers, which is helpful in cases where the application nodes are ephemeral or not committed to the cluster. For example, a single set of Alluxio worker nodes could serve several isolated compute clusters belonging to different users. In this way, the compute clusters do not need to be concerned about having any resources taken by Alluxio due to the workload of other clusters.

The primary function of Alluxio workers is to serve data requests from clients. It can do so in one of two ways, either directly from Alluxio local storage or by fetching data from an underlying data store, for example, Amazon S3. Data fetched from an underlying data store can be cached in Alluxio local storage, so subsequent accesses, even from completely unrelated applications, can be accelerated. This is especially helpful in workloads which focus on a narrow window of data among a larger total dataset, for example, when commonly analyzing the last 30 days of data while keeping several years of data available.

Examples of Application

Enabling Decoupled Compute and Storage

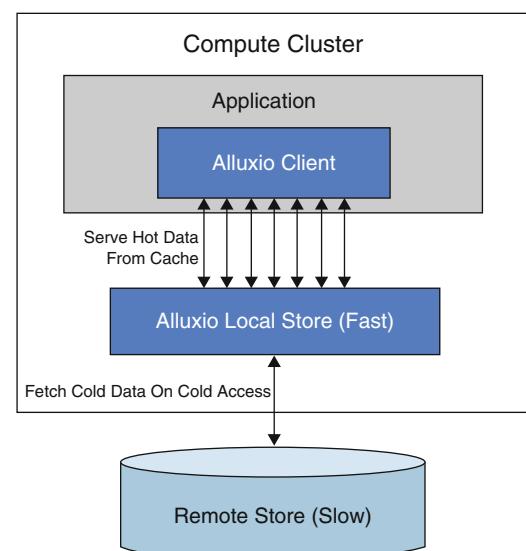

Decoupling compute and storage, and thus allowing optimal allocation of storage and compute resources, brings considerable cost savings as well as ease of innovation. There are two substantial challenges to this architecture, the performance impact due to lower bandwidth and higher latency and the limitations of writing an application against a particular storage interface.

By providing a lightweight cache colocated with the application, Alluxio remedies the performance impact of having remote storage. Organizations from various industry sectors, including some of the largest Internet companies in the world (Alluxio and Baidu 2016), have used Alluxio to great effect in this manner (see Fig. 3 below for a visual representation).

Alluxio also solves the interface limitation problem by allowing applications to choose from a rich set of standard APIs and connect seamlessly to any data store integrated with Alluxio. This greatly improves the flexibility of application and storage teams. Many companies, including the largest geospatial data distributor (ESRI 2017), use Alluxio to logically decouple compute and storage to enable rapid innovation in the storage and application layers.

Accelerating Data Analytics

Faster time to insight for organizations translates to better-informed decisions, which provides a crucial competitive advantage. The Alluxio memory centric architecture enables top travel booking companies (Alluxio and Qunar 2017) to quickly and accurately analyze user

Virtual Distributed File System: Alluxio, Fig. 3
Alluxio accelerates data access by caching hot data

behavior. This analysis then leads to better recommendations and user targeting.

In addition to accelerating I/O, Alluxio enables previously isolated computation to benefit from the data access patterns of other applications. The ability to share data between applications has led to even further performance gains and less data movement. Figure 3 below shows this for a single application, but multiple applications can utilize the same Alluxio local store.

Data Access for Machine Learning

Machine learning, especially deep learning, is reliant on the available training datasets. Often, it is not the algorithm but the training and validation data that produces the best models. Machine learning workloads have mostly been written with local data in mind, whereas the data necessary to fuel the models are stored in scattered data repositories. By using Alluxio, AI-focused companies (Liu and Dawei 2017) can easily expand the datasets available for training and validation to all the data repositories owned by the organization (see Fig. 4 below for a visual representation). This is a big win over traditional approaches which required complex extraction,

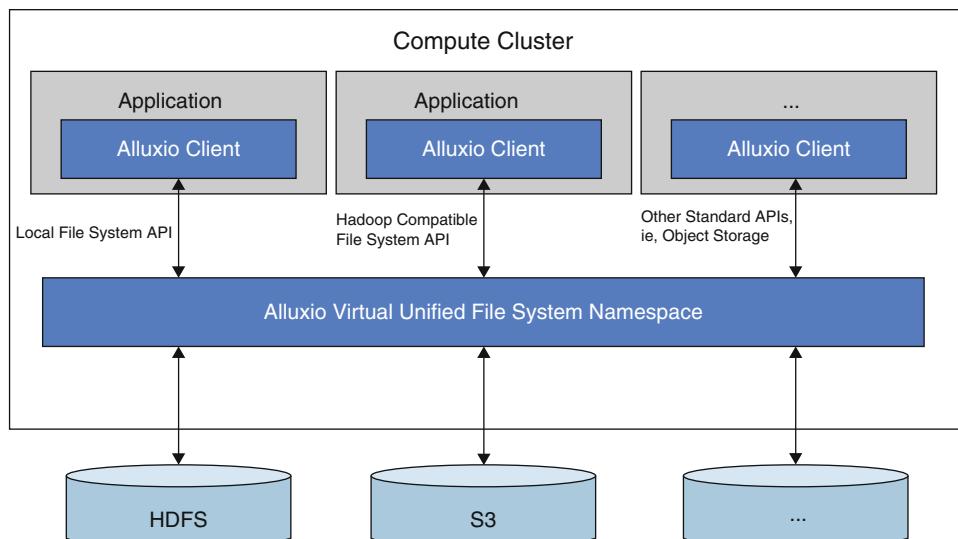

transform, load (ETL) and data tracking to ensure the cleanliness and availability of datasets.

Replacing ETL with Unification

ETL jobs are costly and hard to maintain. Data must be copied from a master source, and any updates must be propagated to the copies to ensure data integrity. Each application or group using the data must also have a separate version of the data, leading to more storage and maintenance requirements.

Alluxio provides applications with virtualization and unification. Organizations such as top financial companies (Alluxio and Barclays 2016) benefit from the huge improvement in manageability and performance gained by using Alluxio as opposed to ETL processes.

Virtualization allows ETL to be transparent, both in terms of any effort required to obtain the data as well as removing the need for users to manage copies of the data. With Alluxio, there is always only one master copy that Alluxio may end up caching at various points. These cached versions are automatically synchronized with the underlying storage in the case of updates or other changes when a client accesses them.

Virtual Distributed File System: Alluxio, Fig. 4 Alluxio provides standard APIs to applications and abstracts disparate data stores in a single unified namespace

Alluxio also provides unification, enabling applications to access various datasets across different storages, without needing to understand where the master data is located. This is especially helpful as organizations try to derive more insights from different data repositories.

Future Research Directions

As more applications and data stores use Alluxio, more sophisticated interfaces will be desired to optimize performance and ease of use. For example, Alluxio currently provides a rich set of file-based APIs to access data, but a large number of applications would prefer APIs such as key-value or SQL.

Alluxio currently acts as a data access layer, providing efficient and simple access to data regardless of data store. As the single layer for data access, Alluxio is in a unique position to collect data metrics and usage patterns. These can give users insight into their data and can also be used by Alluxio to do optimizations in the background. These optimizations could range from data prefetching to data modifications like compression. Many of these optimizations could also be pushed down into the data stores if the data stores support them natively.

Virtualized Big Data Benchmarks

Tariq Magdon-Ismail
 VMware Inc., Palo Alto, CA, USA

Synonyms

[Cloud big data benchmarks](#); [Virtualized hadoop benchmarks](#)

Definitions

Virtualized big data benchmarks measure the performance of big data processing systems, such as Hadoop, Spark, and Hive, on virtual infrastructures (Ivanov et al. (2014)) (The term *virtual infrastructure* could either mean on-premise or cloud infrastructure. While virtualization is not strictly necessary to support cloud computing, it is typically a foundational element of all major

cloud computing services.). They are important for making quantitative and qualitative comparisons of different systems.

Historical Background

Big data applications are resource intensive and, as such, have historically been deployed exclusively on dedicated physical hardware clusters, i.e., bare-metal systems. As big data processing moved out of the specialized domain of Web 2.0 companies into the mainstream of business-critical enterprise applications, enterprises have been looking to take advantage of the numerous benefits of virtualization such as elasticity (Magdon-Ismail et al. (2013)), scalability, agility, multi-tenancy, security, ease of maintenance, and cost savings due to consolidation and better resource utilization. As the prevalence of virtualized big data workloads increases, so does the importance of virtualized big data benchmarks.

Foundation

In the early 2000s, early adopters advised against virtualizing big data workloads, citing I/O performance degradation since big data systems were originally implemented to run in a bare-metal environment. This is similar to the situation that prevailed in the early 1990s, when data centers relied almost entirely on physical servers for traditional applications. That scenario changed completely with the entry of server virtualization and hypervisors in the early 2000s, and today over 75% of all data centers run virtualized server environments.

Virtualization introduces a degree of separation between the compute and storage layers that is contrary to the traditional method of tightly coupling and colocating a compute task with the data it needs, using bare-metal physical servers and direct-attached storage (DAS). While historically this was a requirement for performance given the prevalence of 1 G Ethernet, innovations in network bandwidth have caused speeds to double and quadruple over the recent years, while

disk bandwidth has not progressed at the same rate. Moreover, as data centers rapidly upgrade from 1 G Ethernet switches to 10 G and even 40 G or 100 G switches, network bandwidth will no longer be a bottleneck for virtualized I/O performance.

With advances in hardware and virtualization technology, the overhead of virtualizing big data workloads has been significantly reduced for most use cases, and, in fact, performance could be even better than a physical cluster because of the better resource utilization achieved with virtualization (Buell 2013). However, the performance impact of virtualization varies depending on the workload, and virtualized big data benchmarks play an important role in evaluating and understanding the performance characteristics of these resource-intensive workloads on a virtualized infrastructure.

There could be subtle changes to the durability and availability guarantees provided by the big data processing software platform when run on a virtual infrastructure (compared to bare metal) depending on how the components of the platform are deployed (HADOOP-8468 (2018)). While the benchmark code might not need to be modified to run on virtualized systems, if the underlying physical infrastructure is not carefully considered, the benchmarked system might not have the equivalent durability/availability characteristics compared to that of a physical deployment. For example, the same version of the Hadoop TeraSort benchmark (O’Malley 2008) that runs on bare-metal hardware will successfully run unmodified on a virtual infrastructure, but physical topology needs to be carefully considered when deploying the Hadoop DataNode (HDFS 2018) virtual machines (VMs). Deploying Hadoop such that data block replication occurs between Hadoop DataNode VMs residing on the same physical server would result in better performance, but if a single server fails, data will be lost, defeating the purpose of, and the guarantees provided by, Hadoop’s distributed file system (HDFS 2018).

Some industry standard benchmarks such TPCx-HS (2018) and TPCx-BB (2018) have stringent full disclosure and audit/review

requirements to make sure that durability and availability guarantees are maintained on a virtual infrastructure the same way as they are in a physical environment.

Key Applications

Big data applications span a wide gamut of applications, which include:

- Web crawling and/or text processing
- Log and/or clickstream analysis
- Sophisticated data mining and analytics
- Machine learning and AI
- General archiving, including relational/tabular data for purposes such as compliance

Virtualized big data benchmarks are designed to measure the performance of these applications on big data processing systems running on virtual infrastructure. While the modeled application workload varies depending on the application domain and software stack being targeted, the goal of these benchmarks is to facilitate a quantitative and qualitative comparison of different systems.

Visual Graph Querying

Sourav S. Bhowmick¹ and Byron Choi²

¹Nanyang Technological University, Singapore, Singapore

²Hong Kong Baptist University, Hong Kong, China

Definitions

Visual querying of graphs: Formulation of a graph query by drawing it using a visual query interface.

Overview

Querying graphs has emerged as an important research problem due to the prevalence of graph-structured data in many real-world applications (e.g., social networks, road networks, collaboration networks, cheminformatics, bioinformatics, computer vision). At the core of many of these applications lies a common and important query primitive called *subgraph search*, which retrieves one or more matching subgraphs or data graphs containing *exact* (Han et al. 2013; Yan et al. 2004) or *approximate* (Yan et al. 2005; Tian and Patel 2008) match of a user-specified query graph (aka subgraph query). Since the last decade, a number of graph query languages (e.g., SPARQL, Cypher) have been proposed to facilitate textual formulation of subgraph queries. All these languages assume that a user has programming and debugging expertise to formulate queries correctly in these languages. Unfortunately, this assumption makes it harder for nonprogrammers to take advantage of a subgraph search framework as it requires significant time and effort to learn these languages. For example, domain experts such as chemists cannot be expected to learn the complex syntax of a graph query language in order to formulate meaningful queries over a chemical compound database such as *PubChem* (<http://pubchem.ncbi.nlm.nih.gov/>) or *eMolecule* (<https://www.emolecules.com/>). Hence, it is im-

portant to devise easy and intuitive techniques that reduce the burden of query formulation and thus increase the usability of graph databases.

Fortunately, unlike SQL, graph queries are more intuitive to draw than to compose them in textual format. Consequently, visual query interfaces (aka GUI) that can enable an end user to draw a subgraph query interactively have gained increasing attention in recent times from both academia and industry (e.g., *PubChem*, *eMolecule*, *DrugBank*). This has recently paved the way for research in a variety of directions that are driven by visual query interfaces such as novel visual query processing paradigm and interactive guidance to users by providing relevant and timely feedback and suggestions during query formulation, exploration, and visualization of graph query results, among others (Bhowmick et al. 2017a).

This chapter gives an overview to the topic of visual graph querying, discussing the state of the art in the industry and in the academic world. In particular, we emphasize research efforts that aim to bridge two traditionally disparate topics in computer science, namely, graph querying and human-computer interaction (HCI). In the next section, we present an overview of the key problems and solutions in the arena of visual graph querying. Next, in section “An Example” we present an example to illustrate them. The last section concludes this chapter by highlighting future research directions.

Key Research Findings

Our discussion on research findings follows a top-down approach, starting from visual query formulation, proceeding to visual query processing, and concluding with exploration of query results.

Visual Query Formulation

There are mainly three popular approaches for formulating visual subgraph queries. In the *edge-at-a-time* approach (e.g., Jin et al. 2012), a query is incrementally constructed by adding one edge

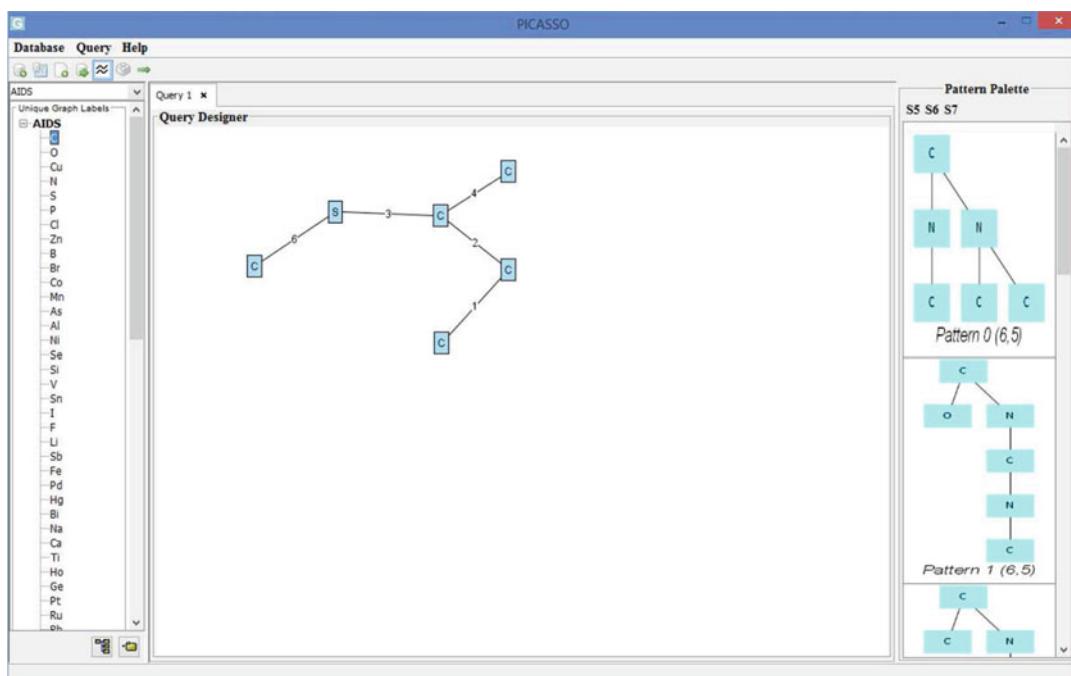

at a time. Note that it may be time-consuming to formulate a query with a large number of edges using this approach. Hence, in the *pattern-at-a-time* approach, one may compose a visual query by dragging and dropping canned patterns or subgraphs (e.g., benzene, chlorobenzene patterns) that are available on the GUI in addition to single edge construction. Figure 1 depicts an example of such an interface. Observe that this approach is more efficient than the former as it typically takes lesser time to construct a query. For instance, instead of drawing six edges incrementally to construct a benzene ring in a query, we can construct it with a single click and drag if it is available as a canned pattern.

Furthermore, the pattern-at-a-time approach can be either *static* or *dynamic* in nature. In the former case, the set of patterns is fixed and displayed in the GUI (e.g., Fig. 1). In the latter case, the patterns are dynamically suggested during visual query formulation by utilizing the knowledge of partially formulated query fragments. The AUTOG (Yi et al. 2017) framework adopts this dynamic strategy. Specifically, it au-

tomatically generates a small list of subgraph as suggestions by considering potential query result size as well as structural diversity. Figure 2 shows an example of subgraph suggestions during query formulation in AUTOG. Note that it is extremely difficult to speculate a priori the subgraph structure that a user wishes to construct during query formulation.

Lastly, recent frameworks such as VISAGE (Pienta et al. 2016) support *query by example* (QBE) for formulating graph queries using examples.

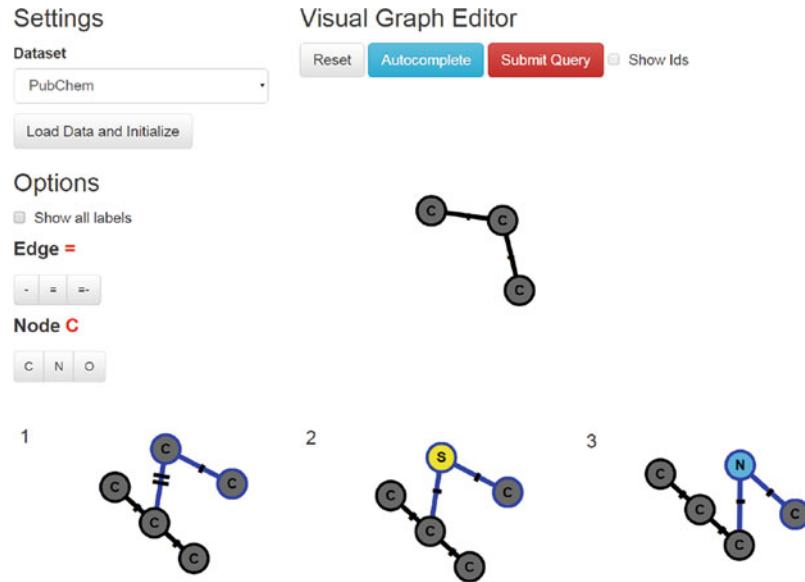

Recently, there has been another line of work that provides opportune *empty result feedback* during visual query formulation. Specifically, the goal is to detect during query construction whether a partially constructed query returns empty results or alerts users in a timely fashion so that one can undertake appropriate remedial action(s). Several recent studies (Bhowmick et al. 2015; Pienta et al. 2016) address this problem by notifying a user opportunely when a partially constructed visual query yields an empty result.

Visual Graph Querying, Fig. 1 Pattern-at-a-time visual query formulation

Visual Graph Querying,

Fig. 2 Subgraph suggestions during query formulation

Blending Visual Query Formulation and Processing

In traditional visual query processing paradigm, query evaluation can be performed in two key steps. First, the visual query is transformed into its textual or algebraic form. Second, the transformed query is evaluated using an existing state-of-the-art graph query processing method (Han et al. 2013). Observe that although the final query that a user intends to pose is revealed gradually in a step-by-step manner during query construction, it is not exploited by the query processor prior to clicking of the Run icon to execute the query. This often results in slower *system response time* (SRT), which is the duration between the time a user presses the Run icon and the time when the user gets the query results (Jin et al. 2012). This traditional view of visual graph query processing is primarily due to the fact that until recently the data management community has traditionally considered visual interface-related issues more relevant to the HCI community and orthogonal to data processing.

