Preface

In the field of computer science, data is considered as the main raw material which is produced by abstracting the world into categories, measures, and other representational forms (e.g., characters, numbers, relations, sounds, images, electronic waves) that constitute the building blocks from which information and knowledge are created. In practice, data generation and consumption has become a part of people's daily life especially with the pervasive availability of Internet technology. We are progressively moving toward being a data-driven society where data has become one of the most valuable assets. Big data has commonly been characterized by the defining 3V's properties which refer to huge Volume, consisting of terabytes or petabytes of data; high in Velocity, being created in or near real time; and diversity in Variety of form, being structured and unstructured in nature.

Recently, research communities, enterprises, and government sectors have all realized the enormous potential of big data analytics, and continuous advancements have been emerging in this domain. This Encyclopedia answers the need for solid and comprehensive research source in the domain of Big Data Technologies. The aim of this Encyclopedia is to provide a full picture of various related aspects, topics, and technologies of big data including big data enabling technologies, big data integration, big data storage and indexing, data compression, big data programming models, big SQL systems, big streaming systems, big semantic data processing, graph analytics, big spatial data management, big data analysis, business process analytics, big data processing on modern hardware systems, big data applications, big data security and privacy, and benchmarking of big data systems.

With contributions of many leaders in the field, this Encyclopedia provides the reader with comprehensive reading materials for a large range of audiences. It is a main aim of the Encyclopedia to influence the readers to think further and investigate the areas that are novel to them. The Encyclopedia has been designed to serve as a solid and comprehensive reference not only to expert researchers and software engineers in the field but equally to students and junior researchers as well. The first edition of the Encyclopedia contains more than 250 entries covering a wide range of topics. The Encyclopedia's entries will be updated regularly to follow the continuous advancement in the

domain and have up-to-date coverage available for our readers. It will be available both in print and online versions. We hope that our readers will find this Encyclopedia as a rich and valuable resource and a highly informative reference for Big Data Technologies.

List of Topics

Big Data Integration

Section Editor: *Maik Thiele*

Data Cleaning
Data Fusion
Data Integration
Data Lake
Data Profiling
Data Wrangling
ETL
Holistic Schema Matching
Integration-Oriented Ontology
Large-Scale Entity Resolution
Large-Scale Schema Matching
Privacy-Preserving Record Linkage
Probabilistic Data Integration
Record Linkage
Schema Mapping
Truth Discovery
Uncertain Schema Matching

Big SQL

Section Editor: *Yuanyuan Tian and Fatma Ozkan*

Big Data Indexing
Caching for SQL-on-Hadoop
Cloud-Based SQL Solutions for Big Data
Columnar Storage Formats
Hive
Hybrid Systems Based on Traditional Database Extensions
Impala
Query Optimization Challenges for SQL-on-Hadoop
SnappyData

Spark SQL

Virtual Distributed File System: Alluxio
Wildfire: HTAP for Big Data

Big Spatial Data Management

Section Editor: *Timos Sellis and Aamir Cheema*

Applications of Big Spatial Data: Health Architectures
Indexing
Linked Geospatial Data
Query Processing – k NN
Query Processing: Computational Geometry
Query Processing: Joins
Spatial Data Integration
Spatial Data Mining
Spatial Graph Big Data
Spatio-social Data
Spatio-textual Data
Spatiotemporal Data: Trajectories
Streaming Big Spatial Data
Using Big Spatial Data for Planning User Mobility
Visualization

Big Semantic Data Processing

Section Editor: *Philippe Cudré-Mauroux and Olaf Hartig*

Automated Reasoning
Big Semantic Data Processing in the Life Sciences Domain
Big Semantic Data Processing in the Materials Design Domain

Data Quality and Data Cleansing of Semantic Data	Python
Distant Supervision from Knowledge Graphs	Scala
Federated RDF Query Processing	SciDB
Framework-Based Scale-Out RDF Systems	R Language: A Powerful Tool for Taming
Knowledge Graph Embeddings	Big Data
Knowledge Graphs in the Libraries and Digital Humanities Domain	Big Data on Modern Hardware Systems
Native Distributed RDF Systems	Section Editor: <i>Bingsheng He</i> <i>and Behrooz Parhami</i>
Ontologies for Big Data	Big Data and Exascale Computing
RDF Dataset Profiling	Computer Architecture for Big Data
RDF Serialization and Archival	Data Longevity and Compatibility
Reasoning at Scale	Data Replication and Encoding
Security and Privacy Aspects of Semantic Data	Emerging Hardware Technologies
Semantic Interlinking	Energy Implications of Big Data
Semantic Search	GPU-Based Hardware Platforms
Semantic Stream Processing	Hardware Reliability Requirements
Visualizing Semantic Data	Hardware-Assisted Compression
Big Data Analysis	Parallel Processing with Big Data
Section Editor: <i>Domenico Talia and</i> <i>Paolo Trunfio</i>	Search and Query Accelerators
Apache Mahout	Storage Hierarchies for Big Data
Apache SystemML	Storage Technologies for Big Data
Big Data Analysis Techniques	Structures for Large Data Sets
Big Data Analysis and IoT	Tabular Computation
Big Data Analysis for Smart City Applications	Big Data Applications
Big Data Analysis for Social Good	Section Editor: <i>Kamran Munir</i> <i>and Antonio Pescape</i>
Big Data Analysis in Bioinformatics	Big Data and Recommendation
Cloud Computing for Big Data Analysis	Big Data Application in Manufacturing
Deep Learning on Big Data	Industry
Energy Efficiency in Big Data Analysis	Big Data Enables Labor Market
Languages for Big Data analysis	Intelligence
Performance Evaluation of Big Data Analysis	Big Data Technologies for DNA
Scalable Architectures for Big Data Analysis	Sequencing
Tools and Libraries for Big Data Analysis	Big Data Warehouses for Smart Industries
Workflow Systems for Big Data Analysis	Big Data for Cybersecurity
Big Data Programming Models	Big Data for Health
Section Editor: <i>Sherif Sakr</i>	Big Data in Automotive Industry
BSP Programming Model	Big Data in Computer Network Monitoring
Clojure	Big Data in Cultural Heritage
Julia	Big Data in Mobile Networks
	Big Data in Network Anomaly Detection
	Big Data in Smart Cities

Big Data in Social Networks
Flood Detection Using Social Media
Big Data Streams

Enabling Big Data Technologies
Section Editor: Rodrigo Neves Calheiros and Marcos Dias de Assuncao

Apache Spark
Big Data Architectures
Big Data Deep Learning Tools
Big Data Visualization Tools
Big Data and Fog Computing
Big Data in the Cloud
Databases as a Service
Distributed File Systems
Graph Processing Frameworks
Hadoop
Mobile Big Data: Foundations, State of the Art, and Future Directions
Network-Level Support for Big Data Computing
NoSQL Database Systems
Orchestration Tools for Big Data
Visualization Techniques

Big Data Transaction Processing
Section Editor: Mohammad Sadoghi

Active Storage
Blockchain Transaction Processing
Conflict-Free Replicated Data Types CRDTs
Coordination Avoidance
Database Consistency Models
Geo-replication Models
Geo-scale Transaction Processing
Hardware-Assisted Transaction Processing
Hardware-Assisted Transaction Processing: NVM
Hybrid OLTP and OLAP
In-Memory Transactions
Transactions in Massively Multiplayer Online Games
Weaker Consistency Models/Eventual Consistency

Distributed Systems for Big Data
Section Editor: Asterios Katsifodimos and Pramod Bhatotia

Achieving Low Latency Transactions for Geo-replicated Storage with Blotter
Advancements in YARN Resource Manager
Approximate Computing for Stream Analytics
Cheap Data Analytics on Cold Storage
Distributed Incremental View Maintenance
HopsFS: Scaling Hierarchical File System
Metadata Using NewSQL Databases
Incremental Approximate Computing
Incremental Sliding Window Analytics
Optimizing Geo-distributed Streaming Analytics
Parallel Join Algorithms in MapReduce
Privacy-Preserving Data Analytics
Robust Data Partitioning
Sliding-Window Aggregation Algorithms
Stream Window Aggregation Semantics and Optimization
StreamMine3G: Elastic and Fault Tolerant Large Scale Stream Processing
TARDiS: A Branch-and-Merge Approach to Weak Consistency

Big Data Security and Privacy
Section Editor: Junjun Chen and Deepak Puthal

Big Data Stream Security Classification for IoT Applications
Big Data and Privacy Issues for Connected Vehicles in Intelligent Transportation Systems
Co-resident Attack in Cloud Computing: An Overview
Data Provenance for Big Data Security and Accountability
Exploring Scope of Computational Intelligence in IoT Security Paradigm
Keyword Attacks and Privacy Preserving in Public-Key-Based Searchable Encryption
Network Big Data Security Issues
Privacy Cube
Privacy-Aware Identity Management

Scalable Big Data Privacy with MapReduce	Microbenchmark
Secure Big Data Computing in Cloud: An Overview	SparkBench
Security and Privacy in Big Data Environment	Stream Benchmarks
	System Under Test
	TPC
	TPC-DS
	TPC-H
	TPCx-HS
	Virtualized Big Data Benchmarks
	YCSB
Business Process Analytics	Graph data management and analytics
Section Editor: Marlon Dumas and Matthias Weidlich	Section Editor: Hannes Voigt and George Fletcher
Artifact-Centric Process Mining	Feature Learning from Social Graphs
Automated Process Discovery	Graph Data Integration and Exchange
Business Process Analytics	Graph Data Models
Business Process Deviance Mining	Graph Exploration and Search
Business Process Event Logs and Visualization	Graph Generation and Benchmarks
Business Process Model Matching	Graph Invariants
Business Process Performance Measurement	Graph OLAP
Business Process Querying	Graph Partitioning: Formulations and Applications to Big Data
Conformance Checking	Graph Path Navigation
Data-Driven Process Simulation	Graph Pattern Matching
Decision Discovery in Business Processes	Graph Query Languages
Declarative Process Mining	Graph Query Processing
Decomposed Process Discovery and Conformance Checking	Graph Representations and Storage
Event Log Cleaning for Business Process Analytics	Graph Visualization
Hierarchical Process Discovery	Graph Data Management Systems
Multidimensional Process Analytics	Historical Graph Management
Predictive Business Process Monitoring	Indexing for Graph Query Evaluation
Process Model Repair	Influence Analytics in Graphs
Queue Mining	Link Analytics in Graphs
Streaming Process Discovery and Conformance Checking	Linked Data Management
Trace Clustering	Parallel Graph Processing
	Visual Graph Querying
Big Data Benchmarking	Data Compression
Section Editor: Meikel Poess and Tilmann Rabl	Section Editor: Paolo Ferragina
Analytics Benchmarks	(Web/Social) Graph Compression
Auditing	Compressed Indexes for Repetitive Textual Datasets
Benchmark Harness	Computing the Cost of Compressed Data
CRUD Benchmarks	
Component Benchmark	
End-to-End Benchmark	
Energy Benchmarking	
Graph Benchmarking	
Metrics for Big Data Benchmarks	

Degrees of Separation and Diameter
in Large Graphs
Delta Compression Techniques
Dimension Reduction
Genomic Data Compression
Grammar-Based Compression
Inverted Index Compression
RDF Compression
Similarity Sketching

Big Stream Processing

Section Editor: *Alessandro Margara*
and Tilmann Rabl

Adaptive Windowing
Apache Apex
Apache Flink
Apache Kafka
Apache Samza

Continuous Queries
Definition of Data Streams
Elasticity
Introduction to Stream Processing Algorithms
Management of Time
Online Machine Learning Algorithms over
Data Streams
Online Machine Learning in Big Data Streams:
Overview
Pattern Recognition
Recommender Systems over Data Streams
Reinforcement Learning, Unsupervised Methods,
and Concept Drift in Stream Learning
Rendezvous Architectures
Stream Processing Languages and Abstractions
Stream Query Optimization
Streaming Microservices
Types of Stream Processing Algorithms
Uncertainty in Streams