The techniques in Jin et al. (2010, 2012) and Hung et al. (2014) take a nontraditional step toward exploring a graph query processing paradigm by blending these two orthogonal areas. Specifically, it *interleaves* (i.e., *blend*) query construction and query processing to prune

false results and prefetch partial query results in a single-user environment by exploiting the availability of GUI *latency* (i.e., the time taken to construct an edge of a query graph visually) during visual query formulation. The key benefits of this paradigm are at least two-fold. First, it significantly improves the SRT (From an end user's perspective, the SRT is crucial as it is the time a user has to wait before she can view the results.) as the query processor does not remain idle during visual query formulation by processing the potential subgraph query early based on "hints" received from the user. Second, as a visual query is iteratively processed during query formulation, it paves way for realizing efficient techniques that can enhance usability of graph databases such as query suggestion and exploratory search (Huang et al. 2017).

This framework constructs offline and online indexes based on underlying features of data graphs. When a user adds a new edge e to a visual subgraph query q , it constructs and maintains an adaptive online index for the edge to facilitate blending of visual query formulation and processing. If the user is interested in exact subgraph matches, then it retrieves the candidates of q (stored in R_q) by leveraging the offline and online indexes. If R_q is empty, then it means that there is no exact match for q after the

addition of e . Consequently, the user can either modify q or retrieve similar matches to q . If the user chooses the latter, then q is regarded as a subgraph similarity query, and corresponding candidate matches are retrieved by leveraging the indexes. On the other hand, if the user chooses the former, then a user-selected edge is removed and the online index is updated. If the user clicks the Run button, then the constructed query q is processed to retrieve result matches. If q is an exact subgraph query, the exact results will be returned after conducting candidates verification (i.e., subgraph isomorphism test), if necessary, on R_q . Otherwise, if it is already a subgraph similarity query, then results that match q approximately are returned to the user.

Note that in the above framework, the expensive candidate verification step is performed only after the Run button is clicked and not during visual construction of the query fragments. Second, it allows a user to execute a query fragment anytime during query formulation and not wait until the entire query is visually formulated. This facilitates exploratory search as a user may formulate a partial query, execute it, browse the results, and then continue expanding it (Huang et al. 2017).

Interactive Exploration of Query Results

The preceding subsection highlights frameworks that exploit human interactions with a visual graph query interface during query formulation to process subgraph queries iteratively. Naturally, it is imperative for such visual subgraph querying frameworks to enable efficient exploration and visualization of result matches of such subgraph queries. This is a challenging problem as it requires effective summarization and visualization of the content and structure of the matching subgraphs involved in a potentially large collection of query results. In this subsection, we briefly describe efforts reported in recent literature to this end.

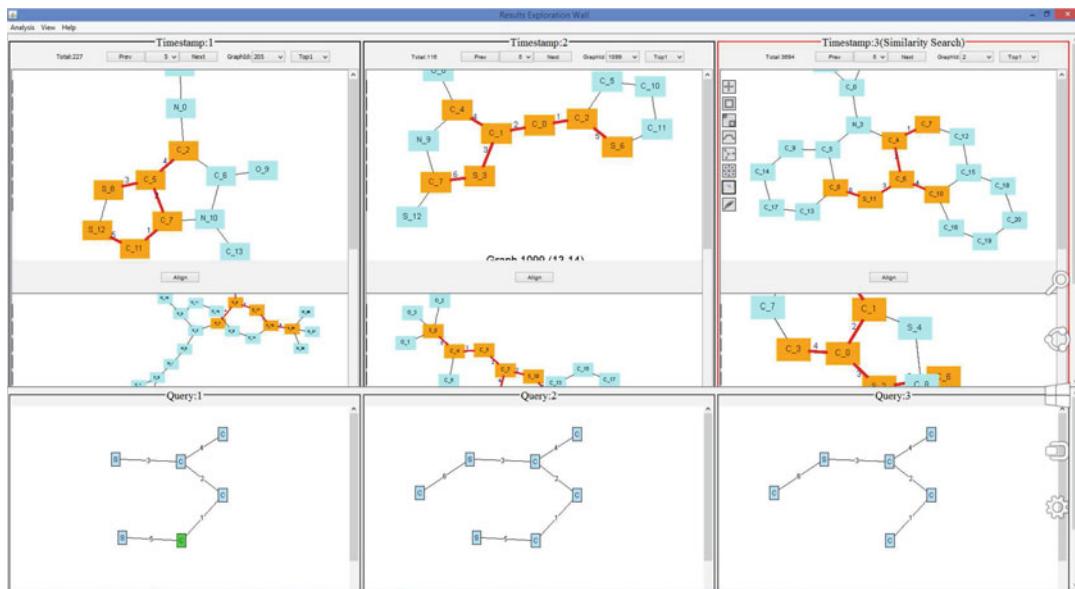

Despite the fact that exploration of query results is the first step toward sensemaking for a user, scant attention has been paid on this problem by both academic and commercial graph data management communities. Specifically, we

can categorize visual exploration of graph query results into two types: (a) visual exploration of query results in a large collection of small- and medium-sized graphs (Jin et al. 2010, 2012; Huang et al. 2017) and (b) visual exploration of result matches in a large network (Hung et al. 2014; Pienta et al. 2016, 2018). We elaborate on them in turn.

Exploration in a large collection of small- and medium-sized graphs. Early efforts for exploration of query results (Jin et al. 2010, 2012) simply displayed result matches in a list, without revealing connections among results. A matching subgraph in each data graph is then highlighted with different colors to identify the component of the data graph that matches a visual query. These results may be further sorted by various measures such as subgraph distance (for approximate match). For instance, in Jin et al. (2010, 2012), a user can only iteratively scroll through each result data graph to view query results. Clearly, this is tedious even for modest-sized query results and cannot easily reveal patterns and relationships between matching subgraphs.

PICASSO (Huang et al. 2017) is a system that utilizes the query processing engine described in the preceding subsection to support visual exploratory search. It accommodates the results of the initial and reformulated query graphs to be juxtaposed in the form of *parallel search streams* (i.e., parallel query-results pairs) that facilitate exploration of the underlying data and possible identification of new search directions. Figure 3 depicts an example of three parallel search streams during exploratory search in PICASSO. Furthermore, it provides a framework to further search and analyze various features of the search results during the exploration process to facilitate understanding of the data.

Exploration of result matches in a large network. It is well known that visualizing large graphs containing thousands of vertices and edges is cognitively challenging. Consequently, the aforementioned approach of highlighting the result matches of a visual subgraph query by color-coding them in the original data graph is

Visual Graph Querying, Fig. 3 Parallel search streams in PICASSO

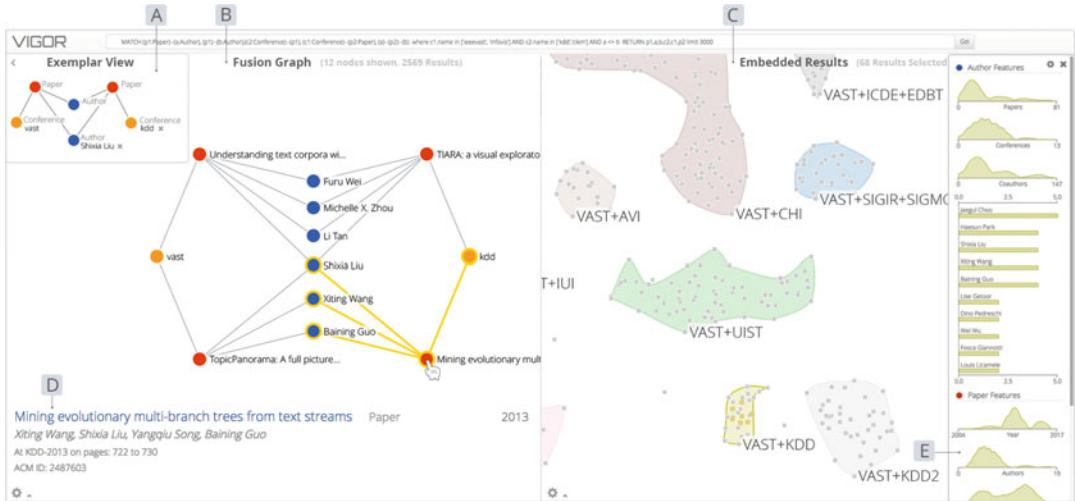

ineffective in the context of large networks as it is not only challenging to locate query results in a giant “hair ball” but also it is extremely difficult to comprehend the structural relationships among the vertices in a matching subgraph overlaid on a large network. Despite these challenges, there are very few works on query results exploration on large networks. Similar to Jin et al. (2010) and Jin et al. (2012), early efforts such as VISAGE (Pienta et al. 2016) simply display the results in form of a list.

Recently, there has been an increasing attention to develop advanced techniques for query results exploration for large networks. This work can be broadly classified into three types, namely, *region-based*, *exemplar-based*, and *feature-based exploration*. Intuitively, a *region-based exploration* scheme iteratively displays a small region of the underlying network containing a result match of a subgraph query. By showing only a fragment of the original network one at a time, it alleviates the cognitive overhead associated with the visualization of all query results on the original network. The approach in Hung et al. (2014) adopts this strategy. In an *exemplar-based exploration* scheme, a user can select a specific query result (i.e., an exemplar)

and relax its constraints to retrieve other similar results. A user can also start the exploration by specifying only the topology (without constraints on node values) and iteratively add constraints to narrow in on specific results. *Feature-based exploration* schemes, on the other hand, take a top-down approach by generating a high-level overview of all the query results. Specifically, it groups the query results based on the structural features and embeds them in a low-dimensional representation. VIGOR (Pienta et al. 2018) supports both exemplar-based and feature-based exploration schemes (Fig. 4).

An Example

Consider a chemical compound repository containing a large collection of small- or medium-sized graphs such as *PubChem*. Suppose a user wishes to formulate the subgraph query shown in Fig. 1. She may visually formulate it either using an interface that supports edge-at-a-time query formulation by adding the five edges iteratively or using a static pattern-at-a-time interface (e.g., Fig. 1) to quicken the formulation by dragging and dropping canned patterns. Alternatively, a

Visual Graph Querying, Fig. 4 Visual interface of VIGOR (Pienta et al. 2018)

dynamic pattern-at-a-time interface such as Fig. 2 can be leveraged where suggestions are generated iteratively as the user formulates her query. Specifically, Fig. 2 depicts the three suggestions generated by AUTOG (Yi et al. 2017) after the addition of two C-C edges. The query is shown in the middle of the GUI, whereas relevant suggestions are presented in the bottom. She may adopt the second suggestion and continue with the query formulation task. Next, AUTOG presents the user’s final query as Suggestion 3 as shown in Fig. 5. Consequently, the selection of this suggestion completes the query formulation task.

The techniques proposed in Jin et al. (2010, 2012) can be utilized to interleave aforementioned query formulation with query processing. Specifically, the query can be iteratively executed during formulation, and corresponding results can be explored to gain insights. Figure 3 depicts such exploration. The original query is shown in the bottom left panel. The modifications to this query with addition and deletion of edges are shown in the bottom middle and right panels, respectively. The corresponding search results for each of these subgraph queries are shown in the top. A user can compare the search results and explore the differences between the result sets and features of the nodes in them using PICASSO (Huang et al. 2017).

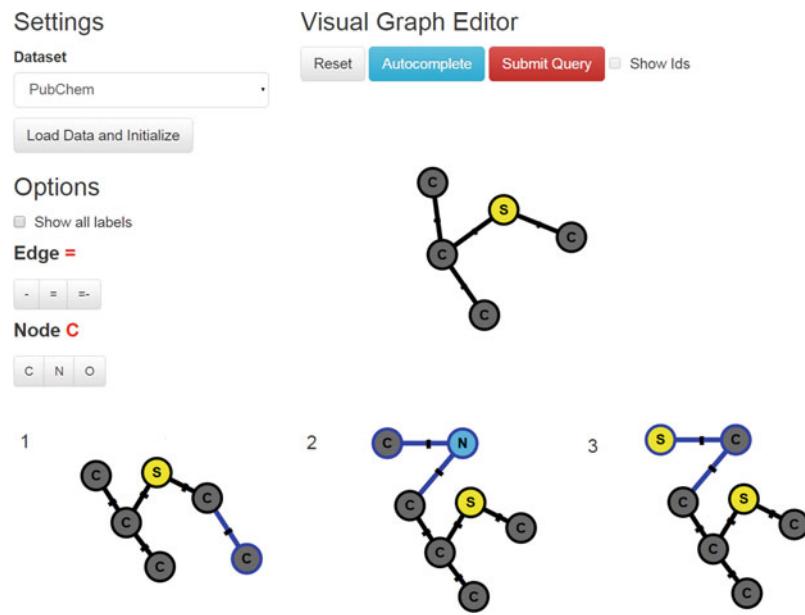

Future Directions

While good progress has already been made, research on visual graph querying opens up many opportunities for continued research as highlighted below. Some of these topics were introduced by recent vision papers (Bhowmick 2014; Bhowmick et al. 2016).

Data-driven construction of visual query interfaces. Most of the real-world GUIs for visual graph querying are constructed and maintained *manually*. That is, details of visual design of a GUI are manually worked out, and contents of various components are created manually by “hard coding” them during GUI implementation. Unfortunately, such manual effort may create GUIs that do not provide sufficient features to aid efficient query formulation, are static in nature when the underlying graph data repository evolves, and have limited portability (Bhowmick et al. 2016). To alleviate these limitations, a recent work introduced the paradigm of *data-driven* GUI construction and maintenance (Zhang et al. 2015), where the goal is to automatically construct the content of various panels of a GUI and maintain them as underlying data evolves. Such a data-driven paradigm has several benefits such as superior support for visual subgraph

Visual Graph Querying.

Fig. 5 Query suggestions of Suggestion 2 of Fig. 2, where Suggestion 3 is the completed query

query construction, significant reduction in the manual cost of maintaining an interface for any graph query-based application, and portability of the interface across diverse variety of graph querying applications. However, these are very early efforts, and there are many opportunities to explore this novel paradigm of GUI construction further.

Visual querying on massive graphs. All researches related to guidance for visual query formulation, visual action-aware query processing, and exploration and visualization of query results have focused either on a large set of small- or medium-sized data graphs or on networks with millions of nodes. A natural extension to this paradigm is to support similar problems on massive graphs (comprising hundreds to billions of nodes), which may demand a distributed framework and novel algorithms built on top of it.

Efficient processing of complex graph queries. Current research demonstrates the viability of blending visual formulation and processing of subgraph containment and subgraph similarity search queries. It is an open problem to enhance the expressiveness of such visual querying

framework to handle more complex subgraph queries such as homomorphism-based subgraph queries (Fan et al. 2010).

Multifaceted exploration and visualization of query results. As remarked earlier, techniques that enable rich, interactive exploration and visualization of graph query results are still in its infancy. *How can we easily explore and visualize results of a variety of subgraph queries to gain better understanding of it?* This is especially a challenging problem when the underlying graph is massive as the entire graph looks like a giant hair ball and the subgraphs that are returned as results to a query are lost in the visual maze. Furthermore, it is interesting to explore additional insights that we may attach to the matched results that may enable end users for further exploration.

Automated performance study. User studies are *sine qua non* for evaluating the performance and effectiveness of the aforementioned visual action-aware query processing techniques. In contrast to the traditional query processing paradigm where the runtime performance of a large number of subgraph queries can be easily measured by automatically extracting

a random collection of subgraphs from the underlying data and executing them (Katsarou et al. 2015), each visual query graph *must* be formulated by a set of users. This is because in this paradigm the availability of the GUI latency at each formulation step is exploited to prefetch and refine candidate matches. To address this challenge, it is important to automatically generate many test subgraph queries having different *user-specified characteristics* (e.g., frequent, infrequent) using indexes and simulate their formulation based on different query formulation sequences *without requiring human users*. A recent effort (Bhowmick et al. 2017b) addresses this by building an HCI-based framework for simulating subgraph query construction on a database containing a large number of small- or medium-sized graphs. It can be used to automate exhaustive evaluation of performances of various visual action-aware query processing techniques. However, this area is still in its infancy with only one notable work.

Definitions

Visualization of big spatial data is the process of generating a pictorial representation of a spatial dataset. What signifies spatial data visualization is that the spatial attributes in the data, e.g., lines and polygons, are mainly used to produce the generated image which results in a wide range of possible visualizations.

Overview

Visualization is one of the most important features used with spatial data processing as it gives a bird's-eye view of the data. It is a natural way to browse and interact with spatial data. As the spatial data gets bigger, interactive visualization of such data is a paramount need for scientists in various domains. It helps in identifying interesting patterns, anomalies, or special conditions which are usually hard to detect. For example, biochemists use visualization to predict protein structure (Cooper et al. 2010), planetary scientists found ice on Mars by visualizing thermal images (Smith et al. 2016), neuroscientists

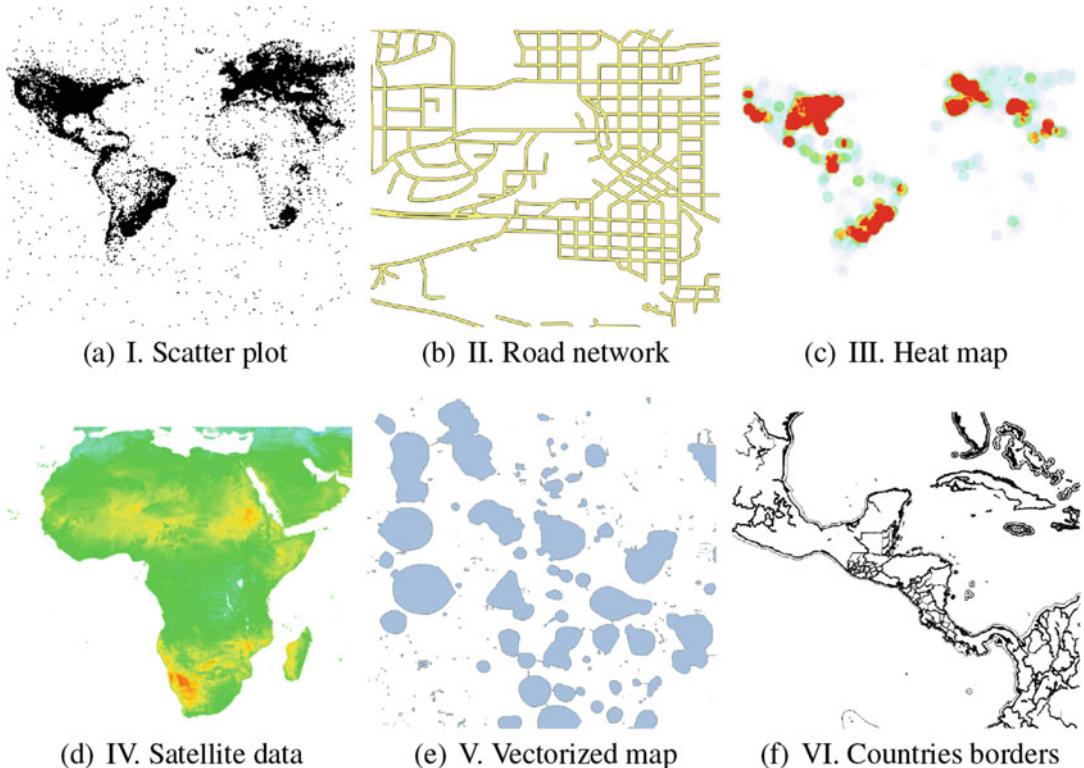

study the functions of the brain via interactive visualization of simulated data (Markram 2006), scientists in the field of connectomics analyze 3D microscopic images to understand the structure of the nervous system (Lichtman et al. 2014), and doctors discover new knowledge by visualizing electronic health records (EHR) (West et al. 2015).

While nonspatial data visualization is usually concerned with aggregating the data to produce bar charts or pie charts, spatial data visualization is more involved as it produces images that describe the input records. It can be as simple as a scatterplot or a heat map for a set of points. But it can also be used to produce more sophisticated images such as visualizing a road network, vehicle trajectories, brain models (Markram 2006), and protein structure (Cooper et al. 2010). Figure 1 portrays a few examples of spatial data visualization.