About the Editors

Professor Sherif Sakr is the Head of Data Systems Group at the Institute of Computer Science, University of Tartu. He received his PhD degree in Computer and Information Science from Konstanz University, Germany, in 2007. He received his BSc and MSc degrees in Computer Science from the Information Systems Department at the Faculty of Computers and Information in Cairo University, Egypt, in 2000 and 2003, respectively. During his career, Prof. Sakr held appointments in several international and reputable organizations including the University of New South Wales, Macquarie University, Data61/CSIRO, Microsoft Research, Nokia Bell Labs, and King Saud bin Abdulaziz University for Health Sciences.

Prof. Sakr's research interest is data and information management in general, particularly in big data processing systems, big data analytics, data science, and big data management in cloud computing platforms. Professor Sakr has published more than 100 refereed research publications in international journals and conferences such as the *Proceedings of the VLDB Endowment* (VLDB), *IEEE Transactions on Parallel and Distributed Systems* (IEEE TPDS), *IEEE Transactions on Service Computing* (IEEE TSC), *IEEE Transactions on Big Data* (IEEE TBD), *ACM Computing Surveys* (ACM CSUR), *Journal of Computer and System Sciences* (JCSS), *Information Systems Journal*, *Cluster Computing*, *Journal of Grid Computing*, *IEEE Communications Surveys and Tutorials* (IEEE COMST), *IEEE Software*, *Scientometrics*, *VLDB*, *SIGMOD*, *ICDE*, *EDBT*, *WWW*, *CIKM*, *ISWC*, *BPM*, *ER*, *ICWS*, *ICSOC*, *IEEE SCC*, *IEEE Cloud*, *TPCTC*, *DASFAA*, *ICPE*, and *JCDL*. Professor Sakr Co-authored 5 books and Co-Edited 3 other books in the areas of data and information management and processing. Sherif is an associate editor of the cluster computing journal and Transactions on Large-Scale Data and Knowledge-Centered Systems (TLDKS). He is also an editorial board member of many reputable international journals. Prof. Sakr is an ACM Senior Member and an IEEE Senior Member. In 2017, he has been

appointed to serve as an ACM Distinguished Speaker and as an IEEE Distinguished Speaker. For more information, please visit his personal web page (<http://kodu.ut.ee/~sakr/>) and his research group page (<http://bigdata.cs.ut.ee/>)

Albert Y. Zomaya is currently the *Chair Professor of High Performance Computing & Networking* in the School of Information Technologies, University of Sydney. He is also the *Director of the Centre for Distributed and High Performance Computing* which was established in late 2009. Dr. Zomaya was an *Australian Research Council Professorial Fellow* during 2010–2014 and held the *CISCO Systems Chair Professor of Internetworking* during the period 2002–2007 and also was Head of school for 2006–2007 in the same school.

Prior to his current appointment, he was a Full Professor in the Electrical and Electronic Engineering Department at the University of Western Australia, where he also led the Parallel Computing Research Laboratory during the period 1990–2002. He served as Associate, Deputy, and Acting Head in the same department and held numerous visiting positions and has extensive industry involvement.

Dr. Zomaya published more than 600 scientific papers and articles and is author, co-author, or editor of more than 20 books. He served as the Editor in Chief of the *IEEE Transactions on Computers* (2011–2014). Currently, he serves as a Founding Editor in Chief for the *IEEE Transactions on Sustainable Computing*, a Co-founding Editor in Chief of the *IET Cyber-Physical Systems: Theory and Applications*, and an Associate Editor in Chief (special issues) of the *Journal of Parallel and Distributed Computing*.

Dr. Zomaya is an Associate Editor for several leading journals, such as the *ACM Transactions on Internet Technology*, *ACM Computing Surveys*, *IEEE Transactions on Cloud Computing*, *IEEE Transactions on Computational Social Systems*, and *IEEE Transactions on Big Data*. He is also the Founding Editor of several book series, such as the *Wiley Book Series on Parallel and Distributed Computing*, the *Springer Scalable Computing and Communications*, and the *IET Book Series on Big Data*.

Dr. Zomaya was the Chair the *IEEE Technical Committee on Parallel Processing* (1999–2003) and currently serves on its executive committee. He is the *Vice-Chair* of the *IEEE Task Force on Computational Intelligence for Cloud Computing* and serves on the advisory board of the *IEEE Technical Committee on Scalable Computing* and the steering committee of the *IEEE Technical Area in Green Computing*.

Dr. Zomaya has delivered more than 180 keynote addresses, invited seminars, and media briefings and has been actively involved, in a variety of capacities, in the organization of more than 700 conferences.

Dr. Zomaya is a Fellow of the IEEE, the American Association for the Advancement of Science, and the Institution of Engineering and Technology (UK). He is a Chartered Engineer and an IEEE Computer Society's Golden Core Member. He received the *1997 Edgeworth David Medal* from the Royal Society of New South Wales for outstanding contributions to Australian science. Dr. Zomaya is the recipient of the *IEEE Technical Committee on Parallel Processing Outstanding Service Award* (2011), the *IEEE Technical Committee on Scalable Computing Medal for Excellence in Scalable Computing* (2011), the *IEEE Computer Society Technical Achievement Award* (2014), and the *ACM MSWIM Reginald A. Fessenden Award* (2017). His research interests span several areas in parallel and distributed computing and complex systems. More information can be found at <http://www.it.usyd.edu.au/~azom0780/>.

Blotter design and protocols; Geo-replicated transactions; Non-monotonic Snapshot Isolation in Geo-replicated Systems

Definitions

Blotter is a protocol for executing transactions in geo-replicated storage systems with non-monotonic snapshot isolation semantics. A geo-replicated storage system is composed by a set of nodes running in multiple data centers

located in different geographical locations. The nodes in each data center replicate either all or a subset of the data items in the database, leading to a full replication or partial replication approach. Blotter was primarily designed for full replication scenarios but can also be used in partial replication scenarios. Under non-monotonic snapshot isolation semantics, a transaction reads from a snapshot that reflects all the writes from a set of transactions that includes, at least, all locally committed transactions and remote transactions known when the transaction starts. Two concurrent transactions conflict if their write set intersects, i.e., if there is a data item written by both. In such case, one of the transactions will abort.

Overview

Many Internet services are backed by geo-replicated storage systems in order to keep data close to the end user. This decision is supported by studies showing the negative impact of latency on user engagement and, by extension, revenue (Hoff 2009). While many of these systems rely on weak consistency for better performance and availability (DeCandia et al. 2007), there is also a class of applications that require support for strong consistency and transactions. For instance, many applications within Google are operating on top of Megastore (Baker et al. 2011), a system that provides ACID semantics within the same shard, instead of Bigtable (Chang et al.

2008), which provides better performance but weaker semantics. This trend also motivated the development of Spanner, which provides general serializable transactions (Corbett et al. 2012) and sparked other recent efforts in the area of strongly consistent geo-replication (Sovran et al. 2011; Saeida Ardekani et al. 2013a; Lloyd et al. 2013; Zhang et al. 2013; Kraska et al. 2013; Mahmoud et al. 2013).

In this chapter, we present Blotter, a transactional geo-replicated storage system, whose goal is to cut the latency penalty for ACID transactions in geo-replicated systems, by leveraging a recent isolation proposal called Non-Monotonic Snapshot Isolation (NMSI) (Saeida Ardekani et al. 2013a). We focus on the Blotter algorithms and discuss how they achieve: (1) at most one round-trip across data centers (assuming a fault-free run and that clients are proxies in the same data center as one of the replicas) and (2) read operations that are always served by the local data center.

To achieve these goals, Blotter combines a novel *concurrency control* algorithm that executes at the data center level, with a carefully configured Paxos-based (Lamport 1998) replicated state machine that replicates the execution of the concurrency control algorithm across data centers. Both of these components exploit several characteristics of NMSI to reduce the amount of coordination between replicas. In particular, the concurrency control algorithm leverages the fact that NMSI does not require a total order on the start and commit times of transactions. Such an ordering would require either synchronized clocks, which are difficult to implement, even using expensive hardware (Corbett et al. 2012), or synchronization between replicas that do not hold the objects accessed by a transaction (Saeida Ardekani et al. 2013b), which hinders scalability. In addition, NMSI allows us to use separate (concurrent) Paxos-based state machines for different objects, on which we geo-replicate the *commit* operation of the concurrency control protocol.

Compared to a previously proposed NMSI system called Jessy (Saeida Ardekani et al. 2013a), instead of assuming partial replication,

we target full replication, which is a common deployment scenario (Baker et al. 2011; Shute et al. 2013; Bronson et al. 2013). Our layering of Paxos on top of a concurrency control algorithm is akin to the Replicated Commit system, which layers Paxos on top of two-phase Locking (Mahmoud et al. 2013). However, by leveraging NMSI, we execute reads exclusively locally and run parallel instances of Paxos for different objects, instead of having a single instance per shard. Furthermore, when a client is either colocated with the Paxos leader or when that leader is in the closest data center to the client, Blotter can commit transactions within a single round-trip to the *closest* data center.

We have implemented Blotter as an extension to the well-known geo-replicated storage system Cassandra (Lakshman and Malik 2010). Our evaluation shows that, despite adding a small overhead in a single data center, Blotter performs much better than both Jessy and the protocols used by Spanner and also outperforms in many metrics a replication protocol that ensures snapshot isolation (Elnikety et al. 2005). This shows that Blotter can be a valid choice when several replicas are separated by high latency links, performance is critical, and the semantic differences between NMSI and snapshot isolation are acceptable by the application.

Key Research Findings

The research conducted to design and implement Blotter led to the following key contributions and findings:

1. A simple yet precise definition of non-monotonic snapshot isolation, a recent isolation model that aims at maximizing parallel execution of transactions in geo-replicated systems.
2. The design of Blotter, which combines a novel concurrency control protocol for a single data-center and its extension toward an arbitrary number of data centers by leveraging a carefully designed state machine replication

solution leveraging a variant of the Paxos algorithm.

3. The demonstration that it is possible to achieve strong consistency in geo-replicated storage systems within a modest latency envelop in fault-free runs.

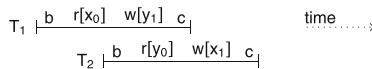

Non-monotonic Snapshot Isolation

We start by providing a specification of our target isolation level, NMSI, and discussing the advantages and drawbacks of this choice.

Snapshot Isolation Revisited

NMSI is an evolution of snapshot isolation (SI). Under SI, a transaction (logically) executes in a database snapshot taken at the transaction begin time, reflecting the writes of all transactions that committed before that instant. Reads and writes execute against this snapshot and, at commit time, a transaction can commit if there are no write-write conflicts with concurrent transactions. (In this context, two transactions are concurrent if the intervals between their begin and commit times overlap.)

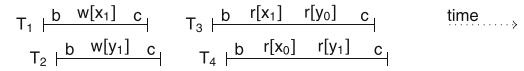

Snapshot isolation exhibits the write-skew anomaly, where two concurrent transactions T_1 and T_2 start by reading x_0 and y_0 , respectively, and later write y_1 and x_1 , as exemplified in the following figure. This execution is admissible under snapshot isolation, as there is no write-write conflict, and each transaction has read from a database snapshot. However, this execution is not serializable.