Traditionally, spatial data visualization was performed using single-machine algorithms that keep all the data in the main memory (Middel 2007; Cruz et al. 2013; Song et al. 2012; Maciejewski et al. 2010; Bezerianos et al. 2010; Elmquist et al. 2008). These techniques focus on defining how the generated image should look like per the application needs, while the performance was out of scope. As the data gets bigger, there is a dire need to improve the performance of the traditional techniques to scale to terabytes of data. However, there are many challenges that have to be addressed in big spatial data visualization as described below.

Data Size: Traditional techniques were designed for small datasets that can fit in the main memory. These techniques were inherently sequential and cannot be easily parallelized to big data.

Abstraction: In order to handle big datasets, parts of the visualization process have to be injected in big data platforms, such as Hadoop or Spark. The challenge is to identify the minimal and representative set of abstract operations that can be parallelized to serve a wide range of visualizations.

Visualization, Fig. 1 Examples for spatial data visualization. (a) I. Scatter plot. (b) II. Road network. (c) III. Heat map. (d) IV. Satellite data. (e) V. Vectorized map. (f) VI. Countries borders

Big Images: Big spatial data visualization is not only about big data but also about big images. As the size of the data increases, there are more details to encode in the generated image which requires producing terapixel images that catch as much details as the users want.

Interactivity: Since big spatial data visualization is about data exploration, the generated visualization has to provide interactive exploration capabilities where users can zoom in and out or pan around the produced image.

The research in big spatial data visualization can be broadly categorized in three categories, *visualization abstraction*, *single-level visualization*, and *multilevel visualization*. The visualization abstraction focuses on defining a descriptive and powerful abstraction that can be used to produce a wide range of visualizations. The single-level visualization is concerned with the generation of a fixed-resolution image that describes

the underlying data with no interactivity such as zoom in and out. Multilevel visualization aims to produce a multilevel image where users can interactively zoom in and out to see more or less details. The rest of this article describes the state-of-the-art research in each of these three topics.

Key Research Findings

Visualization Abstraction

The visualization abstraction defines a set of core functions that can be reused and/or customized to build a wide range of visualizations. In nonspatial data visualization, these abstractions include sampling, aggregation, and filtering (Wu et al. 2014; Battle et al. 2013; Jugel et al. 2014; Wesley et al. 2011). Defining these abstractions allowed some systems to handle big data visualization by injecting these functions inside a database system or a big data platform to scale up to terabytes of

data (Wu et al. 2014; Battle et al. 2013). Unfortunately, these abstractions are not very descriptive when it comes to spatial data visualization such as the visualization of trajectories or road networks.

Protopvis (Bostock and Heer 2009), Vega (Satyanarayan et al. 2016, 2017), and D3 (Bostock et al. 2011) provide more sophisticated visualization abstractions that can be used to produce complex visualizations. They allow users to link data sources to visualizations to produce nice and complex visualizations. In particular, Protopvis focuses on building complex visualizations linked to the input data with the goal of producing more complicated visualizations. D3 is concerned with integrating the visualizations with the data object model (DOM) used in HTML documents to produce web-ready visualizations. Vega aims to add interactivity to these visualizations by allowing the users to define *selectors* that can filter the data being visualized. These systems provide good examples of different visualization abstractions used in various applications. They focused on being descriptive rather than scaling to terabytes of data.

HadoopViz (Eldawy et al. 2016), on the other hand, provides an abstraction that focuses on the scalability. Rather than decomposing the produced image into primitive elements, HadoopViz focuses on data partitioning and image partitioning where small subsets of the data can be processed independently to produce parts of the final image. Then, the partial images are combined together to produce the final image. Unfortunately, this abstraction does not allow any interactivity as the produced image is not linked to the original data used to produce the image. Nonetheless, it can scale to terabytes of data by seamlessly allowing distributed processing using the Hadoop MapReduce platform.

Single-Level Visualization

This part describes the recent research on producing a single-level image with a fixed resolution. A single-level image is a regular image, e.g., PNG, which provides a pictorial representation of a dataset. Notice that the produced single-level image can be in a vector format, e.g., SVG, but it still has a fixed resolution, or level of details,

which is embedded in the generated image. If the user wants a higher or a lower resolution, the image has to be regenerated.

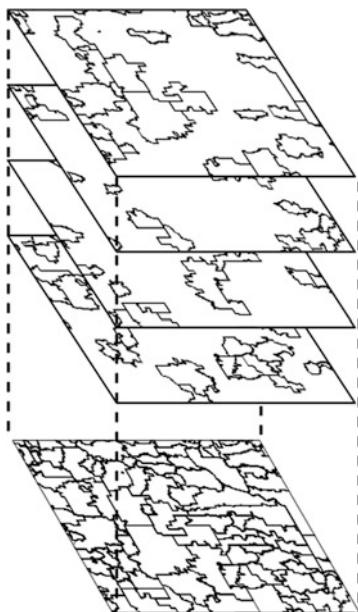

When it comes to big spatial data visualization, the main challenge is how to process all the input data in parallel to produce the final image. The basic idea is to partition the data, allow each machine to visualize each partition to produce a partial image, and finally combine the partial images to produce the final image. Depending on how the data is partitioned, single-level visualization techniques can be categorized into three categories, nonspatial partitioning, pixel-level partitioning, and spatial partitioning.

Nonspatial Partitioning

In nonspatial partitioning, the data is partitioned using any traditional partitioning method, e.g., random, round-robin, or hash partitioning. By default, most big data platforms, e.g., Hadoop and Spark, use a block-based random partitioning where each fixed-size block of data (128 MB) is assigned to three machines chosen at random. As a result of this nonspatial partitioning, each block or partition might contain data from the entire input space. Therefore, when a partition is visualized, the produced partial image will be mostly as big as the final image as it covers the entire input space (Eldawy et al. 2016).

Figure 2 shows an example of visualizing a set of polygons that represent the boundaries of ZIP codes. Each partition contains a set of polygons that cover the entire input space. In order to combine them into one final image, we *overlay* the partial images on top of each other. This requires defining a function that takes the individual pixel values from the partial images and produce one pixel value (or color) in the final image. One example is to initialize each partial image with a transparent background that reveals the corresponding pixels in other partial images as shown in Fig. 2.

The advantage of nonspatial partitioning is that the partitioning step is typically very fast. In many cases, the input data is already partitioned in a distributed file system, such as HDFS, and the partitioning step can be skipped altogether. The drawback is that as the desired image size

Visualization, Fig. 2 Visualization using nonspatial partitioning. The partial images are overlaid to produce the final image

increases, the sizes of partial images become too large and might slow down the overlay step and the entire visualization process. For example, if a giga-pixel image is desired, each partial image will contain a few gigabytes of data that need to be transferred over network to combine in a single machine that will finally process all of them to produce the final image.

Pixel-Level Partitioning

Pixel-level partitioning tries to resolve the drawback of nonspatial partitioning by carefully partitioning the data such that all the data records that affect a single pixel are combined together in one partition. For example, when visualizing satellite data, each pixel in the produced image can be mapped to a region on the Earth surface. If all the data in that region are combined together in one partition, then we can produce the final color of that specific pixel without considering any other data. This technique was used to visualize 3D meshes (Vo et al. 2011) and satellite data (Planthaber et al. 2012).

In pixel-level partitioning, the number of partitions can be as large as the number of pixels

in the desired image. For example, to generate a 1000×1000 pixels image, up to one million partitions will be created. Notice that the number of partitions can be smaller in the case when some partitions do not contain any data, e.g., water areas when visualizing land data. While a huge number of partitions can be created, this technique has two main advantages. First, there is no need to define a logic that combines different pixel values into one final value as each pixel is generated by exactly one partition. Second, regardless of the number of partitions, the output of each partition is always a single pixel value which allows this technique to scale to larger images than nonspatial partitioning techniques.

Spatial Partitioning

This technique is a generalization of the pixel-level partitioning. Instead of creating exactly one partition for each pixel, this technique partitions the input data into regions such that each region covers a rectangular region of the final image which might contain more than one pixel. The spatial partitioning takes into account the data distribution so that each partition contains roughly the same amount of data. Each partition is then processed to produce a partial image that contains only the pixels covered by that partition. The partial images are finally *stitched* together to produce one final image (Eldawy et al. 2016).

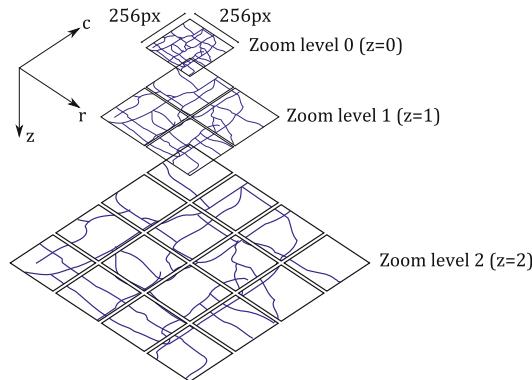

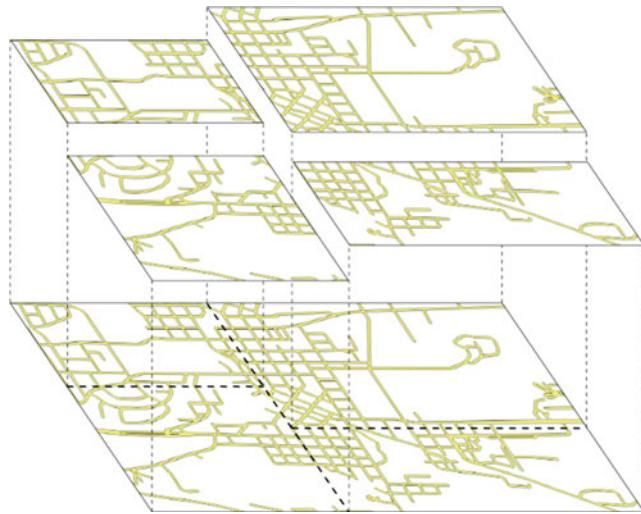

Figure 3 gives an example of visualizing road segments where partial images are stitched together, like a jigsaw puzzle, to produce the final image. This technique can reduce the number of partitions as compared to pixel-level partitioning while still maintaining its advantages. While each partial image can be larger than a single pixel, they are still much smaller than the entire image. If a uniform grid partitioning is used where the number of grid cells is equal to the number of pixels in the output image, it transforms to the pixel-level partitioning technique.

Multilevel Visualization

Figure 4 shows an example of a multilevel image with three levels, also called a three-level pyramid. Unlike a flat single-level image, the multilevel image consists of a large number of

Visualization, Fig. 3

Visualization using spatial partitioning. The partial images are stitched to produce the final image

Visualization, Fig. 4 A multilevel image with three levels

fixed-size tiles arranged in a pyramid structure. The tiles in each level collectively cover the entire input space. Each tile is identified by the tuple (z, c, r) , where z is the zoom level and c and r are the column and row number of the tile in the grid of level z , respectively. As we go deeper in the image, the number of tiles increases; hence, the resolution of the image also increases.

Multilevel visualization processes an input data to produce a multilevel image with a user-specified number of levels and tile resolution. The challenge is to produce all the tiles efficiently. Notice that the number of tiles increases exponentially with the number of zoom levels. For a multilevel image with 10 levels, more than a million tiles might need to be generated. There

are two techniques for multilevel visualization based on the partitioning technique as detailed below.

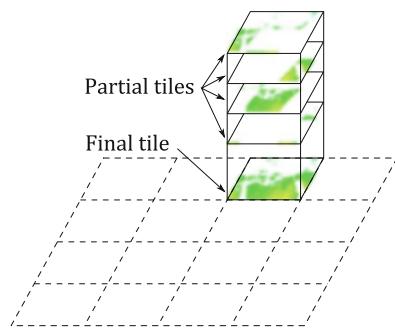

Nonspatial Partitioning

If a nonspatial partitioning is used, e.g., hash partitioning, then the records in each partition might span the entire input space. This means that each partition might contain records that cover *all* the tiles in *all* the zoom levels. Each partition is then processed independently to produce a multilevel image that is as big as the final image, i.e., it contains the same number of tiles as in the final image. However, these tiles are considered partial tiles and need to be merged to produce the final image for that particular tile.

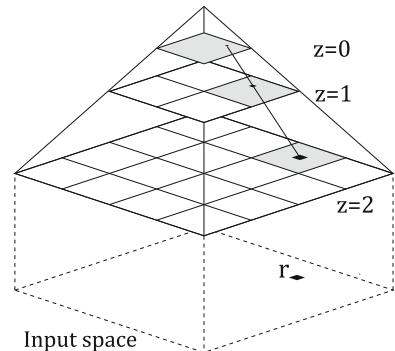

Figure 5 shows an example of how four partial tiles are merged to produce one final tile in the third level of a multilevel image. Similar to the nonspatial partitioning in single-level visualization, the partial tiles are overlaid to produce the final tile. While each tile has a fixed resolution, e.g., 256×256 pixels, there can be millions of tiles which might incur a huge overhead in the merge process.

Pyramid Partitioning

In pyramid partitioning, the data is partitioned according to the pyramid structure such that all the records that contribute to the visualization of one tile are grouped together in one partition.

Visualization, Fig. 5 Overlaying partial tiles in multi-level images

Visualization, Fig. 6 Pyramid partitioning

This means that each tile is generated by only one machine which completely eliminates the need of a merged step.

Figure 6 shows an example of pyramid partitioning when applied to a single record r . As shown in the figure, the record r is assigned to three partitions, one at each level. This means that the same record is processed three times or, in general, as many as the number of zoom levels in the multilevel image. While this technique eliminates the need of the merged step, it suffers from one major limitation; it has to process each tile on a single machine. If one tile overlaps with too many records, that single tile might be a bottleneck in the visualization process. At an extreme case, the single tile at the top of the pyramid always covers the entire input space. Therefore, visualizing that single tile using pyramid partitioning requires a single machine to process all the input dataset. To overcome this limitation, the nonspatial and pyramid partitioning techniques can be combined

together where the nonspatial partitioning is used to produce the first few levels, while the pyramid partitioning is used to visualize the deeper levels of the pyramid (Eldawy et al. 2016).

Examples of Applications

Visualization is used in many applications for interactive exploration. A major application is the visualization of maps which is also known as cartography (Kraak and Ormeling 2011). Biochemists use visualization to predict protein structure (Cooper et al. 2010). Planetary scientists found ice on Mars by visualizing thermal images (Smith et al. 2016). Neuroscientists study the functions of the brain via interactive visualization of simulated data (Markram 2006). Scientists in the field of connectomics analyze 3D microscopic images to understand the structure of the nervous system (Lichtman et al. 2014). Doctors discover new knowledge by visualizing electronic health records (EHR) (West et al. 2015).

Future Directions for Research

There are many open research problems in the area of big spatial data visualization. First, visualizing three-dimensional data is particularly challenging as the final image changes depending on the camera placement. This means that once an image is generated, the user cannot rotate the view without regenerating the entire image. Second, visualizing dynamic data interactively is also challenging as each new record invalidates the generated image. As the rate of record updates increases, there must be a way to partition the records across machines and update the generated image in parallel.

Exploratory Data Analytics; Visual Data Exploration

Definitions

Visualization techniques for big data exploration, also known as *visual data exploration* (both terms will be used interchangeably in this article.), refer to a particular field of data visualization research that aims at devising and employing visualization techniques to aid the understanding of (extremely) large data sets (Keim 2001). These techniques evolved from the original concept of data visualization, which was originally defined as “the use of computer-supported, interactive, visual representations of abstract data to amplify cognition” (Card et al. 1999). The goal is thus to make information ready at hand so that people can make informed decisions in a timely fashion. The use of data visualization is often divided into two basic tasks (and tools thereof): data exploration and data representation. In *data exploration*, users are primarily concerned with investigating a data set in order to manipulate the data, learn more about it, test hypotheses, and the like. In *data representation*, on the other hand, users are primarily concerned with conveying specific information, highlighting particular properties and/or features of the data, and the like. Visual data exploration refers to the processes of achieving the former by means of the latter.

The visual exploration of big data poses unique technological challenges to the development of visualization techniques. Not only is the sheer size of big data a challenge but also its intrinsic characteristics, such as heterogeneity, high-dimensionality, and real-time nature. As Heer and Kandel (2012) put it, big data is tall (extremely large data sets), wide (high-dimensional data), and diverse (very heterogeneous data). Also, big data is fast (dynamic and time-sensitive). These characteristics directly affect the ability of visualization techniques to handle large data sets, often requiring data preprocessing and rendering techniques suitable for conveying appropriately massive amounts of data (Keim et al. 2006). These are long-lasting challenges in the field of information visualization (Chen 2005).

To enable users to extract meanings and gain insights from extremely large sets of data (i.e.,

big data), visualization techniques combine data processing and analysis, visualization techniques, and interactive visual interfaces. This refers to an emerging field known as *visual analytics*. Visual analytics is defined as the science and technique of analytical reasoning supported by interactive visual techniques and interfaces (Cook and Thomas 2005). Its methods and techniques allow decision-making over complex sets of data by leveraging on human’s inherent visual cognitive capabilities and modern interactive data processing technologies (Keim et al. 2008a). It supports a wide range of data processing tasks, but, in particular, it is conducive to visual (big) data exploration.

Overview

Everyday activities are deluged with data that has been growing exponentially in the past 20 years. But, data has no value in itself. It has to be processed, rendered, analyzed, and ultimately interpreted by human beings in order to create value. Approaches that enable them to explore and make sense of such large sets of complex data become paramount. This is not without challenges, notwithstanding. Such a data explosion creates the requirements for approaches that handle not only the sheer size but other intrinsic characteristics of big data, namely (Heer and Kandel (2012) outline the first three):

- Data is **tall**: extremely large data sizes that may contain millions or billions of records;
- Data is **wide**: a single data may contain hundreds or even thousands of features;
- Data is **diverse**: it may come from multiple data sources with varied data types; and,
- Data is **fast**: it may be highly dynamic and time-sensitive.

These characteristics make it rather difficult to extract meanings (and value thereof) from big data without the combination of advanced data analytics and interactive interfaces through which users can steer the exploration processes.

Hence, visualization techniques play a critical and central role in enabling big data exploration and discovery by means of integrating the increasing power of computer algorithms that analyzes extremely large data sets, the power of well-designed visual representations that make evident critical characteristics and relationships of the underlying structures of data, and the human cognitive power that is innately capable of identifying patterns, relationships, and the like from complex visualizations.

Big data exploration can be thus thought of as a process through which users investigate large data sets in attempts to identify useful information and gain insights, often without knowing beforehand what to look for Bikakis et al. (2016). It is an iterative process whereby users continuously process data, gather more information, select and combine different data representations, and incrementally gain new insights to answer a question at hand. To this end, visualization techniques should enable users to manipulate complex data sets in order to identify clusters, gaps, outliers, trends, and relationships in their underlying (often hidden) structures.

According to Thomas and Cook (2006), the aims of visualization techniques for data exploration are as follows:

- To increasingly facilitate understanding of massive and ever-growing collections of heterogeneous data sets;
- To support various data types, such as spatial and temporal data (in addition to unstructured data formats);
- To support understanding of uncertain, incomplete, and even misleading information;
- To enable users to integrate the context of their information needs into the data exploration processes; and
- To support multiple levels of data abstraction, summarization, and integration of data of various formats.

Yet, the effectiveness of these techniques rests on human inherent visual perception and reasoning abilities (i.e., its interpretability). These cog-

nitive capabilities enable humans to detect and recognize visual patterns, such as shapes, sizes, textures (and colors), distances, similarities, and more, effortlessly. Humans have an innate ability of understanding complex information visually (Thomas and Cook 2006). In contrast, human symbolic manipulation capabilities (e.g., dealing with numbers) require greater cognitive effort (and training). Contrary to common wisdom, numbers do not always speak for themselves. The goal of visualization is thus to “show the numbers,” that is, how to best represent and convey numerical (or categorical) information so that one can best extract meanings and values out of data and thus make the most appropriated informed decision.

In this context, many factors affect the effectiveness of visualization techniques, such as:

- **Screen attributes** determine not only the kind and amount of information that can be displayed but the choices of the most appropriate visual metaphor (Bieh-Zimmert and Felden 2014) and the ways in which users will be able to interact with the visualization. Key screen attributes are size, pixel, density, resolution, brightness, contrast, viewing angle, bezels, display technologies, and form factor (Andrews et al. 2011). They do not equally affect the ability of displaying and making sense of large data sets. For instance, the number of data elements in big data scenarios by far exceeds the number of pixels of even ultrahigh-resolution displays. This would lead to overplotting if one attempted to visualize every data point.
- **Visual metaphor** defines the ways in which data is represented visually. The question is to determine the most appropriate visual metaphor (or their combination thereof) that can best convey the intrinsic characteristics of the data being explored. A critical task is to identify the right metaphor that can best identify gestalt (see Human perception below), convey meanings, facilitate discovery and interpretation, enhance detection and recognition, and the like (Meirelles 2013).