Specification of NMSI

NMSI weakens the SI specification in two ways. First, the snapshots against which transactions execute do not have to reflect the writes of a monotonically growing set of transactions. In other words, it is possible to observe what is called a “long fork” anomaly, where there can exist two concurrent transactions t_a and t_b that commit, writing to different objects, and two other transactions that start subsequently, where

one sees the effects of t_a but not t_b , and the other sees the effects of t_b but not t_a . The next figure exemplifies an execution that is admissible under NMSI but not under SI, since under SI both T_3 and T_4 would see the effects of both T_1 and T_2 because they started after the commit of T_1 and T_2 .

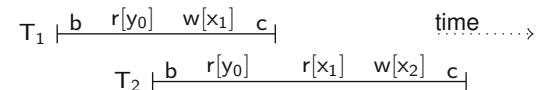

Second, instead of forcing the snapshot to reflect a subset of the transactions that committed at the transaction begin time, NMSI gives the implementation the flexibility to reflect a more convenient set of transactions in the snapshot, possibly including transactions that committed *after* the transaction began. This property, also enabled by serializability, is called *forward freshness* (Saeida Ardekani et al. 2013a).

Definition 1 (Non-Mon. Snapshot Isol. (NMSI))

An implementation of a transactional system obeys NMSI if, for any trace of the system execution, there exists a partial order \prec among transactions that obeys the following rules, for any pair of transactions t_i and t_j in the trace:

1. if t_j reads a value for object x written by t_i then $t_i \prec t_j \wedge \nexists t_k$ writing to $x : t_i \prec t_k \prec t_j$
2. if t_i and t_j write to the same object x then either $t_i \prec t_j$ or $t_j \prec t_i$.

The example in Fig. 1 obeys NMSI but not SI, as the depicted partial order meets Definition 1.

$$T_0 \prec T_1 \prec T_2$$

Achieving Low Latency Transactions for Geo-replicated Storage with Blotter, Fig. 1 Example execution obeying NMSI but not SI. This assumes the existence of a transaction T_0 that writes the initial values for x and y

The Benefits of NMSI in Replicated Settings

NMSI weakens the specification of SI in a way that can be leveraged for improving performance in replicated settings.

The possibility of having “long forks” allows, in a replicated setting, for a single (local) replica to make a decision concerning what data the snapshot should read. This is because it is not necessary to enforce a serialization between all transaction begin and commit operations, although it is still necessary to check for write-write conflicts,

In the case of “forward freshness,” this allows for a transaction to read (in most cases) the most recent version of a data object at a given replica, independently of the instant when the transaction began. This not only avoids the bookkeeping associated with tracking transaction start times but also avoids a conflict with transactions that might have committed after the transaction began.

Impact of NMSI for Applications

We analyze in turn the impact of “forward freshness” and “long forks” for application developers. Forward freshness allows a transaction t_a to observe the effects of another transaction t_b that committed after t_a began (in real time). In this case, the programmer must decide whether this is a violation of the intended application semantics, which is analogous to decide if serializability or strict serializability is the most adequate isolation level for a given application. Long forks allow two transactions to execute against different branches of a forked database state, provided there are no write-write conflicts. In practice, the main implication of this fact is that the updates made by users may not become instantly visible across all replicas. For example, this could cause two users of a social network to each think that they were the first to post a new promotion on their own wall, since they do not see each other’s posts immediately (Sovran et al. 2011). Again, the programmer must reason whether this is admissible. In this case, a mitigating factor is that this anomaly does not cause the consistency of the database to break. (This is in contrast with the “write-skew” anomaly, which is present in both SI and NMSI.) Furthermore, in the

particular case of our protocol, the occurrence of anomalies is very rare: for a “long fork” to occur, two transactions must commit in two different data centers, form a quorum with a third data center, and both complete before hearing from the other.

Finally, NMSI allows consecutive transactions from the same client to observe a state that reflects a set of transactions that does not grow monotonically (when consecutive transactions switch between two different branches of a long fork). However, in our algorithms, this is an unlikely occurrence, since it requires that a client connects to different data centers in a very short time span.

Blotter Protocols

We now describe the Blotter protocols, introducing first the concurrency protocol algorithm in a single data center scenario, and then how this protocol can be replicated to multiple data centers. A more detailed explanation of the protocols including their evaluation can be found elsewhere (Moniz et al. 2017).

System Model

Blotter is designed to run on top of any distributed storage system with nodes spread across one or multiple data centers. We assume that each data object is replicated at all data centers. Within each data center, data objects are replicated and partitioned across several nodes. We make no restrictions on how this intra-data center replication and partitioning takes place. We assume that nodes may fail by crashing and recover from such faults. When a node crashes, it loses its volatile state, but all data that was written to stable storage is accessible after recovery.

We use an asynchronous system model, i.e., we do not assume any known bounds on computation and communication delays. We do not prescribe a fixed bound on the number of faulty nodes within each data center – this depends on the intra-data center replication protocol used.

Blotter Architecture

The client library of Blotter exposes an API with the expected operations: begin a new

transaction, *read* an object given its identifier, *write* an object given its identifier and new value, and *commit* a transaction, which either returns commit or abort.

The set of protocols that comprise Blotter are organized into three different components:

Blotter intra-data center replication. At the lowest level, we run an intra-data center replication protocol to mask the unreliability of individual machines within each data center. This level must provide the protocols above it with the vision of a single logical copy (per data center) of each data object and associated metadata, which remains available despite individual node crashes. We do not prescribe a specific protocol for this layer, since any of the existing protocols that meet this specification can be used.

Blotter Concurrency Control. These are the protocols that ensure transaction atomicity and NMSI isolation in a single data center and, at the same time, are extensible to multiple data centers by serializing a single protocol step.

Inter-data Center Replication. This completes the protocol stack by replicating a subset of the steps of the concurrency control protocol across data centers. It implements state machine replication (Schneider 1990; Lamport 1978) by judiciously applying Paxos (Lamport 1998) to the concurrency control protocol to avoid unnecessary coordination across data centers.

Single Data Center Protocol

The single data center concurrency control module consists of the following three components: the client library and the transaction managers (TM), which are non-replicated components that act as a front end providing the system interface and implementing the client side of the transaction processing protocol, respectively; and the data managers (DM), which are the replicated components that manage the information associated with data objects.

Client Library. This provides the interface of Blotter, namely, *begin*, *read*, *write*, and *commit*.

The *begin* and *write* operations are local to the client. *Read* operations are relayed to the TM, who returns the values and metadata for the objects that were read. The written values are buffered by the client library and only sent to the TM at *commit* time, together with the accumulated metadata for the objects that were read. This metadata is used to set the versions that running transactions must access, as explained next.

Transaction Manager (TM). The TM handles the two operations received from the clients: *read* and *commit*. For *reads*, it merely relays the request and reply to or from the data manager (DM) responsible for the object being read. Upon receiving a *commit* request, the TM acts as a coordinator of a two-phase commit (2PC) protocol to enforce the all-or-nothing atomicity property. The first phase sends a *dm-prewrite-request*, with the newly written values, to all DMs storing written objects. Each DM verifies if the write complies with NMSI. If none of the DMs identifies a violation, the TM sends the DMs a *dm-write* message containing the metadata with snapshot information aggregated from all replies on the first phase; otherwise, it sends a *dm-abort*.

Data Manager (DM). The core of the concurrency control logic is implemented by the DM, which maintains the data and meta-data necessary to provide NMSI. Algorithm 1 presents the handlers for the three types of requests. Now, we explain how these functions enforce NMSI rules presented in our definition.

Partial order \prec . We use a multi-version protocol, i.e., the system maintains a list of versions for each object. This list is indexed by an integer version number, which is incremented every time a new version of the object is created (e.g., for a given object x , overwriting x_0 creates version x_1 , and so on). In a multi-versioned storage, the \prec relation can be defined by the version number that transactions access, namely, if t_i writes x_m and t_j writes x_n , then $t_i \prec t_j \Leftrightarrow m < n$; and if t_i writes x_m and t_j reads x_n , then $t_i \prec t_j \Leftrightarrow m \leq n$.

Algorithm 1: Single data center DM protocols

```

    // read operation
1  upon { dm-read, T, x } from TM do
2      processRead { T, x, TM };

    // prewrite operation
3  upon { dm-prewrite, T, x, value } from TM do
4      if x.prewrite ≠ ⊥ then
5          // another prewrite is pending
6          x.pending ← x.pending ∪ {(T, x, value, TM)};
7      else
8          processPrewrite { T, x, value, TM };

    // write operation
9  upon { dm-write, T, x, agg-startd-before } from TM do
10     for each T' in agg-startd-before do
11         if T' not in x.snapshot then
12             x.snapshot[T'] ← x.last;
13
14         x.last ← x.last + 1;
15         x.value[x.last] ← x.nextvalue;
16         finishWrite { T, x, TM };

    // abort operation
17  upon { dm-abort, T, x } from TM do
18      finishWrite { T, x, TM };

    // process read operation
19  processRead { T, x, TM }
20      if T ∉ x.snapshot then
21          if x.prewrite ≠ ⊥ then
22              x.buffered ← x.buffered ∪ {(T, TM)};
23              return
24          else
25              x.snapshot[T] ← x.last;

26      version ← x.snapshot[T];
27      value ← x.value[version];
28      send { read-response, T, value, {T'|x.snapshot[T'] < version} } to TM;

    // process dm-prewrite request
29  processPrewrite { T, x, value, TM }
30      if x.snapshot[T] ≠ ⊥ ∧ x.snapshot[T] < x.last then
31          // there is a write-write conflict
32          send { prewrite-response, reject, ⊥ } to TM;
33      else
34          x.prewrite ← T;
35          x.nextvalue ← value;
36          send { prewrite-response, accept, {T'|T' ∈ x.snapshot} } to TM;

    // clean prewrite information and serve buffered reads and pending prewrites
37  finishWrite { T, x, TM }
38      if x.prewrite = T then
39          x.nextvalue ← ⊥; x.prewrite ← ⊥;
40
41      for each (T, TM) in x.buffered do
42          processRead { T, x, TM };
43
44      if x.pending ≠ ⊥ then
45          (T, x, value, TM) ← removeFirst(x.pending);
46          processPrewrite { T, x, value, TM };

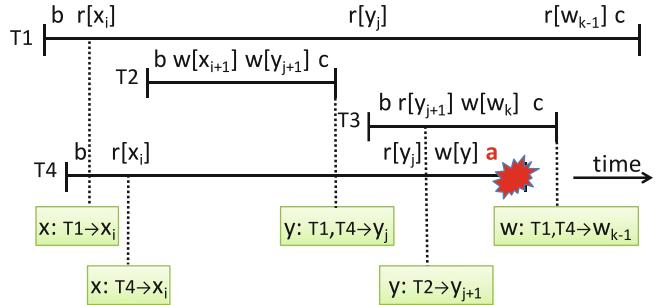

```

NMSI rule number 1. Rule number 1 of the definition of NMSI says that, for object x , transaction t must read the value written by the “latest” transaction that updated x (according to \prec). To illustrate this, consider the example run in Fig. 2. When a transaction T_1 issues its first read operation, it can read the most recently committed version of the object, say x_i written by T_0 (leading to $T_0 \prec T$). If, subsequently, some other

transaction T_2 writes x_{i+1} ($T_0 \prec T_2$), then the protocol must prevent T_1 from either reading or overwriting the values written by T_2 . Otherwise, we would have $T_0 \prec T_2 \prec T_1$ and T_1 should have read the value for object x written by T_2 (i.e., x_{i+1}) instead of that written by T_0 (i.e., x_i). Next, we detail how this is achieved first for reads, then writes, and then how to enforce the rule transitively.