- **Interactivity** is the mechanism by which users can manipulate and explore large data sets by means of selecting, filtering, zooming, brushing, scaling, and panning the data. Doing so, users can overview the data, select particular perspective(s) by zooming and filtering, and drill down to any particular area of interest. In addition, users may select different color palettes to best represent different data characteristics, different metaphors, and the like in order to make sense of the data. To coordinate actions across multiple representations is also critical to enable users to explore more complex, multidimensional data sets.
- **Data preprocessing** refers to the use of data analysis algorithms in order to reduce the amount and determine the kind of information to be rendered and displayed. In many visualization techniques, the direct mapping between data points and visual items results in occlusion and cluttering (Liu et al. 2013). Data analytics enables users to visualize just the “right” data. It is comprised of techniques and algorithms for aggregating, clustering, filtering, sorting, and the like the data.
- **Human perception** is a critical factor in determining the effectiveness of a visualization technique for big data exploration. Human’s innate cognitive capability of identifying visual patterns or outliers in images, as described in Gestalt psychology, plays a critical role in enabling visual exploration of large data sets. For instance, linearities and nonlinearities, continuities and discontinuities, clusters and outliers, and grouping and distinctions are important Gestalt features that affect how humans perceive and consequently make sense of visual data (Buja et al. 1996).

Visualization Techniques for Big Data Exploration

Visualization techniques for data exploration are a means for making information ready at hand so that people can make the most informed decisions in a timely fashion. And, many are those

techniques, as aforementioned. They primarily refer to a set of algorithms and approaches that convert data into visual structures based on different visual encodings so that it can be rendered and displayed. Those encodings depend on the nature of the data (i.e., its structure and composition). Some data will be best represented by pixel-oriented methods (e.g., dense pixel), icon-based methods (e.g., “glyphs”), axis-based methods (e.g., scatterplot matrices, parallel coordinates), graph-oriented methods (e.g., network data), or their combination.

While the next sections will cover individually the most critical visualization techniques for data exploration, it is noteworthy that most of the practical visual data exploration solutions employ various combinations of these techniques as well as others. Significantly, there are many ways in which these techniques can be “snapped together” in support of exploration tasks, such as **linking and brushing** (Becker and Cleveland 1987; Ward 2009), **panning and zooming**, **focus-plus-context**, and the like. The overall idea is to interconnect and coordinate the actions (e.g., selecting, filtering, zooming, etc.) on one visualization across all other available ones. In sum, multiple coordinated visualization techniques are critical to enable complex data exploration (North and Shneiderman 2000).

Pixel-Oriented Methods

Pixel-oriented (Keim 2000) or **dense pixel** (Keim 2001) techniques render each data point as a colored pixel where each dimension value is represented by a particular color and all pixels that are part of the same dimension are grouped into adjacent areas. In so doing, they in general partition the screen in N subarea, where N is the number of dimensions (or attributes/features) of the data. The resulting visualization allows users to identify local correlations, dependencies, and key areas within and across dimensions (or data attributes). These techniques aim at supporting the visualization and exploration of large amounts of multidimensional data. These techniques tend to suffer from the problems of occlusion and cluttering when attempting to display very large data sets (Liu et al. 2013).

Icon-Based Methods

Icon-based techniques (Nocke et al. 2005) render each data item as an icon and data attributes (or dimensions) as features of the icons. This is a proved approach for visualizing multivariable or multidimensional data, where data variables are mapped onto geometric (e.g., shape, size, orientation, position) and nongeometric (e.g., color, texture) visual attributes. Those visual “icons” are also known as “glyphs” (Ward 2002), which are defined as graphical entities that display one or more data values by means of those visual attributes (see Ward 2008 for a thorough description of how to generate and organize effective glyphs for multivariate data). The value of this approach stems from effectively communicating data attributes or supporting the detection of similarities, differences, clustering, outliers, and relationships in multivariable data. Certain mapping choices between data attributes and visual attributes might lead the users to privilege some relationship over others because of perception biases. It is thus critical to select the attributes in a systematic way as well as to employ techniques for reducing clutter and to order the attributes effectively.

Axis-Based Methods

Axis-based methods represent data item dimensions, and/or variables are represented as axial relationships in a 2D plane (Liu et al. 2015). The most well-known visualization techniques of this class are parallel coordinates and scatterplot matrices.

Parallel coordinates techniques are non-projective mapping between N -dimensional and two-dimensional sets (Inselberg and Dimsdale 1987, 1990). In essence, it differs from other multidimensional visualization techniques by representing the relations rather than finite point sets. On a two-dimensional plane with xy-Cartesian coordinates, the N -dimensional space is represented as N parallel and equidistant lines perpendicular to the x-axis. A point C with coordinates (c_1, c_2, \dots, c_N) is represent as a polygonal lines whose i -vertex is at c_i distance from x-axis for $i = 1, \dots, N$. This

technique allows multivariate relation patterns to be revealed by showing all dimensions simultaneously. Liu et al. (2015) point out that since this is essentially a linear ordering of N parallel lines in the x-axis, there are $N!$ possible permutations. Hence, the greatest challenge is to determine the most appropriate order of those features. Overplotting and visual clutter also become an issue when the number of points to be represented becomes too big. A data technique, called **focus+context**, has been employed to reduce clutter while at the same time highlighting key features in a parallel coordinate plot (Novotny and Hauser 2006), where both trends and outliers are captured and treated appropriately: trends that capture the overall relationship between axes are rendered as regions (polygon strips) and outliers are rendered as single lines. This is also an interactive technique in that selected data items are visually highlighted (line or regions of different colors).

Scatterplot matrix techniques (Carr et al. 1987) represent N dimensions as $N(N-1)$ ordered bivariate scatterplots. They are comprised of a collection of scatterplots, each of which representing the relationship between two dimensions (or features). In essence, they allow users to view multiple bivariate relationships simultaneously (Liu et al. 2015). For large data sets, the goal of each scatterplot is to represent data density and the matrix to allow the comparison of those density distributions across dimensions. Scatterplots are axis-based techniques for depicting the relationship between two variables/dimensions. The density representation could employ different visualization artifacts, such as color palettes, gray scale, and shapes (e.g., hexagons, circles, and the like). For very large data sets, visual cluttering is a common problem with scatterplots as many values may appear in the same location – though high-resolution displays may help to alleviate the overplotting problem (Andrews et al. 2011). In addition, since the number of bivariate scatterplots increases quadratically with the increase in the number of dimensions, approaches have been introduced to automatically or semiautomatically identify or rank the most interesting ones (see Liu et al. 2015).

Graph-Based Methods

Methods for graph visualization essentially aim at rendering relational data (i.e., data that is structured as nodes and edges) (Herman et al. 2000). There are a number of visualization techniques for representing graph structures. The size of the graph is one of the determining factors in the selection of the appropriate graph visualization. Comprehensibility is one of the major issues when one attempts to visualize a large graph as the display becomes clutter, and it becomes difficult to discern the difference between nodes and edges. The type of graph structure to be visualized, such as hierarchy, directed acyclic graph (DAG), and directed graph, also influences the graph visualization technique to be employed. For general graph, the most common approach is the **node-link diagram** which may utilize different layout algorithms, such as grid-variant algorithm (GVA), fast multi-scale (FMS), fast multipole multilevel (FM³), etc., for drawing nodes of a graph.

One particular type of graph structure is a tree, which is basically a hierarchical data structure. Tree structures are not limited to traditional organizational charts, file structures, subroutine call graphs, logic programming, and the like; they can also represent other complex data types, such as evolutionary and phylogenetic trees in biology or biochemical pathways and protein functions in chemistry. Traditional **tree layout** positions children nodes equally distant from parent ones, which reflects the intrinsic hierarchy of the data. A number of tree layout algorithms have been proposed, such as H-tree, balloon view, radial view, and others (see Herman et al. 2000 for more details). **Treemaps** (Johnson and Shneiderman 1991) is a particular method, based on the space-filling technique that maps hierarchical data into a rectangular-shaped 2D display, where 100% of the designated area is utilized. The area of each individual graph node will represent a numerical attribute of the data defined by the user (such as counts, size, etc.). The bounding boxes of each area represent a level in the hierarchy, and the location placement of items will recursively follow the hierarchical structure of the data.

Yet, as other visualization techniques, traditional graph visualization techniques fall short of supporting large graphs. Interactive approaches, such as **hyperbolic layout** (Lamping et al. 1995), which is a **focus+context** method that distorts the tree view using, for instance, fish-eye distortion, emerged in attempts to tackle the challenges of visualizing very large graphs. Graph clustering technique (Mukherjea et al. 1995) is another important data reduction technique for enabling the use of graph visualization for large graph data sets. However, data aggregation techniques are solely effective if each aggregated level can be effectively visualized as a node-link diagram and if the navigation between levels can maintain the necessary continuity so that users do not lose context (Elmqvist et al. 2008).

Adjacency matrix (Abello and van Ham 2004) has emerged as an alternative, effective technique for visualizing large networks. It couples a matrix representation with hierarchical aggregation to allow large network visualization and navigation. One of the greatest challenges of adjacency matrix is to determine the most appropriate ordering of rows and columns so that users can make sense of the graph data and extract insights. Elmqvist et al. (2008) propose a “zoomable” approach for adjacency matrix, named **Zoomable Adjacency Matrix Explorer**, which is a tool for large graph exploration at a scale of millions of nodes and edges. It allows users to “explore a graph at many levels, zooming and panning with interactive performance from an overview to the most detailed views” (Elmqvist et al. 2008, p. 215).

Nowadays, with the advent of the Internet, graphs, such as social network graphs, are in the order of billions of nodes, which pose unprecedented challenges to the visualization technique. For instance, Leskovec and Horvitz (2008) presented a study of 30 billion conversations generated by 240 million distinct Messenger accounts, which in turned created a communication graph of 180 million nodes and 1.3 billion undirected edges and a “buddy” graph of 9.1 billion edges. In order to gain insights from this massive graph, in addition to employing traditional social network analysis techniques, they utilized the concept

of **heat-maps** (or density) on top of traditional scatterplots and maps. In so doing, they displayed the density of the information for the various attributes of interest (such as number of communications, conversation duration, messages per conversation, and the like) as opposed to displaying individual notes and edges.

Data Aggregation Methods

Although the aforementioned visualization methods, namely, pixel-oriented, icon-based, and axis-based, attempt to tackle both multidimensionality and scalability issues, Yang et al. (2003) assert that they tend not scale well when data is wide (large numbers of dimensions) and tall (huge numbers of data points). In fact, they alone do not effectively scale even to moderately small data sets (Eick and Karr 2002). According to Liu et al. (2013), techniques that directly map each data point into a visual item tend not be well suited for visualizing very large data sets (tall data), due to occlusion and cluttering issues. Putting it simply, the challenge stems from how to “squeeze a billion records into a million pixels” (Shneiderman 2008). On a similar note, Elmqvist and Fekete (2010) assert that visualization techniques, such as scatterplots (Ward 2009), parallel coordinates (Inselberg and Dimsdale 1990), and treemaps (Johnson and Shneiderman 1991), alone do not handle large-scale data sets well, in that they result in clutter that hinders visual understanding. Hence, visualization techniques for big data exploration require the combination of visualization techniques, data processing, and interactive interfaces.

To address this problem, **data aggregation** techniques have been proposed. They aim to tackle both rendering and occlusion problems as they limit the number of items to be displayed (Elmqvist and Fekete 2010). For instance, Guo (2003) proposes a framework and approach for coordinating computational algorithms (e.g., feature selection) and interactive visualization to allow data analysts to explore high-dimensional data. According to him, feature selection is a nontrivial task that may render data visualization useless if not properly employed. He thus argues for a greater integration and coordination be-

tween data analytics and visualization techniques by means of a “human-centered and component-oriented knowledge discovery approach” (Guo 2003, p. 233) for big data exploration.

Data aggregation is part of a large set of data reduction techniques which also include **filtering** (e.g., Ahlberg and Shneiderman 1995), **sampling** (e.g., Bertini and Santucci 2006), and **clustering** (e.g., Jain et al. 1999). Both filtering and sampling techniques pin down a subset of the data that will be displayed by a standard visualization technique. The challenge is then to decide which subset to select. Different sampling techniques have been proposed, such as random sampling (every data point has the same probability of being selected), systematic sampling (a regular sampling interval/pattern is employed throughout the entire data set), and stratified sampling (disjoint subgroups are created and random and systematic sampling are applied in each group or “strata”) (Liu et al. 2013).

Data aggregation, on the other hand, does not reduce the data to be displayed but orderly group them out in “bins” – thus also known as **binned aggregation**. Bins can thus be defined as “adjacent intervals over a continuous range” (Liu et al. 2013, p. 423) or **density plots** (Shneiderman 2008). The benefit of this technique results from keeping both global patterns (e.g., density) and local features (e.g., outliers) in the same visualization while enabling multilevel resolution via different bin sizes. In sum, it focuses on limiting the “resolution” rather than the “data” to be displayed. On a separate note, Ellis and Dix (2007) systematically review and evaluate a number of data processing techniques relative to their effectiveness in addressing particular data clutter issues, including data aggregation. In particular, they look into their benefits and losses in clutter reduction techniques and, consequently, propose a guideline for future technique developments.

The ultimate goal of data aggregation methods is to improve visual scalability. Putting visualization and data aggregation techniques together sets the backstage against which visualization techniques will be able to effectively and efficiently interact with big data and consequently support data exploration. Choo and Park (2013)

nevertheless suggest that data analysis methods (or computational methods) need to be customized in order to effectively support visualization tasks. They argue that computational methods are often treated as “black boxes,” which hinder data analysts’ proper understanding of their internal “mechanics” in order to make appropriate adjustments and choices. On the other hand, they require intense computation and significant run-time, hindering real-time, interactive visualization. The authors thus propose customizing those methods based on the precision and convergence requirements of the visual exploration task at hand. Ultimately, the goal of data aggregation techniques is to provide data analysts with the most appropriate level of data resolution (or approximation) in order to allow them to interactively explore the data set and consequently extract deeper insights.

Interactive Techniques

Despite the recent advances in data analysis techniques, humans are still required to be involved so as to make sense of those large data sets. Current technologies fall short of general reasoning capabilities that would allow them to extract useful meanings out of those data sets, in particular when little is known about the data and the exploration goals are not fully defined. Thus current approaches for visual data exploration seek to integrate humans in the data exploration processes.

For visualization techniques to support (big) data exploration, they are required to allow data explorers to “slice and dice” large data sets by means of interactive visual interfaces. It should enable users to manipulate, search, and analyze those data sets in attempts to identify useful information and ultimately extract relevant insights to the problem at hand. In reality, users often start with no clear understanding or hypothesis about the data. Through the iterative process of data investigation, they incrementally construct meanings and a better comprehension of the data structures and contents, which allows them to start formulating an increasingly clearer hypothesis. The process of exploring large data sets is thus not simply a process of extracting information

from represented data patterns but a synergistic process of human-machine interaction by which machines contribute with their data processing and rendering power and humans contribute with their inherent reasoning and visual aptitudes.

Interactivity means not only adding humans to the loop but empowering them to effectively explore the data spaces (by quick testing hypotheses, switching views, and the like) at the rate of human thought (Heer and Kandel 2012). Visual exploration of big data thus requires an interplay between analytical reasoning interactive visual data manipulation and exploration. Visual data exploration workflow has been traditionally described by Shneiderman (2003) as “overview first, zoom/filter, details on demands” (a.k.a. the infamous *information seeking mantra*). However, big data demands a greater deal of data analyses (often automated) in order to allow more profound understandings of the data in question. In light of this, Keim et al. (2006) proposed a *visual analytics mantra*: “analyze first, show the important, zoom/filter, analyze further, details on demand.” This new *mantra* underscores the importance of combining and integrating data analytics methods and interactive visual interfaces. Putting it simply, it shows the role of employing **visual analytics** in support of big data exploration.

In the past 10 years, **visual analytics** emerged with the aim of further integrating those three critical aspects of big data exploration: visualization techniques, data analytics, and human visual reasoning (Keim et al. 2008b). This is a multidisciplinary field of research that combines analytical reasoning techniques, interactive visualization, and data analytics in order to tackle the challenges of handling massive, heterogeneous, and dynamic data sets. It enables the exploration of big data by providing technological tools and techniques by which users can manipulate, examine, select, and compare those complex data sets. To this end, it combines visual and data analysis methods, which allow progressive evaluation of the data and refinement of analysis results (Sun et al. 2013). By tapping into human’s inherent visual cognitive capabilities, visual analytics enables the discovery of critical visual similarities,

patterns, and relationships that allow incremental refinements of data models and consequently a deeper understanding of the data. In turn, data analytics transform the data so that it becomes better suited for its visualization. As a result, visual exploration aided by advanced data analytics provides an effective approach for exploring very large sets of data.

Future Directions of Research

Thomas and Cook (2006), back in 2006, proposed a list of issues to which the visualization research community was supposed to attend in order to address the data challenges they were starting to face. Six years later, Wong et al. (2012) outlined a list of ten major challenges in extreme-scale visual analytics – dealing with exabyte (10^{18}) data. Both also resonate with Heer and Kandel's (2012) questions for future research in interactive (big) data analysis. Interestingly, their lists and questions are still up-to-date and relevant today, with minor exceptions. In fact, the challenges have only abounded due to the data deluge of the past 20 years. Thus, it is reasonable to assert that the next advances in interactive visualization and visual analytics research will have to take into consideration the following challenges:

- To further expand visual analytic techniques to help data analysts to understand massive and continually growing collections of heterogeneous data. This implies, among other things, (1) being able to perform data and visual analyses with the data on memory (*in situ*) so as to allow human-thought speed (this is a major issue, in particular, when operating in cloud environments), (2) devising user-driven data reduction approaches so that data analysts would have more control of the process, and (3) devising new data summarization and triage for interactive queries.
- To deal with increasingly more complex and heterogeneous data. For instance, it will be important to devise frameworks and techniques

for spatial-temporal data analyses, semantic extraction of multimodal data, and multiple data-type fusion.

- To devise new approaches and techniques for tackling and understanding uncertain, incomplete, and often misleading data. In this context, it will be critical to create new mechanisms for representing evidence and uncertainty in extreme-scale data while minimizing visual “biases.”
- To support multiple levels of data abstraction and data-type integration in the same visual representation. And,
- To create new methods and approaches for allowing data analysts to more easily reason from extremely large data sets.

An open research field is to take a human-centric agenda to investigate the (social, physical, and virtual) environments for visual data exploration. As repeatedly pointed out here, human involvement is key in big data exploration. Hence, one future research direction would be to investigate how to improve human visual perception and understanding of big data. For one, alternative interaction techniques have been proposed, such as the use of augmented reality and virtual reality (Olshannikova et al. 2015), i.e., mixed reality as a means to allow data analysts to visually explore large data sets by embedding virtual content into the physical world in which they act. Reda et al. (2013) propose a hybrid reality environment, a large-scale visualization environment, in which the line between virtual environment and wall displays is blurred. They incorporate high-resolution, stereoscopic displays in order to provide a more immersive data exploration experience. On a different note, Heer et al. (2007) propose an approach for asynchronous collaboration on information visualization as a means of supporting collective sensemaking. Today's approaches and techniques tend to focus on individual data analysts exploring large, complex data sets by themselves. However, most of the data explorations are collective practices involving more than one individual. Thus,

creating conditions for supporting group visual data exploration becomes a necessary area of research.

While visualization techniques for big data exploration will continue to evolve with the development of incredibly richer visual metaphors, real-time interactive interfaces, sophisticated data analytic algorithms, ultrahigh-definition display walls, and the like, the most promising future technological directions will come out from an interdisciplinary collaboration between this field and artificial intelligence (AI). On the one hand, AI will become a site for employing advanced visual data exploration techniques in order to address major data/model understanding problems. On the other hand, visualization techniques will be able to benefit from the recent advances in AI, in particular in machine learning techniques (be they supervised or unsupervised) to allow the development of more sophisticated and complex data models, eliminating (at least in part) the need for human feature engineering. In this context, instead of direct data manipulation, data analysts will be interacting through the interface with models and algorithms. Today, they are already interacting with data models, but AI will turn that interaction more nuanced as models will increasingly become more like complex autonomous agents. This creates a host of new research questions not only relative to new visualization techniques for better conveying meaning out of machine learning-based data analyses but interactive interfaces through which data analysts will be able to meaningfully operate those increasingly more complex models.