Achieving Low Latency Transactions for Geo-replicated Storage with Blotter, Fig. 2

Example run

Reading the latest preceding version. The key to enforcing this requirement is to maintain state associated with each object, stating the version a running transaction must read, in case such a restriction exists. In the previous example, if T_2 writes x_{i+1} , this state records that T_1 must read x_i .

To achieve this, our algorithm maintains a per-object dictionary data structure ($x.snapshot$), mapping the identifier of a transaction t to a particular version of x that t either must read or has read from. Figure 2 depicts the changes to this data structure in the shaded boxes at the bottom of the figure. When the DM processes a read of x for t (function `processRead`), if the dictionary has no information for t , the most recent version is read, and this information is stored in the dictionary. Otherwise, the specified version is returned.

In the previous example, T_1 must record the version it reads in the $x.snapshot$ variable. Subsequently, when the commit of T_2 overwrites that version of x , we are establishing that $T_2 \not\propto T_1$. As such, if T_2 writes to another object y , creating y_{j+1} , then it must also force T_1 to read the preceding version y_j . To do this, when transaction T_2 commits, for every transaction t that read (or must read) an older version of object x (i.e., the transactions with entries in the dictionary of x), the protocol will store in the dictionary of every other object y written by T_2 that t must read the previous version of y , unless an even older version is already prescribed (`dm-write` handler). In this particular example, $y.snapshot$ would record that T_1 and T_4 must read version y_j , since, at commit time, $x.snapshot$ indicates that these transactions read x_i .

Preventing illegal overwrites. In the previous example, we must also guarantee that T_1 does not overwrite any value written by T_2 . To enforce this, it suffices to verify, at the time of the commit of transaction t , for every object written by t , if T should read its most recent version. If this is the case, then the transaction can commit, since no version will be incorrectly overwritten; otherwise, it must abort (function `processPrewrite`). In the example, T_4 aborts, since $y.snapshot$ records that T_4 must read y_j and a more recent version exists (y_{j+1}). Allowing T_4 to commit and overwrite y_{j+1} would lead to $T_2 \prec T_4$. This breaks rule number 1 of NMSI, since it would have required T_1 to read x_{i+1} written by T_2 , which did not occur.

Applying the rules transitively. Finally, for enforcing rule number 1 of the definition of NMSI in a transitive manner, it is also necessary to guarantee the following: if T_2 writes x_{i+1} and y_{j+1} , and subsequently another transaction T_3 reads y_{j+1} and writes w_k , then the protocol must also prevent T_1 from reading or overwriting the values written by T_3 , otherwise we would have $T_0 \prec T_2 \prec T_3 \prec T_1$, and thus T_1 should also have read x_{i+1} .

To achieve this, when transaction T_3 (which read y_{j+1}) commits, for every transaction t that must read version y_l with $l < j + 1$ (i.e., the transactions that had entries in the dictionary of y when t_o read y), the protocol will store in the dictionary of every other object w written by T_3 that t must read the previous version of w (if an older version is not already specified). In the example, since the state for $y.snapshot$ after T_2 commits specifies that T_1 must read version y_j , then, when T_3 commits, $w.snapshot$ is updated

to state that T_1 and T_4 must read version w_{k-1} . This is implemented by collecting dependencies in read and pre-write functions and use these information to update the snapshot information for all objects in the write function.

NMSI rule number 2. Rule number 2 of the NMSI definition says that any pair of transactions that write the same object x must have a relative order, i.e., either $t_i \prec t_j$ or $t_j \prec t_i$. This order is defined by the version number of x created by each transaction.

Therefore, it remains to ensure that this is a partial order (i.e., no cycles). A cycle could appear if two or more transactions concurrently committed a chain of objects in a different order, e.g., if t_m wrote both x_i and y_{j+1} and t_n wrote both x_{i+1} and y_j . To prevent this, it suffices to use a two-phase commit protocol where, for each object, a single accepted prepare can be outstanding at any time.

Geo-Replication

Blotter implements geo-replication, with each object replicated in all data centers, using Paxos-based state machine replication (Lamport 1998; Schneider 1990). In this model, all replicas execute a set of client-issued commands according to a total order, thus following the same sequence of states and producing the same sequence of responses. We view each data center as a state machine replica. The state is composed by the database (i.e., all data objects and associated metadata), and the state machine commands are the `tm-read` and the `tm-commit` of the TM-DM interface.

Despite being correct, this approach has three drawbacks, which we address in detail in a separate paper (Moniz et al. 2017).

First, read operations in our concurrency control protocol are state machine commands that mutate the state, thus requiring an expensive consensus round. To address this, we leverage the fact that the NMSI properties allow for removing this information from the state machine, since the modified state only needs to be used locally.

Second, the total order of the state machine precludes the concurrent execution of two com-

mits, even for transactions that do not conflict. In this case, we leverage the fact that the partial order required by the NMSI definition can be built by serializing the `dm-prewrite` operation on a per-object basis, instead of serializing `tm-commits` across all objects. As such, instead of having one large state machine whose state is defined by the entire database, we can have one state machine per object, with the state being the object (including its metadata), and supporting only the `dm-prewrite` operation.

Finally, each Paxos-based state machine command requires several cross-data center message delays (depending on the variant of Paxos used). We adjusted the configuration of Paxos to reduce the cross data center steps to a single round-trip (from the client of the protocol, i.e., the TM) for update transactions, by using Multi-Paxos (Lamport 1998) and configuring Paxos to only tolerate one unplanned outage of a data center. In fact, this assumption is common in existing deployed systems (Ananthanarayanan et al. 2013; Corbett et al. 2012). (Planned outages are handled by re-configuring the Paxos membership Lamport et al. 2010.)

Examples of Applications

Blotter can be leveraged to design multiple large-scale geo-distributed applications, and in particular web applications whose semantics are compatible with the guarantees (and anomalies) associated with NMSI.

In particular, we have explored how to implement a set of the main operations of a microblogging platform, such as Twitter.