Automated creation of infographics; Visualizing linked data; Visualizing RDF data

Definitions

Visualizing semantic data describes the task of using the additional self describing features of semantic data (Linked Data/RDF) to inform the process of creating vector or bitmap drawings.

Overview

Visualizations are representations of data solely created for humans. The primary objective of a visualization is to clearly and efficiently communicate information to a target audience. A visualization allows us to focus on particular aspects of data by choosing specific types of primitives and aggregates. Furthermore a visualization optimizes for efficiently delivering the intended message to the end user.

Creating meaningful and efficient visualizations of data is a difficult task. It integrates the understanding of the data at hand, the knowledge of valid aggregations and transformations, and finally the selection of the right type of visualization to convey the intended message. There exist multiple professions like infographic design, data

journalism, and data science specializing in these tasks. These professions rely on a variety of tools to create visualizations. The tools are informed by a plethora of implicit knowledge, based on raw data mostly.

With semantic data, i.e., data which is provided with additional information regarding its form and content, new possibilities open up for data visualization. The modeling of the data and its relations is defined by well-known vocabularies and ontologies. Furthermore, with the use of RDF (see <https://www.w3.org/RDF/>), semantic data can be represented in a common representation regardless of the form of its original or underlying data model.

Examples of such data models include:

- Dimensionally organized data (linear data models): time series, statistical data, and geographic data
- Structural data: trees, taxonomies, and graph data
- Annotated multimedia: images, audio, video, and 3D models

A tool without any external information and that is also missing knowledge on the data model at hand cannot propose any sensible visualization. Thus, there exist several tools for creating visualizations specific to a data model.

The process adopted to create a visual representation based on semantic data can be described end-to-end; this provides the inherent advantage that the outcome is reproducible by the system without further external intervention by the user or developer in case of corrections or updates to the underlying data.

Future research directions could propose systems which can fulfill the demand of efficient and effective visualizations by allowing users to craft visual representations based on their formulated intent combined with the inspection of the provided data.

Because semantic data in RDF is represented as graph data, a number of methods were proposed for visualizing this graph data as graph

drawings (node-link diagrams) (Graziosi et al. 2017). Recent examples on the web are VOWL (<http://vowl.visualdataweb.org/>) and LodLive (<http://en.lodlive.it/>). However, researchers have argued that there exist only a small number of specific use cases (e.g., exploration of ontologies Lohmann et al. 2016) where the graph representation is actually efficient for the task at hand. For most tasks, other forms of visualizations tend to be more efficient (Dadzie and Pietriga 2016).

In the following sections, the current state of research and available tools for the creation of visualizations with semantic data (in our example represented in RDF) are described. First, a number of *requirements regarding the data model* of the semantic data are introduced. Then, a *taxonomy for the overall task* of creating visualizations based on semantic data is provided. In addition, the different *steps necessary to create visualizations* based on semantic data are discussed. Finally, an overview on the *spectrum of tools* used for visualizations, from handcrafted to automated approaches, is provided.

Semantic Data Requirements

Semantic data provides information to machines which help to understand the data itself. Apart from having the data expressed in a valid form like RDF, it is necessary for the data to be modeled by an ontology or described in an RDF Schema. This allows the reuse of any visualization on similar datasets following the same ontology. In the following, a selection of ontologies which are leveraged for visualization techniques is described. The ontologies are organized by the data model they provide for visualization.

V

Dimensional

Dimensional data organizes related data points on a dimension; in the case of semantic data, it additionally describes its content. Typical examples of dimensional are the *time* dimension or dimensions from a data-specific categorical attribute like *gender* or *age*.

A good starting point for arbitrary dimensional data is the *Data Cube vocabulary* (<https://www.w3.org/TR/vocab-data-cube/>). Not only does this vocabulary allow for a clear definition of the dimensions and properties inside a dataset, it also defines additional descriptions like titles, dimension descriptions, and units which can be attached to the data points, dimensions, and datasets, respectively.

Another base for dimensional data is to use the standard mode output of *csv2rdf* (<https://www.w3.org/TR/csv2rdf/>). This is especially useful as the data to visualize is often provided in CSV format anyway.

Hierarchical/Structural

For the modeling of hierarchical and structural information, the use of the *SKOS Ontology* (<https://www.w3.org/TR/skos-reference/>) is widely spread. It is also feasible to represent structural information directly with the *OWL Web Ontology Language* (<https://www.w3.org/TR/owl-overview/>).

Geographical

Geo-spatially located data points often use the simple *Basic Geo Ontology* (<https://www.w3.org/2003/01/geo/>). For more complex geospatial data, one can refer to the *GeoSPARQL* (<http://www.opengis.net/standards/geosparql>) documentation which is using *well-known text (WKT)* (<http://www.geoapi.org/3.0/javadoc/org/opengis/referencing/doc-files/WKT.html>).

Miscellaneous

Further media data (pictures, video, or audio) can be described and annotated with the *Web Annotation Vocabulary* (<https://www.w3.org/TR/annotation-vocab/>). The power of semantic data also comes with the possibility to combine and mix different data models. This is possible as all the data models introduced above are organized by the same RDF formalisms.

Taxonomy

In this section, a high level taxonomy with the goal to situate the different available approaches

is provided. The taxonomy is influenced by prior work on visualization taxonomies: Brunetti et al. (2013) provide a formal framework in this context, while Graziosi et al. (2017) focus on the visualization of graph drawings.

The task of creating visualizations based on semantic data is split into the following steps:

1. View selection: when necessary, a specific subset of the available data is chosen.
2. Visual primitive selection: a fitting type of visualization is selected.
3. Data mapping: data then needs to be projected onto the visual primitive.

At the end of this section, interactive visualizations in line with this taxonomy are shortly discussed.

Selection of the Data View

The semantic data to be visualized can be accessed in multiple ways, from data dump files through server calls or a generic query language.

Typically, the data to be visualized is a part of all the available data points in a dataset. Hence, there is the need to select a view on the data, which is a subset of all available data. The decision on which data points are part of the visualization is determined by the application logic which also handles the interaction with the visualization itself.

The selection of the data view is dependent of primitives available for data access and filtering. In case the semantic data is preprocessed in a file, the selection was probably already done during its creation process. In case there is a (REST Style) API defined to provide the semantic data, the possible views are then defined through the API design.

On the contrary, if semantic data is consumed through a query language (like SPARQL), the application logic can define the view on the data in more detail. The generated visualizations also might have the potential to interact with the view selection mechanism in order to get updated iteratively.

Selection of the Visual Primitive

Once the decision is made about which data points should be visualized, selecting a suitable visual primitive is necessary. A visual primitive is a description of how to transform (render) the structured data on a canvas to create a visualization. Two approaches to select the appropriate visual primitives can be identified: an explicit selection during the data creation process or an implicit selection at run time.

Generally, the selection of the visual primitive is *explicitly* defined, either in the programming code itself or through annotating the data with hints which visualization to use.

For systems where the selection is *implicit*, the selection of the visual primitive becomes a ranking problem based on a catalog of available visual primitives. Rule-based systems leverage properties of the semantic data to decide on a visual primitive. Many properties can be leveraged in that sense, including the size or the dimension of data objects or the level of a hierarchy. In addition, the rule engine can also leverage features from the semantic model itself, for example, the use of specific ontologies (as introduced in the section above).

Rule-based engines can be further informed by the context of the application or use cases, including the mode of interaction with the user (role, language) and the current device(-type) she uses (desktop, mobile).

Future research is needed to provide applications to solve the selection of visual primitives with machine learning approaches based on the features described above.

Explicit and implicit approaches are not mutually exclusive, and systems profit from a combination of both these methods.

Data Mapping

Once the view on the data and the visual primitive has been fixed, both need to be connected.

Projection of the Data

For the majority of visual primitives (e.g., line and bar charts), the data needs to be projected from the graph representation of the semantic data onto one or multiple continuous dimensions.

If the data is consumed through SPARQL, this step is often solved early on by using a SELECT query. The SELECT query provides by design as an output a projection of the data to a table structure. This provides a dimensional structure which can be consumed by the mentioned visual primitives. The disadvantage of using a SELECT query is that the output of the query is no longer semantic data but rather a flat table. This has the drawback that additional annotations on the data that might be useful for the visualization are stripped away.

This is why several tools making an implicit visual selection use CONSTRUCT queries in SPARQL instead. The output of such a query is a subset of the source of the semantic data, but it keeps all semantic aspects.

Mapping Based on Semantic Data

If the decision is made to keep the semantic data intact all the way to the creation of the visual primitive, the need to bind the data from the graph structure to the input format of a visual primitive arises. Two approaches are possible in this context.

The more traditional approach is to leverage the information which is held in a TBOX (i.e., the data model, also called an ontology or a schema) to create the mapping for the visual primitive. Thus, the explicit conceptual model of a data structure which informs the mapping is kept. The advantage is that the ontology at hand defines the form of the content itself. This approach has the disadvantage that explicit formulation of the ontology needs to be available during the mapping process.

There are also frameworks which simply rely on the ABOX (the instance data itself). Here, the mapper inspects the data and the input expected by the visual primitive to discover a suitable mapping. In this case the expected input of the visual primitive figures as an implicit TBOX.

Interaction

The interaction with the visual primitives is generally orchestrated through the application logic. In addition, the different visual primitives often come with elements to interact with the

visualization itself. Possible interaction elements are filters on dimensions and values, controls for the selection of dimensions, or controls on the extent to which the data should be shown in the visual primitive.

These controls can either adapt the output of the visual primitive or trigger the demand for another visual primitive altogether.

Tools

In this section, a selection of the available research and tools related to the creation of visualizations based on semantic data is provided, with a focus on tools that create graphics rendered in web browsers. To set a common base for all tools, an overview of the facilities from a web browser to enable drawing of visual elements is first given.

In the first two sections below (*Visualization Libraries and Frameworks* and *SPARQL Specific Frameworks*), approaches where the visualization is explicitly defined are discussed. In the third section (*Selection and Mapping Frameworks*), the current state of research for utilizing implicit selection of visualization primitives is discussed.

Table 1 provides an overview of current tools and sets them in relation with the taxonomy introduced above.

The *HTML5 Canvas Element*, the *HTML WebGL Element*, and the *HTML SVG Element* are the most basic elements for creating visualizations. While the HTML5 Canvas is a pixel-based canvas which provides basic drawing facilities, WebGL provides a 3D context based on OpenGL to draw graphics, while SVG allows to create vector-based visualizations by dynamically creating SVG files. Web-based libraries and frameworks use one or multiple of these elements to perform the visualization inside a web browser.

Visualization Libraries and Frameworks

Visualization libraries differ greatly in their flexibility. A plethora of libraries (<https://developers.google.com/chart/>, <http://www.chartjs.org/>, <https://www.highcharts.com/>) provide catalogs of visual primitives, which expect the input data

to be in a specific format. Most of these libraries provide only basic visualization possibilities.

The most prominent example of a more flexible framework is *D3.js* (<http://d3js.org>). *D3.js* provides developers with a set of tools to create visual primitives that are highly customizable.

SPARQL Specific Frameworks

Sgvizler Skjaeveland (2012) is the first widely used framework to create visualizations directly based on semantic data. Sgvizler fetches data from a SPARQL endpoint with SELECT queries and relies heavily on Google Charts for the visual primitives. It also provides an interface to write custom plug-ins which to create arbitrary visualizations.

The *D3SPARQL* project Katayama (2014) is comparable to Sgvizler in its functionality, as it provides a set of visual primitives based on *D3.js*.

Finally, the D3.js component *d3-sparql* (<https://github.com/zazuko/d3-sparql>) seamlessly integrates in the D3.js code base. It is a drop-in replacement for the d3-csv component. In that way, existing D3.js visualization can be informed through data originating from a SPARQL endpoint.

Selection and Mapping Frameworks

The frameworks presented in the following all provide an implicit selection of the visual primitive.

Tabulator Berners-Lee et al. (2006) introduced a generic data browser, along with the concept of an implicit selection of a user interface component informed through semantic data. Some of these components were featuring visual primitives.

Balloon synopsis (Schlegel et al. 2014) is a jQuery Plugin which allows to easily enhance a website with semantic data. For the mapping *ontology templates* were introduced.

In Uduvudu (Luggen et al. 2015) a framework for adaptive user interface generation is proposed. The Uduvudu framework uses a two-step ruled-based approach to select the user interface elements and the visual primitives. By separating the selection and the rendering step, it puts a focus on the reusability by maximizing dynamic

Visualizing Semantic Data, Table 1 Presented tools located in the introduced taxonomy

Tool/Framework	View selection	Visual primitive	Mapping
Sgvizler	SELECT	Explicit	Hard coded catalog
D3SPARQL	SELECT	Explicit	Hard coded catalog
d3-sparql	SELECT	n/a	n/a
Tabulator	None (Browser)	Implicit/rule-based	In code
Balloon synopsis	Ontology template	Implicit/rule-based	Handlebars
Uduvudu	CONSTRUCT	Implicit/rule-based	Matchers
RSLT	SQM/DQM	Implicit/rule-based	HTML templates
Linked data reactor	Scopes	Implicit/rule-based	Web component
Phuzzy	None (Browser)	Implicit/rule-based	In code (plugin)

composition capabilities. Furthermore, the framework can take the context of the end user (user preferences, used device, language) into account whenever available.

RSLT (Peroni and Vitali 2015) provides a library inspired by the XSLT transformation language. The semantic data is transformed from its RDF model by using templates. The templates are matched with a newly proposed selector language.

Linked Data Reactor (Khalili 2016) is a framework to build reactive applications realized with hierarchical *web components*. The mapping to a component can be done on the level of a dataset, resource, property, or value.

Phuzzy (Regalia et al. 2017) introduces the capability of dynamically downloading plug-ins providing rendering facilities for visual primitives.

Weaker Consistency Models/Eventual Consistency

Faisal Nawab
University of California, Santa Cruz, CA, USA

Definitions

Weaker consistency and eventual consistency models are classes of consistency in data management systems that trade off consistency for performance.

Overview

Data management systems have employed replication and distribution of data for many objectives, including fault tolerance, load balancing, and read availability, among others (Kemme et al. 2010; Bernstein and Goodman 1981). Having data be distributed or replicated on various nodes raises a problem of how to coordinate access to data across all nodes. Specifically, a client accessing data may affect the state of multiple nodes concurrently. With simultaneous access from different clients, the distributed state of the data may be inconsistent due to overwrites, race conditions, and other concurrency anomalies. Distributed and replicated data management

systems are more susceptible to such problems compared to parallel data management systems because the communication delay between nodes is orders of magnitude larger than inter-process communication.

In environments where the communication latency is large, such as geo-scale distributed or replicated data management systems, the coordination cost is exacerbated even more. Additionally, environments with a large number of machines also suffer from high coordination cost. These two characteristics, geo-scale and large-scale deployments, are increasingly adopted due to their benefits, such as increasing the levels of fault tolerance and availability. Also, they are increasingly adopted due to their accessibility through public cloud providers that offer a large amount of resources at various data centers around the world. This has made the coordination cost a pressing problem for data management systems. One of the main approaches that enjoyed wide success in tackling coordination cost is the relaxation and weakening of consistency semantics. Unlike strong consistency semantics, weaker and relaxed semantics can potentially lead to anomalies and thus may be unsuitable for some classes of applications. The explorations in weaker and relaxed consistency semantics aim at understanding the anomalies and models of weaker and relaxed consistency in addition to building data management protocols that achieve these consistency levels while maximizing performance.

Key Research Findings

This section surveys the key advancements in weak and relaxed consistency semantics, with an emphasis on cloud and geo-scale deployments.

Eventual Consistency

Eventual consistency trades off strong consistency for better performance. It has been adopted widely in environments where the coordination cost and performance demands are high. A major influence to this line of work is due to the CAP theorem (Gilbert and Lynch 2002; Brewer 2000). CAP stands for three properties: consistency (different copies or multisite copies of data are consistent), availability (ability to always respond to requests), and partition tolerance (a network failure that separates nodes does not interrupt operation). The conjecture is that only two out of the three properties can be achieved in a replicated system. The implication of this conjecture is that systems that are available and partition-tolerant cannot be consistent. This has influenced eventual consistency, which focuses on availability and partition tolerance in the expense of consistency.

Eventual consistency, broadly defined, is the guarantee that in the absence of updates, all copies of data converge to a common state eventually. Therefore, the results returned at a given time might be inconsistent with a latter view of the data. Although this is a weak model of consistency, it enables higher levels of performance and is especially favorable for applications that require high performance and availability. Methods that resemble eventual consistency in the context of strongly consistent systems dates back to Thomas' majority voting algorithm (Thomas 1979). In that work, multiple copies of a database may have different versions of a data item as a number of write operations may be applied in a different orders in different copies. To choose between the write operations, a database copy picks the one with the largest time stamp. Because all copies pick the write with the largest timestamp, eventually all copies agree on the value of the data item in the absence of further write operations to that data item. In general,

this convergence property relies on the ability to propagate across nodes and the ability to reach a consistent ordering. Often, eventual consistency has been used as a guarantee for replication services that are used by higher-level services that guarantee more complex, stronger consistency guarantees (Terry et al. 1994).

However, more recently, as the need for available high-performance systems grew, eventual consistency has been used as the consistency guarantee observed by programmers (DeCandia et al. 2007; Cooper et al. 2008; Bailis and Ghodsi 2013; Lakshman and Malik 2010). The wide adoption of eventual consistency has shown that a weak model of consistency is capable of supporting large services and a wide range of applications. More importantly, it demonstrated how an eventually consistent system can be built for real-world scenarios by providing a better understanding of the guarantee of eventual consistency, the design principles for building eventually consistent systems, and the best practices in programming with eventual consistency.

An important characteristic of eventually consistent system is that for many workloads, the observed state of data resembles that of a strongly consistent system most of the time (Bailis et al. 2012). Probabilistically bounded staleness (PBS) (Bailis et al. 2012) is an example of modeling and quantifying this behavior on Cassandra, a popular eventually consistent system (Lakshman and Malik 2010). PBS models the behavior and the expected consistency of read data by estimating the probability of deviating from strong consistency. Specifically, given a certain configuration and workload, it is possible to estimate the probability of reading the most up-to-date data value (representing the consistent state). This, and similar models, can also be used to configure the eventually consistent system to satisfy probabilistic guarantees. This is significant as many systems allow configuring the parameters that affects the probability of a consistent outcome.

An enabler of eventual consistency is the set of practical designs and principles that were used to build eventually consistent systems. Although the

basis of many eventually consistent systems is the guarantee of eventual convergence, many higher-level access methods were built on top of that basis to provide better access semantics while maintaining the performance and availability features of eventual consistency. PNUTS (Cooper et al. 2008) is an example of such systems. In PNUTS, data is replicated in many copies, and one of these copies is a primary. A primary receives all write requests and propagates them to secondary copies. PNUTS leverages this write pattern to order writes at the primary. This results in a useful, simple consistency model – called per-record timeline consistency – where writes, which are ordered at the master, are guaranteed to be ordered at the secondary copies. Another example from PNUTS of a higher-level access method on top of eventually consistent data systems is that it provides three ways to read data. A **read-latest** forces the read to be served from the primary, a **read-critical** forces the read to go to a copy that has a recent enough copy according to an input timestamp, and a **read-any** can be sent to any copy and thus provides the highest performance.

In addition to the ability to provide stronger notions of consistency on top of eventual consistency, providing alternative methods to perform the same operation allows the developer to control the consistency-performance trade-off. Some systems take this concept further and build a layer on top of an eventually consistent system to provide stronger consistency guarantees (Zhang et al. 2015; Bailis et al. 2013). TAPIR (Zhang et al. 2015) provides strongly consistent replication on top of an eventually consistent replication service, and Bolt-on (Bailis et al. 2013) provides causally consistent replication on top of an eventually consistent data store.

Another facilitator of the success of eventually consistent systems is the way programmers use them. Being aware of the underlying consistency level may influence programmers to adopt data structures and programming techniques that ameliorate the negative outcomes of eventual consistency. One such class of data structures is the class of commutative operations. Commutative

operations are ones that can be reordered arbitrarily while leading to the same final state, such as increment/decrement operations. Convergent and commutative replicated data types (CRDTs) (Shapiro et al. 2011) is an approach to programming that ensures that the execution of a set of operations would be guaranteed to converge with the final outcome of the execution of the same operations at any order. There have been many data structures based on CRDTs; however, they are constrained and are not applicable to all operation types. Another approach adopted in eventually consistent systems is the ordering of execution at all copies, which guarantees convergence to the same value, such as the example of PNUTS' per-record timeline consistency (Cooper et al. 2008) and the example of Thomas' write rule (Thomas 1979). In PNUTS, a centralized authority orders writes, and in Thomas' write rule, unique time stamps guarantee order. Ordering writes could also be relaxed, adopting partial ordering techniques such as vector clocks (Mattern et al. 1989). The benefit of partial ordering in this context is that ordering is not enforced for concurrent writes, which may reduce overhead. Although there exist a lot of techniques and approaches to reduce the negative outcomes of eventual consistency, they are not applicable to many operations and tasks. For applications that use such operations with eventual consistency, conflict resolution is tricky, requiring intervention or specialized conflict-resolution logic. Helland and Campbell (2009) propose a framework to reason about such conflict resolution methods. Specifically, they divide application logic fall into *memories* which are the states of a local node, *guesses* which are the actions that a node takes based on its current (eventually consistent) knowledge, and *apologies* which are the reactions to mistaken guesses that led to a conflict. An apology can be through human intervention but can also be conducted through carefully crafted conflict-resolution modules.

W

Relaxed Consistency

A large body of work explored the spectrum of the consistency-performance trade-off, that is,

works that explore consistency levels that are stronger than eventual consistency but weaker than strong notions of consistency such as serializability (Bernstein et al. 1987) and linearizability (Herlihy and Wing 1990). The motivation of these explorations is that strong consistency and eventual consistency are two extremes in the spectrum and that for many applications, the consistency and performance requirements are diverse. In such applications, an intermediate consistency level may be ideal as it provides the necessary consistency guarantees while maximizing performance by reducing the overhead of coordination.

Causal consistency (Lamport 1978) is an example of relaxed consistency levels. It is a guarantee to order events according to their causal relations. Causal relations are defined to be one of the following: (1) It has two events that are generated in the same node are totally ordered. That is, they maintain the same order at all nodes. (2) It has an event that is received by a node is ordered after all previous events at that node. This is called the happens-before relation. (3) The causal order is transitive, and thus a chain of causal relations translates to be a causal relation. An alternate definition of causality may depends on the type of operations. For read and write operations, for example, a happens-before relation is substituted with a gets-from relation from a write operation to a read operation if the read has read the value of the write operation (Ahmad et al. 1990; Lloyd et al. 2011). This definition of causal consistency is widely used in data management systems as it is specialized for read and write operations on data items.

An interesting feature of causal consistency is that it does not require synchronous coordination across nodes. An operation that is executed in a node may be served without any coordination with other nodes (propagation of updates and events can happen asynchronously). This makes it possible for causally consistent systems to be both available and partition-tolerant while providing a notion of consistency stronger than eventual consistency. This motivated an exploration of causal consistency in the context of cloud and

geo-scale deployments with high coordination cost (Lloyd et al. 2011, 2013; Bailis et al. 2013; Nawab et al. 2015; Du et al. 2013a). However, an issue that may arise with causal consistency is that multiple write operations on the same data object might not converge to the same value at all locations. This is because two write operations that are issued at different nodes may have no causal relation between each other. This has been tackled by some causally consistent systems. An example is the causally consistent geo-scale data store COPS (Lloyd et al. 2011), where data objects are guaranteed to converge in all locations. COPS formally defines the convergence property in the context of causality by introducing the causal+ consistency. Causal+ consistency adds convergence as a guarantee to traditional causal consistency.

Another challenge with causal consistency is reasoning about causally consistent transactions. Causal relations are traditionally defined in the level of operations and events. It is not immediately clear how these relations can be applied to data transactions that consist of bundles of read and write operations. Raynal et al. (1996) tackle this problem by defining causal-based guarantees for transactional access: causal consistency and causal serializability. Causal consistency defines a causal relation between two transactions if one transaction contains a read operation that reads a value written by the other transaction. Causal serializability augments causal consistency with a guarantee that all writes are observed with a sequential order in all nodes. This addition of a sequential order makes it necessary to synchronously coordinate with other nodes for write operations. However, the other types of access (causal consistency transactions and causal serializability read transactions) can be performed without synchronous coordination. More recently, COPS (Lloyd et al. 2011) and Eiger (Lloyd et al. 2013) explore adding transactional semantics to causal consistency. COPS introduces a read-only transaction interface that is causally consistent. COPS guarantees the consistency of the read-only transaction via a two-phase protocol that,

in the first phase, reads a local snapshot of the data and, in the other phase, updates the read data items with any missing dependencies. Eiger explores similar mechanisms to support both read-only and write-only causally consistent transactions.

Snapshot isolation (SI) is another relaxed consistency guarantee that is widely used in database management systems (Berenson et al. 1995). SI was intended to reduce the concurrency control overhead of serializability. It is defined as a guarantee to (1) read a consistent snapshot of the data and (2) avoid write-write conflicts between transactions. This relaxed notion of consistency, compared to serializability, introduces a short fork anomaly. In this anomaly, two concurrent transactions that write over each other's read data can both commit if their write sets are disjoint. For example, consider two transactions, t_1 and t_2 , that both read the same versions of x and y . Transaction t_1 writes a new value of x , and t_2 writes a new value of y . Both transactions can commit with SI but not serializability. An anomaly is caused when a future transaction reads the values of x and y which do not reflect a serial ordering of transactions. Despite this anomaly, SI has shown to be useful for many applications and to enable higher performance. However, because write conflicts must still be detected, SI requires synchronous coordination between nodes.

SI has been explored in the context of cloud and geo-scale deployments to reduce the expensive cost of coordination (Sovran et al. 2011; Daudjee and Salem 2006; Lin et al. 2005, 2007; Du et al. 2013b). In these bodies of work, efficient designs of SI are explored. Additionally, SI is relaxed further to accommodate geo-scale deployments and enable higher performance in a new consistency level called parallel snapshot isolation (PSI) (Sovran et al. 2011). PSI relaxes SI in a number of ways. PSI requires that a transaction reads a snapshot of the local copy in the data center rather than a snapshot of all copies in all data centers. Also, it extends the definition of write-write conflict to accommodate for the multi-data center nature of geo-scale de-

ployments. Finally, it introduces a causal relation between transactions at different data centers; where a transaction that commits before another starts, then they must be ordered. The relaxation of the snapshot guarantee and extension of write-write conflict definition enables PSI systems to replicate asynchronously between data centers in the absence of write-write conflicts. However, PSI introduces a long-fork anomaly that is similar to the short fork anomaly, but with the possibility of intermediate steps (transactions) before the anomaly is observed (Sovran et al. 2011).

Additionally, there have been other relaxed consistency notions with various consistency and performance attributes, many of which have been explored in the context of cloud and geo-scale deployments. One such consistency guarantee is read committed that is the default consistency level in MDCC, a Paxos-based protocol (Kraska et al. 2013; Pang et al. 2014). Read committed guarantees that only committed values are read. Read committed introduces a lost update anomaly, which is an anomaly that arises when a transaction overwrites the writes of another transaction, rendering them lost. MDCC augments read committed with a guarantee to detect write-write conflicts, which removes the possibility of lost update anomalies. MDCC also incorporates various relaxed notions of consistency such as atomic visibility that ensures that all or none of a transaction's effects are observed and non-monotonic snapshot isolation (Ardekani et al. 2013) which relaxes SI in a way similar to PSI.

An alternative way to provide consistency guarantees is from the context of a client's session, which is what a single client does and observes (Terry et al. 1994). These guarantees include *read your writes* which guarantees that a read observes all the client's writes, *monotonic reads* that guarantees that reads reflect a progressive state of data, *writes follow reads* that guarantee that writes are observed after the reads they depend on, and *monotonic writes* that guarantee an ordered propagation of writes. These guarantees can be selectively combined and implemented on top of an

eventually consistent data store, which allows customizing the solution to the needs of specific applications.

Conclusion

The high cost of coordination, which is exacerbated in cloud and geo-scale environments, motivates the exploration of weaker and relaxed forms of consistency. These forms of consistency enable higher performance while providing some weaker forms of consistency guarantees. The spectrum of the consistency-performance trade-offs includes many protocols that have various performance and consistency characteristics. The study and exploration of points in this spectrum help identify the suitable consistency levels for various classes of applications. Also, an important problem is finding efficient designs of relaxed and weak consistency notions to maximize the performance gains of relaxing consistency. The adoption of weak and relaxed consistency models has also impacted how programmers interact with storage systems by navigating the best practices of using weaker and relaxed guarantees in addition to reasoning about the consistency of applications.

Examples of Application

Weaker and relaxed consistency models are used by various data storage engines for the web; traditional database management systems, in the cloud; and geo-scale deployments.

Future Directions for Research

The growth and evolution of computing platforms (e.g., geo-scale deployments and hardware-based techniques) and application classes (e.g., data science and machine learning) invite a continued exploration of consistency guarantees in the consistency-performance trade-off to better suit these platforms and applications.

Compressed representations for complex networks; Data structures for graphs; Graph compression

Definitions

In this section, we discuss the problem of representing large graphs in core memory using suitable compressed data structures; after defining the problem, we survey the most important techniques developed in the last decade to solve it, highlighting the involved trade-offs.

A *graph* is a pair (N, A) , where N is the set of *nodes* and $A \subseteq N \times N$ is the set of *arcs*, that is, a directed adjacency relation. We use n for the number of nodes, that is, $n = |V|$, and write $x \rightarrow y$ when $(x, y) \in A$.

Overview

Many datasets come with a natural relational structure, that is, a graph, that contains a wealth of information about the data itself, and many data mining tasks can be accomplished from this information alone (e.g., detecting outlier elements, identifying interest groups, estimating measures of importance, and so on). Often, such tasks can be solved through suitable (sometimes, variants of standard) graph algorithms which typically assume that the graph is stored into core memory. However, this assumption is far from trivial when large graphs are dealt with; for example, the Facebook graph has more than 2 billion nodes

and hundreds of billions of edges. And while it is difficult to provide reliable estimates of the size of the web, search engines index dozens of billions of pages and consequently manage graphs with trillions of arcs.

Finding effective techniques to store and access large graphs that can be applied fruitfully to these situations is one of the central algorithmic issues in the field of modern data mining. A *compressed data structure* for a graph must provide very fast access to the graph (let us say, slower but comparable to the access time required by its uncompressed representation) *without decompressing* it; on the contrary, a *data compression scheme* for a graph is a compressed representation whose only evaluation criterion is the compression ratio (in the case of a graph, the number of bits per arc). While this definition is not formal, it clearly excludes methods in which the successors of a node are not accessible unless, for instance, a large part of the graph is decompressed. Research has concentrated on compressed data structures, as data compression schemes for graphs are relatively easy to design using standard compression techniques.

When a compressed data structure for graphs is evaluated, the following aspects should be considered:

- The *compression time*, that is, the time required to produce a compressed representation from an uncompressed one.
- Whether the data structure is *static* or *dynamic*, that is, whether it allows for changes (addition/deletion of nodes/arcs).
- Whether the data structure is designed for *directed* or *undirected* graphs (or both).
- The *compression ratio*, that is, the ratio between the size of the compressed data structure and its uncompressed counterpart, measured in bits per arc.
- The *access primitives* that the structure allows for and their corresponding performance. The four basic operations are sequential enumeration of all arcs (usually in lexicographical order), enumeration of the successors of a node x (i.e., enumerating the nodes y such

that $x \rightarrow y$), enumeration of the predecessors of a node x (i.e., enumerating the nodes y such that $y \rightarrow x$), and adjacency test between two nodes x and y (i.e., determining whether $x \rightarrow y$).

In most cases, these aspects can only be evaluated experimentally on a certain number of datasets, although in some rare circumstances, it is possible to provide worst-case lower bounds under some assumption on the network structure (e.g., assuming some probabilistic or deterministic graph model and evaluating the compression performances on that model).

WebGraph Compression

A pioneering attempt at compressing the WebGraph is the LINK database (Randall et al. 2001), where the authors exploit two basic observations: suppose that nodes are ordered lexicographically by URL (i.e., node i is the node representing the i -th URL in lexicographic order); then the following two properties are true:

- *Locality*: most arcs are between nodes that are close to each other in the order, because most links are intra-site, and URLs from the same site share a long prefix, which makes them close in lexicographical order. Locality can be exploited using *gap compression*: if node x has successors y_1, y_2, \dots, y_k , gap compression stores for x the compressed successor list $y_1, y_2 - y_1, \dots, y_k - y_{k-1}$; by locality, most values in this list will be small. Then, any variable-length encoding that uses fewer bits for small values will then provide compression: in Randall et al. (2001), the authors use variable-length nibble codes.
- *Similarity*: nodes that are close to each other in the order tend to have similar sets of neighbors. Similarity can be exploited by using *reference compression*: some successor lists are represented as a difference with respect to the successor list of a previous nearby node. In

other words, if node x has a list of successors that is “similar enough” to the successor list of node $x - r$, we just refer to that reference node, store a bitmap which selects which successors of $x - r$ must be copied, and write the remaining successors explicitly.

The authors of Randall et al. (2001), in their experiments on a real-world web crawl, state that the two techniques together provide a compression of about 5.44 bits/arc for the actual graph and 5.27 for its transpose (i.e., the graph obtained by reversing all arcs). Naturally, while gap compression does not impact much on compression or access time, reference compression can (and does) increase compression and access time, especially for random-access.

Some years later, building on the same approach, the WebGraph framework (Boldi and Vigna 2004) attained using the BV scheme a compression of less 3 bits/arc (even less than 2 for the transpose graph) with a random-access successor enumeration time of a few hundreds of nanoseconds per arc (and much less than that for sequential access). Present timings are in the range of a few dozens nanoseconds per arc.

The BV scheme introduced a more aggressive reference compression, by using inclusion-exclusion blocks instead of bitmaps, and the idea of *intervalizing* successor lists by writing separately segments of consecutive integers. The latter idea is essential for the compression of a transposed WebGraph, as in a graph with strong similarity, the same node x appears in many consecutive successor lists: when we transpose the graph, this feature becomes an interval of consecutive nodes in the successor list of x . In other words, similarity and intervalization are complementary features, exchanged by transposition, and should be always considered together.

Compression methods based on the principles described above can be applied to every graph; in particular, gap compression is always effective, as it reduces the number of bits required to write a successor. However, the effectiveness of similarity is limited to graphs in which successor lists

of nodes with close identifiers have a nontrivial intersection.

Note that any approach based on gaps and similarity can only provide successor lists and sequential enumeration. Obtaining predecessors requires storing the transpose graph, too, and answering an adjacency query requires scanning the successor list of the source node. Additional data structures may be added to make this search faster but at the expense of the compression ratio. Moreover, these approaches exploit data structures that cannot be updated easily.

k^2 -Trees

A complementary and, in some sense, more general approach is that of k^2 -trees (Brisaboa et al. 2014). In this case, rather than representing the successor list, we aim at representing compactly the *adjacency matrix* of the graph, exploiting its sparseness. A k^2 -tree subdivides recursively the adjacency matrix in k^2 squares. For each level of recursion, we look at each square: if it contains at least a one, we write a one, otherwise we write a zero. When we consider lower levels, we do not write information for subsquares of a square for which we wrote a zero. The leaf containing a specific cell can be found quickly using constant-time *rank* operations, which compute the number of ones up to a given position in a bit vector (see the reference above).

In general, in k^2 -trees the access time to a successor list is an order of magnitude slower than approaches based on gap and similarity. Nonetheless, they provide predecessors, successors, and adjacency queries in the same data structure. Moreover, they can be made dynamic with a reasonable increase in access time and storage (Brisaboa et al. 2017), which would be hardly possible with gap-based approaches.

Compression-Friendly Orderings

The techniques described above are strongly sensitive to the numbering of the nodes: this is not

a big issue when applied to WebGraphs, because the lexicographical ordering of URLs is available, but makes it difficult to apply the same techniques to networks (e.g., social networks) that do not have similarly meaningful node identifiers.

The authors of the LINK database showed that a useful intrinsic ordering is obtained by sorting the nodes in lexicographical order of their row in the adjacency matrix. Even better, one can use a Gray code (Boldi et al. 2010), that is, an ordering of the n -bit strings in which adjacent strings differ by just one bit.

A surprisingly effective approach to ordering is simply that of enumerating nodes following a *visit*: in particular, a breadth-first visit (Apostolico and Drovandi 2009) numbers nodes in such a way that an *ad hoc* compression scheme based on gap compression and reference to previous nodes provides excellent compression and very fast access times.

The problem of finding compression-friendly orderings was studied from a theoretical viewpoint in Chierichetti et al. (2013), where the authors show that the problem of determining the optimal renumbering of nodes is NP-hard but propose a heuristic (called “shingle ordering”) for the problem, based on a fingerprint of the out-neighborhoods.

A set of different approaches is based on *clustering*: *layered labelled propagation* (Boldi et al. 2011) is a very scalable reordering technique which combines the information from a number of clusterings to reorder the nodes in a very effective way. More recently, Dhulipala et al. (2016) extended the theoretical model developed by Chierichetti et al. (2013) and designed a novel ordering technique, called *recursive graph bisection*, that yields in several cases the most competitive compression ratios. The basic idea is to divide recursively the graph in two clusters of the same size so to minimize an objective function that estimates the compressibility of the overall graph when nodes in the first cluster have smaller identifiers than nodes in the second cluster. Both methods then rely on the BV scheme from WebGraph to perform compression.

Succinct Approaches

Since the successor lists are increasing sequences of numbers, one can simply use a *succinct data structure* (Navarro 2016) to store them. Technically, a succinct data structure does not *compress* data – simply, it represents it using the minimum possible number of bits. More precisely, if an object requires z bits to be represented, a succinct data structure uses $z + o(z)$ bit. For example, there is a succinct representation of binary trees using $2n + o(n)$ bits (Jacobson 1989) for a tree with n nodes.

Nonetheless, the practical effect is that of reducing sensibly the storage. Succinct approaches are particularly useful when the graph has no evident structure (as in that case, reference compression does not really help) and when reordering the nodes is not possible (as the compression obtained is agnostic with respect to the distribution of gaps and to similarity).

A simple, practical data structure of this kind is the *Elias–Fano representation of monotone sequences* (Elias 1974). This representation is technically not succinct and in fact usually named *quasi-succinct*, but it lends itself to very efficient practical implementations.

An advantage of the Elias–Fano representation is the possibility of finding in constant time both the k -th successor and the first successor greater than or equal a given bound b . In particular, the last property makes it possible to compute adjacency in constant time and neighborhood intersections in sublinear time.

Partitioned Elias–Fano (Ottaviano and Venturini 2014) is a improvement over the basic Elias–Fano representation: given a number k of parts, an algorithm splits the successor lists in k blocks in such a way that the space used is minimized. In this way, dense blocks as those generated by similarity can be compressed efficiently, with a constant additional cost for the access operations.

We remark that using a separate succinct encoding for each successor list can be more efficient than encoding succinctly the entire graph (e.g., using an Elias–Fano list to represent the

positions of the ones in the adjacency matrix or using truly succinct representations Farzan and Munro 2013). This happens because by Jensen’s inequality the average cost *per successor* is necessarily lower. However, if one takes also into account the constant costs associated to storing each successor list, there is a trade-off that has to be evaluated on a case-by-case basis.

The Elias–Fano representation has been recently made dynamic (Pibiri and Venturini 2017) when the universe is polynomial in the list size, which makes it possible to use it in the case of dynamic graph representation.

Metadata

Recent work (Ferragina et al. 2015) has extended the idea of compression so to include strings labeling the nodes, with a corresponding enlargement in the set of available queries, which include search by label prefix on successor lists and on nodes at distance two.

Wildfire: HTAP for Big Data

Ronald Barber¹, Vijayshankar Raman¹, Richard Sidle¹, Yuanyuan Tian¹, and Pinar Tözün²

¹IBM Research – Almaden, San Jose, CA, USA

²IT University of Copenhagen, Copenhagen, Denmark

Definitions

The popularity of large-scale real-time analytics applications keeps rising. These applications require distributed data management systems that can handle fast concurrent transactions (OLTP) and analytics on the recent data. Some of them even need running analytical queries (OLAP) as part of transactions. For the kind of data processing that requires both analytics and transactions simultaneously in the same system, Gartner recently coined the term *Hybrid Transactional/Analytical Processing (HTAP)*.

Overview

Traditional database management systems (DBMSs) have been the strongest for transactions based on the ACID properties and complex analytics over structured data where data is loaded into a closed format. In the past decade, several specialized DBMSs have emerged exploiting modern hardware (e.g., multicore parallelism, large main memories) and following leaner system designs: in-memory optimized row-stores for OLTP (Diaconu et al. 2013; Stonebraker and Weisberg 2013) and column-stores for OLAP (Boncz et al. 2005; Lamb et al. 2012; Raman et al. 2013). Even though these new-gen systems strengthen the capabilities of traditional DBMSs, they fall short in handling applications that require both transactions and different types of complex analytics as well as processing of different big data sources at a large scale.

These weaknesses of DBMSs largely motivated the development of big data ecosystems

such as Hadoop <http://hadoop.apache.org/> and Spark <http://spark.apache.org/>, which were designed almost exclusively for (1) scaling out over thousands of commodity servers and (2) performing complex and long-running analytics cost-effectively on extremely large and diverse data sets. These systems also promote a much more open and flexible environment, both of functions (e.g., external machine learning and graph processing libraries) and standard open data formats (e.g., Parquet, JSON), allowing any function to access any data without the obligation of going through a centralized gatekeeper.

However, these big data ecosystems have their own shortcomings. Since platforms like Spark are heavily optimized for big data analytics, data ingest and point lookup requests are relegated to external systems (e.g., with connectors to key-value stores, DBMSs). Having two different systems for transactions and analytics, however, delays the time it takes to query recently ingested data. In addition, most of the systems that can handle the high ingest rates required to capture data from new Internet of Things (IoT) applications (e.g., key-value stores such as Cassandra <http://cassandra.apache.org>, Aerospike <http://www.aerospike.com/>), lack support for complex transactions (multi-statement/row), and ACID.

To serve the needs of the emerging applications that require both complex transactions and analytics at large scale in a unified platform over the latest, almost latest, and historical data, there is a need to build systems that can handle hybrid transactional and analytical processing (HTAP) efficiently. In addition to the challenge of supporting HTAP, these systems must handle the evolution of the data from the time it gets ingested to the time it becomes historical as the data lies over several storage mediums (memory, SSD, HDD, shared file systems, local or remote storage) and possibly in different data formats (row, column, hybrid).

This article presents Wildfire (Barber et al. 2017), an HTAP system for big data. Wildfire exploits Spark by (1) utilizing a non-proprietary storage format (Parquet), open to any reader, for all data, (2) using and extending Spark APIs and the Catalyst optimizer for SQL queries,

and (3) automatically replicating data for high availability, scale-out performance, and elasticity. To enable HTAP, Wildfire augments these features via (1) making the latest committed data immediately available to analytics queries; (2) having support for indexes for fast point queries; (3) exploiting recent advances for accelerating analytics queries by orders of magnitude, including compression on the fly, cache-aware processing, automatic creation and exploitation of synopses, (a form of) column-wise storage, and multi-threaded parallelism; and (4) enterprise-quality SQL, including more robust optimization and time travel that permits querying historical data AS OF a particular time.

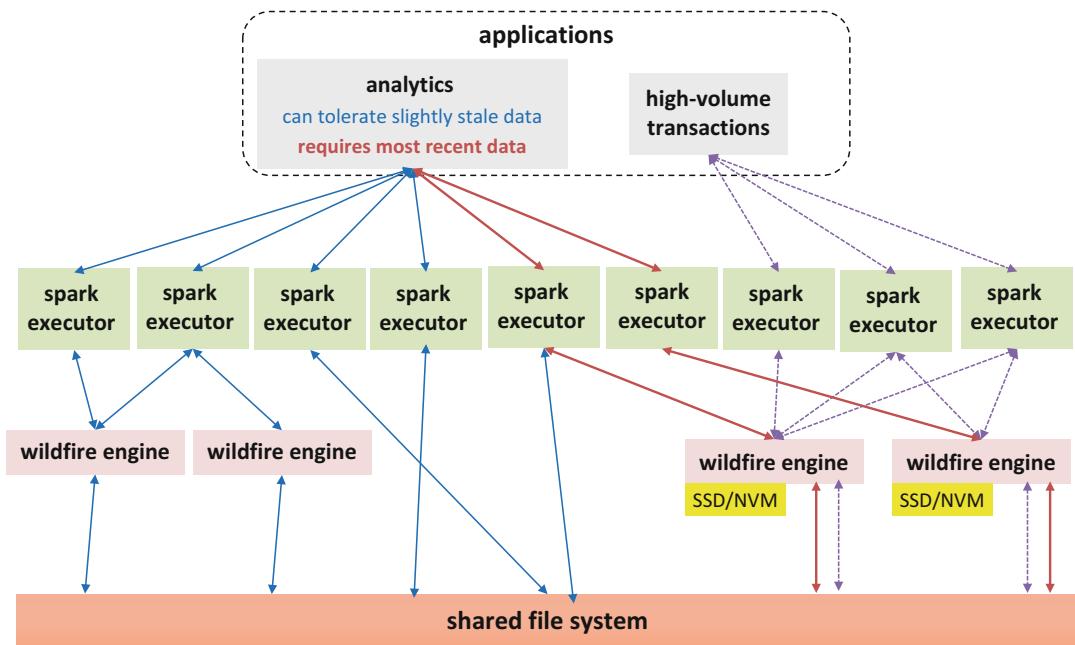

Wildfire Architecture

Figure 1 shows the Wildfire architecture, which combines the Spark ecosystem with the Wildfire engine. Spark serves as the entry point for all the requests (transactions and analytics) from the applications that Wildfire targets and provides a scalable and integrated ecosystem for various types of analytics on big data. The Wildfire engine, on the other hand, processes transactions, accelerates the analytical requests, and enables querying the newly ingested data.

Processing of Requests

All requests to Wildfire go through Spark APIs. Each request spawns Spark executors across a cluster of machines whose nodes depend upon the type of that request. The majority of the nodes in the cluster execute only analytical requests and require only commodity server hardware (the solid arrows in Fig. 1 show the request and data flow in these nodes). Other beefier nodes, with faster local persistent storage (SSDs or, soon, NVRAM) and more cores for increased parallelism, handle concurrently both transactions and analytical queries on the recent data from those transactions (the dashed arrows in Fig. 1 show the request and data flow in these nodes).

The Wildfire engine is a columnar data processing engine. Each engine instance is a daemon serving on a Wildfire node. Each daemon is

Wildfire: HTAP for Big Data, Fig. 1 Data lifecycle in Wildfire

connected to a Spark executor, which delegates various transactional and analytical requests to the daemons. Based on the nodes they serve on, these daemons either handle only read-only requests over a snapshot of the data or serve transactions and analytical requests over the latest version of the data.

Transactions always go through the Wildfire engine daemons that serve on the beefier server nodes responsible for transaction processing. In addition to handling ingest, update, and lookup operations, these daemons publish the ingested data to a shared file system in an open data format (Parquet <https://parquet.apache.org/>) and can also read any data that is in the shared file system for analytical queries.

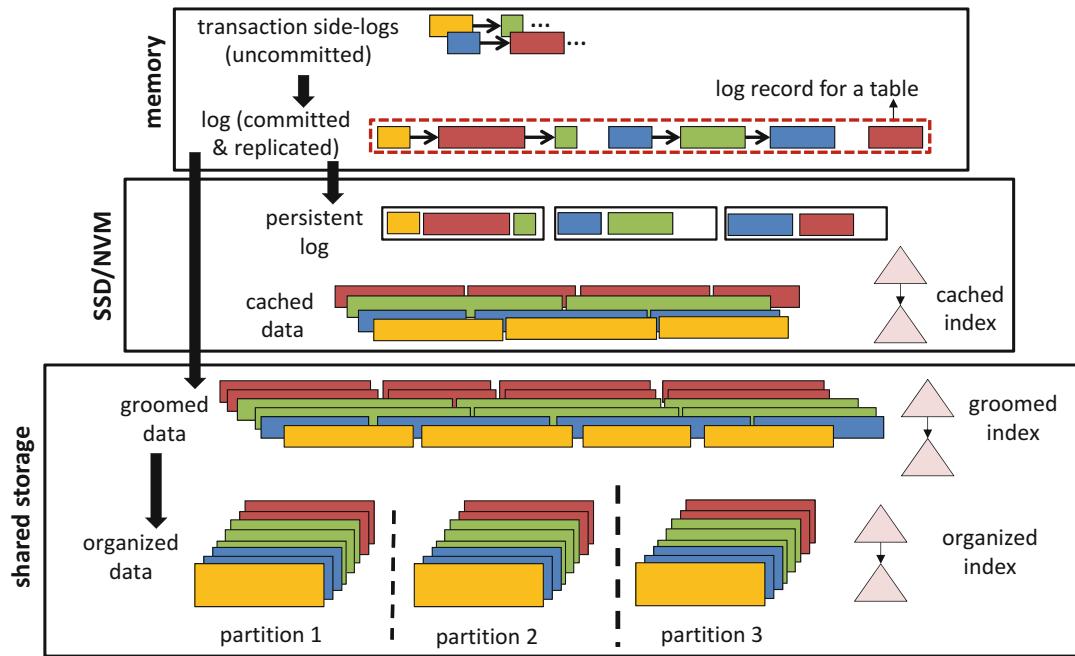

To speed ingest through parallelism, non-static tables in the system are sharded across nodes handling transactions based upon a subset of a primary (single-column or composite) key. A table shard is also assigned to (a configurable number of) multiple nodes for higher availability. A distributed coordination system manages the meta-information related to sharding and replica-

tion, and a catalog maintains the schema information for each table.

The analytical requests in Wildfire can either be handled solely by Spark or the Wildfire engine or both. Wildfire openly allows any external reader to read data ingested by the Wildfire engine using Spark APIs without involving the Wildfire engine component but that reader will be unable to see the latest transactional data. Wildfire can also push down the whole or part of analytical requests into the Wildfire engine. This way one can accelerate the processing of the analytical requests using the Wildfire columnar engine and access the latest data for analytics.

Data Life Cycle

Wildfire adds the following three hidden columns to every table to keep track of the life of each record, which allows supporting snapshot isolation and time travel queries. beginTS indicates when a record is first made available in shared storage; endTS is the time when a record is updated; prevRID is the id of the new record who replaces this record.

Wildfire: HTAP for Big Data, Fig. 2 Data lifecycle in Wildfire

Data in Wildfire evolves over time from live to groomed to organized zone and is kept in Parquet format across all zones. Figure 2 illustrates the data life cycle in a shard replica in Wildfire.

Live zone keeps the latest data and is composed of transaction logs. Each transaction in the Wildfire engine keeps its uncommitted changes in a transaction-local side-log at a shard replica. At commit time, the transaction appends its side-log to the committed-log of that shard, which is kept both in memory and persisted on the local disk (SSD or NVRAM). In addition, this log is copied to each of the other replica nodes for that shard.

Groomed zone keeps a recent (~1 s) snapshot of the data. One of the replicas of a shard hosts a groomer daemon, which periodically invokes a grooming operation periodically (every second) to move the data from the live zone to the groomed zone. This operation merges transaction logs from shard replicas based on the commit time order, resolves conflicts by setting the monotonic increasing beginTS for each record, and creates Parquet files larger than the log blocks for the corresponding table shard. These files are then flushed to

the shared storage (HDFS <http://hortonworks.com/apache/hdfs/>, GlusterFS (<https://www.gluster.org/>), S3 <https://aws.amazon.com/s3/>, Swift <https://www.swiftstack.com/product/openstack-swift>). Finally, the groomer notifies a distributed coordinator (Zookeeper <https://zookeeper.apache.org/>) about the groom high watermark and then prunes the log records that are successfully groomed. This allows us to safely switch the shard replicas that are responsible from the grooming operation (i.e., upon a failure of the node that hosts the groomer of a shard replica).

Organized zone keeps an almost recent (~10 mins) and more analytics-friendly snapshot of the data. The groomed zone (1) has still relatively small Parquet files, (2) organizes data based on the sharding key, and (3) has only the beginTS field set among the hidden columns of the records. In order to evolve the data into a more analytics-friendly state, a separate operation called post-groom takes places periodically (every 10 mins). Post-groom takes the files in the groomed zone and merges them into bigger Parquet files. It further partitions the data in a

shard if the user/application specifies a partition key as part of a tables' definition to accelerate common analytics tasks. For example, an IoT application handling large volumes of sensor readings could use the sensorID as the sharding key but the date column as the partition key to speed up time-based analytics queries. Finally, it also fills up the endTS and prevRID fields of the records to enable time travel queries and faster snapshot isolation. To optimize the data organization further for the analytics, the latest versions of the records are also separated from the records where the endTS is set.

Indexes in Wildfire are an LSM-like (O’Neil et al. 1996) structure with a list of index runs, where each groom operation produces a new index run. Runs are organized into levels and are merged over time to limit the total number of runs and improve lookup performance. Index instances are associated with each table shard and are built over the groomed and organized zones. There are no indexes over the live zone to not to impact ingest rate. The data in live zone is very small since grooming runs very frequently, and one can just scan this zone to find the items they need.

Finally, Wildfire assumes the recently ingested data is accessed more often by the applications. Therefore, the recently groomed data files and their corresponding indexes are also cached in the local storage of the nodes based on the space utilization.

Transactions

In addition to being a columnar query accelerator for the Spark ecosystem, the Wildfire engine also supports transactions with inserts, updates, and deletes. Wildfire targets both high availability and ACID, which is infeasible. Therefore, Wildfire adopts last-writer-wins (LWW) semantics for concurrent updates to the same key and snapshot isolation of quorum-readable content for queries, without having to read the data from a quorum of replicas to satisfy a query. The remainder of this section describes the design choices and methods to reach this goal.

Writes, Inserts, Updates, and Deletes

A table in Wildfire is sharded across nodes using a subset of the primary key columns of the table. The writes of a transaction are sent to any node that contains a shard replica. As section “[Data Life Cycle](#)” describes, Wildfire first writes the transactional changes to logs persisted in local storage, since it is impractical to flush them to the shared file system directly. For high availability, these shard logs are replicated to multiple nodes (a minimum of three) at commit time. Then, a background grooming process propagates these changes in a batched fashion to the shared file system, which is optimized for append-only access and large blocks.

Transactions with write operations have to perform a status-check at the end in Wildfire to ensure that the side-log of the transaction is replicated at least to a quorum of nodes. Similarly, the read-only queries return only quorum-replicated data. The status-check may timeout if a node is poorly connected. In such cases, Wildfire returns a warning message to the client about the uncertainty of the status of that transaction. Due to this delayed-commit semantics, one cannot check integrity constraints at commit. Updates to the same key based on prior values may suffer from the lost update problem. Wildfire resolves this by adopting LWW as mentioned above.

Wildfire also offers a SyncWrite option for the applications with idempotent writes, where it reissues any timed out transaction on other nodes till they succeed. If a non-idempotent write times out or the client connection breaks, there is no easy way to figure out whether that write has succeeded.

The conflict resolution in Wildfire is handled with the collaboration of the grooming and the post-grooming operations. The post-grooming operation sets the endTS of a record with the beginTS of the next version of that record, as well as the prevRID field of a record to the record id of the previous version of that record. Post-grooming heavily relies on the indexes built on the primary key of a table while determining the correct values of for these fields efficiently. The grooming operation sets the beginTS fields

of records and builds the corresponding index blocks over the data it grooms adding them as part of the top level of the Wildfire index structure, which resembles an LSM-based index. After the post-grooming operation, the corresponding portions of the index are replaced asynchronously to ensure that records point to the right Parquet blocks.

Reads

Snapshot isolation needs a system-generated predicate: $\text{beginTS} \leq \text{snapshotTS} < \text{endTS}$. The snapshotTS is usually the transaction start time but can be changed to allow time travel. Depending on the currency of data needed by queries in Wildfire, data in the shared file system may be sufficient. However, certain classes of queries read the log along with the data in the shared file system, whereas grooming itself (treated as a specialized query in Wildfire) reads only the quorum-visible log to perform its processing.

Queries that only read the organized zone do not have to perform additional conflict resolution to determine the correct version of the records, since post-groom already handles that. Queries that have to read the groomed zone might find unresolved duplicates, on the other hand, and have to perform an index lookup over the primary index to determine the correct version under LWW. Finally, queries that require reading the live zone can do so without accessing all the replicas, since each instance of Wildfire tracks the log replication points for all replicas it is responsible for and computes a current high watermark of the data that is quorum-visible.

To not to disrupt the older queries that are still reading the log blocks that have been groomed or the groomed blocks that have been post-groomed, Wildfire performs lazy garbage collection of such blocks. In other words, data blocks are garbage collected only when there is no possibility of a query reading them. When a new query has to access multiple data zones, though, Wildfire checks the groom and post-groom high watermarks to ensure that it does not read duplicate data streams.

Analytics

This section describes the major extensions in Spark for Wildfire: (1) the new OLTP interface OLTPContext, (2) extensions to the Spark Catalyst optimizer and the existing OLAP SQLContext to enable the push-down of queries into the Wildfire engine, and (3) using these two contexts to enable HTAP in Wildfire.

New Interface for OLTP

To enable HTAP, Wildfire has to support functionality required for OLTP operations such as point queries, inserts, or upserts. However, the Spark ecosystem, which is the entry point for applications running on Wildfire, does not currently support such functionality. Therefore, Wildfire implements a new interface in Spark called OLTPContext. OLTPContext is separated from Sparks SQLContext but plays well with the existing APIs of Spark such as Spark SQL and Spark Streaming.

OLTPContext has to figure out the right set of nodes to send the specific OLTP requests to. Therefore, it contacts the distributed coordination service to retrieve and cache the information regarding where each table shard replica is hosted as well as the reference to the catalog service. Based on this information, if a sharding key is associated with a transaction (or a batch of transactions), OLTPContext is able to route the request(s) to the right node. If no sharding key is given as part of transaction, the request is broadcasted to all shards.

OLTPContext also handles node failures. If a transaction fails due to the failure of a node that is responsible from a shard replica for the shard corresponding to that transaction, then OLTPContext will retry that transaction on one of the other nodes who host another replica of that shard.

W

Extensions to SparkSQL for OLAP

Wildfire aims a seamless integration of Spark SQL and the Wildfire engine for analytics queries. Users should be able to query the tables in Wildfire using Spark SQL and join a table in Wildfire with an external table accessible by Spark.

Wildfire achieves this integration by extending both Spark SQL Data Source API and the Catalyst query optimizer. It is easy to plug a new data source using the Data Source API through Spark SQL. Wildfire just exploits this and extends Spark's SQLContext. The Catalyst optimizer, on the other hand, is able to push down projection and filtering operations to the data sources. The Wildfire engine, however, provides more advanced query capabilities. Therefore, Wildfire extends the Catalyst optimizer to push down more complex analytics operations such as partial aggregations, joins, and even scalar user-defined functions and aggregates (by efficiently utilizing the JNI interface). Wildfire's complex push-down analysis is also able to generate compensation plans for the remaining portions of the analytics queries that cannot be pushed down into Wildfire's columnar engine.

Finally, Wildfire's extensions to the Data Sources API and the Catalyst optimizer are general and not just for Wildfire. Therefore, this general method of push-down enables Spark to be a federation engine for big data systems.

Using OLTPContext and SQLContext for HTAP

To utilize Wildfire's HTAP capabilities, applications should instantiate both the new OLTPContext and the SQLContext with the Wildfire extensions in the Spark driver. The transactions and point queries go through the OLTPContext. SQLContext handles the analytical queries, and assigns a snapshot to them based on the queries maximum tolerable staleness of the data. If this staleness is less than the grooming interval, the query is either delayed till the next grooming cycle for the corresponding shard(s) or sent to the Wildfire nodes with the latest data (logs) for the corresponding shard(s) in their local storage. The latter case may have negative impact on the transaction throughput on nodes assigned to OLTP tasks due to resource consumption of the analytical tasks. This is, however, similar to the resource management challenges of the traditional database systems that need to handle both transactions and analytics. Wildfire can process the queries that can tolerate a staleness

longer than the grooming or post-grooming interval more inexpensively, since such queries can be sent to any Wildfire node and access the data from the shared file system.

Conclusions

This article presented the Wildfire HTAP system, which is a distributed big data platform designed to handle high-volume transactions and complex analytics over the latest and almost latest data concurrently. Wildfire leverages Spark for large-scale complex analytics, adopts an open data format to be compatible with the big data ecosystem, and implements a columnar processing engine that supports transactions and accelerates the analytical queries that are issued through the SparkSQL API.

Workflow Systems for Big Data Analysis

Loris Belcastro and Fabrizio Marozzo
DIMES, University of Calabria, Rende, Italy

Definitions

A *workflow* is a well-defined, and possibly repeatable, pattern or systematic organization of activities designed to achieve a certain transformation of data (Talia et al. 2015).

A *Workflow Management System* (WMS) is a software environment providing tools to define, compose, map, and execute workflows.

Overview

The wide availability of high-performance computing systems has allowed scientists and engineers to implement more and more complex applications for accessing and analyzing huge amounts of data (Big Data) on distributed and high-performance computing platforms. Given the variety of Big Data applications and types

of users (from end users to skilled programmers), there is a need for scalable programming models with different levels of abstractions and design formalisms. The programming models should adapt to user needs by allowing (i) ease in defining data analysis applications, (ii) effectiveness in the analysis of large datasets, (iii) and efficiency of executing applications on large-scale architectures composed by a massive number of processors. One of the programming models that meets these requirements is the workflow, which through its convenient design approach has emerged as an effective paradigm to address the complexity of scientific and business Big Data analysis applications.

According to the definition of the Workflow Management Coalition (WFMC 1999), a workflow is “*the automation of a business process, in whole or part, during which documents, information or tasks are passed from one participant to another for action, according to a set of procedural rules.*” The term “process” here indicates a set of tasks, or activities, linked together with the goal of creating a product, calculating a result, providing a service and so on. Hence, each task represents a piece of work that forms one logical step of the overall process (Georgakopoulos et al. 1995). The same definition can be used for scientific workflows composed of several tasks (or activities) that are connected together to express data and/or control dependencies (Liu et al. 2004). Thus, a workflow can be also defined as a “*well defined, and possibly repeatable, pattern or systematic organization of activities designed to achieve a certain transformation of data*” (Talia et al. 2015).

From a practical point of view, a workflow consists of a series of tasks, activities, or events that must be performed to accomplish a goal and/or obtain a result. For example, a data analysis workflow can be designed as a sequence of preprocessing, analysis, post-processing, and evaluation tasks. It can be implemented as a computer program and can be expressed in a programming language for describing the workflow tasks and mechanisms to orchestrate them. Important benefits of the workflow formalism are the following: (i) it provides a declarative way for

specifying the high-level logic of an application, hiding the low-level details that are not fundamental for application design; (ii) it is able to integrate existing software modules, datasets, and services in complex compositions that implement scientific discovery processes; (iii) and once defined, workflows can be stored and retrieved for modifications and/or re-execution, by allowing users to define typical patterns and reuse them in different scenarios (Bowers et al. 2006).

A Big Data analysis workflow can be designed through a script- or a visual-based formalism. The *script-based formalism* offers a flexible programming approach for skilled users who prefer to program their workflows using a more technical approach. Moreover, this formalism allows users to program complex applications more rapidly, in a more concise way, and with higher flexibility (Marozzo et al. 2015). In particular, script-based applications can be designed in different ways: (i) with a programming language that allows to define tasks and dependencies among them, (ii) with annotations that allow the compiler to identify which instructions will be executed in parallel, and (iii) using a library in the application code to define tasks and dependencies among them. As an alternative, the *visual-based formalism* is a very effective design approach for high-level users, e.g., domain expert analysts having a limited knowledge of programming languages. A visual-based application can be created by using a visual programming language that lets users develop applications by programming the workflow components graphically. A visual representation of workflows intrinsically captures parallelism at the task level, without the need to make parallelism explicit through control structures (Maheshwari et al. 2013).

Key Research Findings

To cope with the need of high-level tools for the design and execution of Big Data analysis workflows, in the past years, many efforts have been made for the development of distributed Workflow Management Systems (WMSs), which are devoted to support the definition, creation, and

execution of workflows. A WMS is a software environment providing tools to define, compose, map, and execute workflows. A key function of a WMS during the workflow execution is co-ordinating the operations of individual activities that constitute the workflow. There are several WMSs on the market, most of them targeted to a specific application domain. Existing WMSs can be grouped roughly into two main classes:

- *Script-based systems*, which permit to define workflow tasks and their dependencies through instructions of traditional programming languages (e.g., Perl, Ruby, or Java) or custom-defined languages. Such languages provide specific instructions to define and execute workflow tasks, such as sequences, loops, while-do, or parallel constructs. These types of instructions declare tasks and their parameters using textual specifications. Typically data and task dependencies can be defined through specific instructions or code annotations. Examples of script-based workflow systems are Swift (Wilde et al. 2011), COMPSs (Lordan et al. 2014) and DMCF (Marozzo et al. 2015).
- *Visual-based systems*, which allows to define workflows as a graph, where the nodes are resources and the edges represent dependencies among resources. Compared with script-based systems, visual-based systems are easier to use and more intuitive for domain-expert analysts having a limited understanding of programming. Visual-based workflow systems often incorporate graphical user interfaces that allow users to model workflows by dragging and dropping graph elements (e.g., nodes and edges). Examples of visual-based systems are Pegasus (Deelman et al. 2015), CloudFlows (Kranjc et al. 2012), and Kepler (Ludäscher et al. 2006).

Another classification can be done according to the way a workflow is represented. Although a standard workflow language like Business Process Execution Language (BPEL) (Juric et al. 2006) has been defined, scientific workflow

systems often have developed their own workflow representations. Other than BPEL, other formalisms are used to represent and store workflows, such as JSON (Marozzo et al. 2015), Petri nets (Guan et al. 2006), and XML-based languages (Atay et al. 2007). This situation makes difficult sharing workflow codes and limits interoperability among workflow-based applications developed by using different workflow management systems. Nevertheless, there are some historical reasons for that, as many scientific workflow systems and their workflow representations were developed before BPEL existed (Margolis 2007).

In the following, we present some representative example of workflow systems that can be used to implement applications for Big Data analysis. Some of them have been implemented on parallel computing systems, others on Grids; recently some have been made available on Clouds.

Swift (Wilde et al. 2011) is a system for creating and running workflows across several distributed systems, like clusters, Clouds, Grids, and supercomputers. Swift is based on a C-like syntax and uses an implicit data-driven task parallelism (Wozniak et al. 2014). In fact, it looks like a sequential language, but all variables are *futures*; thus the execution is based on data availability (i.e., when the input data is ready, functions are executed in parallel).

COMPSS (Lordan et al. 2014) is another workflow system that aims at easing the development and execution of workflows in distributed environments, including Grids and Clouds. With COMPSS, users create a Java sequential application and select which methods will be executed remotely by providing annotated interfaces. The runtime intercepts any call to a selected method creating a representative task and finding the data dependencies with all the previous ones that must be considered along the application run.

Data Mining Cloud Framework (DMCF) (Marozzo et al. 2016) is a software system for designing and executing data analysis workflows on Clouds. A workflow in DMCF can be developed using a visual- or a script-based language. The visual language, called VL4Cloud (Marozzo et al. 2016), is based on

a design approach for end users having a limited knowledge of programming paradigms. The script-based language, called JS4Cloud (Marozzo et al. 2015), provides a flexible programming paradigm for skilled users who prefer to code their workflows through scripts. Both languages implement a data-driven task parallelism that spawns ready-to-run tasks to Cloud resources.

Pegasus (Deelman et al. 2015) is a workflow management system developed at the University of Southern California for supporting the implementation of scientific applications also in the area of data analysis. Pegasus includes a set of software modules to execute workflow-based applications in a number of different environments, including desktops, Clouds, Grids, and clusters. It has been used in several scientific areas including bioinformatics, astronomy, earthquake science, gravitational wave physics, and ocean science.

CloudFlows (Kranjc et al. 2012) is a Cloud-based platform for the composition, execution, and sharing of interactive data mining workflows. It provides a user interface that allows programming visual workflows in any Web browser. In addition, its service-oriented architecture allows using third-party services (e.g., Web services wrapping open-source or custom data mining algorithms). The server side consists of methods for the client side workflow editor to compose and execute workflows and a relational database of workflows and data.

Microsoft Azure Machine Learning (Azure ML) (<https://azure.microsoft.com/en-us/services/machine-learning-studio/>) is a SaaS that provides a Web-based machine learning IDE (i.e., Integrated Development Environment) for creation and automation of machine learning workflows. Through its user-friendly interface, data scientists and developers can perform several common data analyses/mining tasks on their data and automate their workflows. Using its drag-and-drop interface, users can import their data in the environment or use special readers to retrieve data from several sources, such as Web URL (HTTP), OData Web service, Azure Blob Storage, Azure SQL Database, and Azure Table.

Taverna (Wolstencroft et al. 2013) is a workflow management system developed at

the University of Manchester. Its primary goal is supporting the life sciences community (biology, chemistry, and medicine) to design and execute scientific workflows and support in silico experimentation, where research is performed through computer simulations with models closely reflecting the real world. Even though most Taverna applications lie in the bioinformatics domain, it can be applied to a wide range of fields since it can invoke any REST- or SOAP-based Web services.

Kepler (Ludäscher et al. 2006) is a graphical workflow management system that has been used in several projects to manage, process, and analyze scientific data. Kepler provides a graphical user interface (GUI) for designing scientific workflows, which are a structured set of tasks linked together that implement a computational solution to a scientific problem.

Examples of Application

Workflows are widely used by scientists to acquire and analyze huge amount of data for complex analysis, such as in physics (Brown et al. 2007), medicine (Lu et al. 2006), and sociology (Marin and Wellman 2011).

The Pan-STARRS astronomical survey (Deelman et al. 2009) used Microsoft Trident Scientific Workflow Workbench for loading and validating telescope detections running at about 30 TB per year. Similarly, the USC Epigenome Center is currently using Pegasus for generating high-throughput DNA sequence data (up to eight billion nucleotides per week) to map the epigenetic state of human cells on a genome-wide scale (Juve et al. 2009). The Laser Interferometer Gravitational Wave Observatory (LIGO) uses workflows to design and implement gravitational wave data analysis, such as the collision of two black holes or the explosion of supernovae. The experiment records approximately 1 TB of data per day, which is analyzed by scientists in all parts of the world (Brown et al. 2007). In this scenario, workflow formalism demonstrates its effectiveness in programming Big Data scientific applications.

The workflow formalism has been also used for implementing and executing complex data mining applications on large datasets. Some examples are *Parallel clustering* (Marozzo et al. 2011), where multiple instances of a clustering algorithm are executed concurrently on a large census dataset to find the most accurate data grouping; *Association rule analysis* (Agapito et al. 2013), which is a workflow for association rule analysis between genome variations and clinical conditions of a group of patients; and *Trajectory mining* (Altomare et al. 2017) for discovering patterns and rules from trajectory data of vehicles in a wide urban scenario. In some cases, the workflow formalism has been integrated with other programming models, such as MapReduce, to exploit the inherent parallelism of the application in presence of Big Data. As an example, in Belcastro et al. (2015), a workflow management system has been integrated with MapReduce for implementing a scalable predictor of flight delays due to weather conditions (Belcastro et al. 2016).

Future Directions for Research

Workflow systems for Big Data analysis require high-level and easy-to-use design tools for programming complex applications dealing with huge amount of data. There are several open issues that will require research and development in the near future, such as:

- *Programming models.* Several scalable programming models have been proposed, such as MapReduce (Dean and Ghemawat 2008), Message Passing (Gropp et al. 1999), Bulk Synchronous Parallel (Valiant 1990), Dryad (Isard et al. 2007), or Pregel (Malewicz et al. 2010). Some development works must be done for extending workflow systems to support different programming models, which could improve their capabilities in terms of efficiency, scalability, and interoperability with other systems.
- *Data storage.* The increasing amount of data generated every day needs even more scal-

- able data storage systems. Workflow systems should improve their capabilities to access data stored on high-performance storage systems (e.g., NoSQL systems, Object based storage on Clouds) by using different protocols.
- *Data availability.* Workflow systems have to deal with the problem of granting service and data availability, which is an opened challenge that can negatively affect performances. Several solutions have been proposed for improving exploitation, such as using a cooperative multi-Cloud model to support Big Data accessibility in emergency cases (Lee et al. 2012), but more studies are still needed to handle the continuous increasing demand for more real-time and broad network access.
 - *Local mining and distributed model combination.* As workflow-based applications often involve several local and distributed data sources, collecting data to a centralized server for analysis is not practical or, in some cases, possible. Scalable workflow systems for data analysis have to enable local mining of data sources and model exchange and fusion mechanisms to compose the results produced in the distributed nodes. According to this approach, the global analysis can be performed by distributing the local mining and supporting the global combination of every local knowledge to generate the complete model.
 - *Data and tool interoperability and openness.* Interoperability is a main open issue in large-scale distributed applications that use resources such as data and computing nodes. Workflow systems should be extended to support interoperability and ease cooperation among teams using different data formats and tools.
 - *Integration of Big Data analysis frameworks.* The service-oriented paradigm allows running large-scale distributed workflows on heterogeneous platforms along with software components developed using different programming languages or tools. This feature should improve the integration between workflows and other scalable Big Data analysis software systems, such as frameworks for fine-grain in-memory data access and analysis. In such way,

it will be possible to extend workflows toward exascale computing, since exascale processors and storage devices must be exploited with fine-grain runtime models.

Hamburg, Hamburg, Germany

Definitions

The Yahoo! Cloud Serving Benchmark (YCSB) is an open-source framework originally developed by Yahoo! to characterize and compare the performance of different *NoSQL database systems* (Cooper et al. 2010). YCSB can be classified as a *CRUD benchmark*, because the supported workloads are limited to a mix of CRUD (create, read, update, and delete) and scan operations.

It is a highly generic general-purpose benchmark that can easily be extended to support additional databases as it only requires the implementation of this simple CRUD interface.

The database system under test is stressed with the customizable mix of operations by a configurable number of client threads. At the same time, request latency and throughput (operations per seconds) are measured. The actual database

records consist of a number of synthetically generated string attributes.

Both *workload generation* and *data generation* are highly configurable. The workload generator randomly selects the CRUD operations according to their respective probabilities specified by the user. Different random distributions (uniform, exponential, Zipfian, or latest) can be selected. These determine the selection of the keys to work on, the number of records for the scan operation, and the length of the generated string attributes. YCSB comes with a set of basic workloads, which are based on typical web application workloads observed at Yahoo!

Furthermore, it is possible to configure runtime parameters like the number of operations to perform, the maximum execution time, the number of records to insert, and the desired target throughput.

Its extensibility and the generic workloads make YCSB suitable to explore general tradeoffs in a wide range of storage systems and finally led to its status as the de facto standard for comparative performance evaluation of NoSQL database systems.

Overview

Since the 1980s, relational database management systems (RDBMSs) have been regarded as the “one-size-fits-all” solution for persisting and querying data, and they have reached an

unmatched level of reliability, stability, and standardization through decades of development. Especially the standard query language (SQL) made it easy to develop domain-specific benchmarks with real application workloads, such as the famous TPC-C (2010). The TPC-C belongs to a series of benchmark specifications of the Transaction Processing Performance Council. Most of these specifications have in common that they expect the database system under test to support ACID-compliant transactions.

To achieve horizontal scalability and high availability, NoSQL database systems usually forgo the relational data model, join operations, transactions, and the consistency guarantees offered by traditional RDBMSs. Therefore, the TPC standards for benchmarking relational database systems can no longer be applied to the NoSQL systems. In consequence, YCSB was developed in order to enable a performance comparison between them.

However, some recent TPC specifications also take NoSQL database systems into account. For example, the implementation of the *TPCx-IoT* is even based on YCSB.

Scientific Fundamentals

The Benchmark Handbook for Database and Transaction Systems edited by Jim Gray (1993) can be regarded as the first reference work of database benchmarking. It includes several early benchmarking efforts for RDBMS, such as the first TPC standards and the Wisconsin benchmark. While the former became established as the standard for relational database system benchmarking, the Wisconsin benchmark had to accept a lot of criticism, partly because it did not model a real application workload. Nevertheless, it has been extensively used in research on parallel relational database systems for shared-nothing architectures. In this context, DeWitt (1993) already described the three fundamental metrics size-up, scale-up, and speedup, which cover important nonfunctional properties of distributed database systems. YCSB adapts them to the concept of different benchmark tiers:

- **Tier 1 – Performance** measures the latency of the system as the throughput is increased in different runs. This experiment class is very similar to the **sizeup** metric of the Wisconsin benchmark.

- **Tier 2 – Scalability and Elasticity**

Scalability measures the latency while the capacity is increased between different workload runs. Usually, in each step, another server is added and more data is loaded into the system. This corresponds to the **scaleup** metric described by DeWitt. **Elasticity** measures the impact on latency and throughput when one or more servers are added to the database system while the workload is running. This is similar to the **speedup** metric.

Kuhlenkamp et al. (2014) provide an overview of scalability and elasticity experiments carried out in various research projects with YCSB. They classify them into finer categories given their specific experimental designs and repeat some benchmarks in order to verify results.

In addition to these two tiers, Cooper et al. (2010) also proposed **Tier 3 Availability** and **Tier 4 Replication** for future research. The availability tier measures the performance impact of failures on the system. So far, there have only been initial research efforts that consider single-server outages in their benchmarks (Fior et al. 2013; Rosselli et al. 2016). The replication tier, on the other hand, considers the performance impact of different replication techniques or configurations (Klems et al. 2012; Haughian et al. 2016).

A lot of research was done in the area of consistency measurement of replicated database systems. For this purpose, YCSB has been extended and has also been used as workload generator while conducting consistency measurements with specialized tools. Friedrich et al. (2014) give an overview of the various research projects.

Finally, the book *Cloud Service Benchmarking* by Bermbach et al. (2017) can be used as a modern reference book in which the fundamentals of database benchmarking are adapted to today's cloud and Big Data requirements.

Beyond CRUD Operations

YCSB is criticized for not considering functionality beyond that of simple key-value stores and for abstracting from many differences, such as data models. In response to these criticisms, many extensions have been developed.

For example, YCSB + T wraps the CRUD operations into transactional context to model a simple “closed economy workload” (Dey et al. 2014). It was used to evaluate the performance of a generic multi-item transaction protocol for key-value stores. Pilman et al. (2017), on the other hand, added some additional scan queries (e.g., with aggregation) to benchmark their proposed SQL-over-NoSQL architecture. In this context, they examine the performance of various NoSQL systems offering a simple scan operator.

Other extensions allow benchmarking advanced query capabilities of certain classes of NoSQL databases. These include XGDBBench for graph databases (Dayarathna and Suzumura 2012) and YCSB-TS to measure the performance of time-series database functionalities.

Improving YCSB

Given the fundamental requirements of database system benchmarks, namely, relevance, simplicity, portability, and scalability (Gray 1993), YCSB favors portability and simplicity over relevance. Unlike the TPC benchmarks, it does not model a real application workload and is therefore not very relevant for one particular application domain. But its generic workloads and the simple CRUD interface ensure the highest portability. However, there are some research efforts to improve the relevance and scalability aspect.

Patil et al. (2011) have added a coordination service in their extension called YCSB++, which distributes the originally centralized benchmarking framework across several benchmark machines. The extension KV-replay (Boza et al. 2017) includes the option to replay realistic workloads by reading in trace files of real application workloads. Friedrich et al. (2017), on the other hand, implemented a load generator based on an *open system model*, in addition to YCSB’s implementation following a *closed system model*.

In the closed system model, a fixed number of threads repeatedly request the system, whereby a new request can only be sent after a response. In the open system model, requests are independent of each other and can be issued without any constraints linked to responses. Since the implementation of an open system model is similar to modern asynchronous web frameworks, this leads to more realistic web application workloads.

Key Applications

Currently, YCSB is used for experimental evaluation in almost all scientific work in the field of distributed data management. It is also extensively used in studies that investigate the performance behavior of certain system or protocol designs. For example, Harding et al. (2017) recently compared the performance characteristics of six classic and modern concurrency control protocols for distributed transactions. Other research activities deal with general quality tradeoffs like the consistency/latency tradeoff of NoSQL database systems (Rahman et al. 2017).

Of course, YCSB is also used by NoSQL vendors to carry out comparative studies for marketing and advertising purposes. The presented results should always be viewed critically, as the experimental design and the presentation of the results are usually chosen in favor of the advertised system.