In our implementation of a simplistic version of Twitter, we model the timeline (sometimes called wall in the context of social network applications) as a data object in the (geo-replicated) data storage service. Furthermore, we associate with each user a set of followers and a set of followees. Each of these sets is modeled as an independent data object in the data storage.

We have supported three different user interactions. We selected these operations by relying on the model presented in Zhang et al. (2013):

- *Post-tweet* appends a tweet to the timeline of a user and its followers, which results in a transaction with many reads and writes, since one has to read the followers of the user posting the tweet and then write to the timeline of both the user and each corresponding follower.
- *Follow-user* appends new information in the set of followers to the profiles of the follower and the followee, which results in a transaction with two reads and two writes.
- *Read-timeline* reads the wall of the user issuing the operation, resulting in a single read operation.

In this case, the long fork anomaly can only result in a user observing (slightly) stale data, and perhaps even updating its own state based on that data, e.g., a user that decides to follow another can miss a few entries of that new user in his own timeline. Note that reading stale data can be addressed by waiting for the information about transactions to be propagated across all data centers in the deployment.

We also implemented the RUBiS benchmark, which models an auction site similar to eBay, on top of Blotter.

We ported the benchmark from using a relational database as the storage back end to using a key-value store. Each row of the relational database is stored with a key formed by the name of the table and the value of the primary key. We additionally store data for supporting efficient queries (namely, indexes and foreign keys).

In this benchmark, users issue operations such as selling, browsing, bidding, or buying items and consulting a personal profile that lists outstanding auctions and bids. All of these operations were implemented as Blotter transactions. In this application, the long fork anomaly that is allowed by NMSI has a few implications. In particular, when browsing the items that are available to be sold (or in auction), users can observe stale data, in the form of missing a few objects that are relevant for their queries.

Surprisingly, since bidding and buying an item involves writing to a single object in the data store in our adaptation, the long fork anomaly does

not affect these semantics, since all transactions that write on this object are totally ordered by the Paxos leader that is responsible for mediating the access to it.

The experimental results that evaluate the performance of these implementations can be in a separate paper (Moniz et al. 2017).

Future Directions of Research

In this chapter, we have presented the design of Blotter, a novel system architecture and set of protocols that exploits the benefits of NMSI to improve the performance of geo-replicated transactional systems.

Blotter demonstrates the practical benefits that can be achieved by relaxing the well-known and widely used SI model. To better frame the applications that can benefit from the Blotter design, we have presented a simple yet precise specification of NMSI and discussed how this specification differs in practice from the SI specification.

An interesting direction for future research in this context is to explore automatic mechanisms to check if an existing application designed for the SI model could safely be adapted to operate under NMSI. This could be achieved by exploiting application state invariants, and modeling transactions through their preconditions and post-conditions.

Overview

In brief, *Active Storage* refers to an architectural hardware and software paradigm, based on co-location storage and compute units. Ideally, it will allow to execute application-defined data- or compute-intensive operations in situ, i.e., within (or close to) the physical data storage. Thus *Active Storage* seeks to minimize expensive data movement, improving performance, scalability, and resource efficiency. The effective use of *Active Storage* mandates new architectures, algorithms, interfaces, and development toolchains.

Over the last decade, we are witnessing a clear trend toward the fusion of the compute-intensive and the data-intensive paradigms on architectural, system, and application level. On the one hand, large computational tasks (e.g., simulations) tend to feed growing amounts of data into their complex computational models; on the other hand, database applications execute computationally intensive ML and analytics-style workloads on increasingly large data sets. Both result in massive *data transfers* across the memory hierarchy, which block the CPU, causing unnecessary CPU waits and thus impair performance, scalability, and resource efficiency. The root cause

for this phenomenon lies in the generally low data locality as well as in traditional architectures and algorithms, which operate on the *data-to-code* principle. It requires data and program code to be transferred to the processing elements to be executed. Although *data-to-code* simplifies development and system architectures, it is inherently bounded by the *von Neumann bottleneck*.

These trends are impacted by the following recent developments: (a) *Moore's law* is said to be cooling down for different types of semiconductor elements, and *Dennard scaling* is coming to an end. The latter postulates that performance per watt grows at approximately the rate mandated by Moore's law. (Besides the scalability of cache coherence protocols, *Dennard scaling* is among the frequently quoted reasons as to why modern many-core CPUs do not have the 128 cores that would otherwise be technically possible by now – see also Muramatsu et al. (2004) and Hardavellas et al. (2011)) As a result compute performance improvements cannot be based on the expectation of increasing clock frequencies and therefore mandate changes in the hardware and software architectures. (b) Modern systems can offer much *higher levels of parallelism*, yet scalability and the effective use of parallelism are limited by the programming models as well as by amount and type of data transfers. (c) *Access gap* and Memory Wall storage (DRAM, Flash, HDD) is getting larger and cheaper; however access latencies decrease at much lower rates. This trend also contributes to slow data transfers and to blocking processing at the CPU. (d) Modern data sets are large in volume (machine data, scientific data, text) and are growing fast (Szalay and Gray 2006). (e) Modern workloads (hybrid/HTAP or analytics-based such as OLAP or ML) tend to have low data locality and incur large scans (sometimes iterative) that result in massive data transfers.

In essence, due to system architectures and processing principles, current workloads require transferring growing volumes of large data through the virtual memory hierarchy, from the physical storage location to the

processing elements, which limits performance and scalability and worsens resource and energy efficiency.

Nowadays, three important technological developments open an opportunity to counter these drawbacks. Firstly, hardware manufactures are able to *fabricate combinations of storage and compute elements at reasonable costs* and package them within the same device. Secondly, the fact that this trend covers virtually all levels of the memory hierarchy: (a) CPU and caches, (b) memory and compute, (c) storage and compute, (d) accelerators – specialized CPUs and storage, and eventually (e) network and compute. Thirdly, as magnetic/mechanical storage is being replaced with semiconductor nonvolatile technologies (Flash, Non-Volatile Memories– NVM), another key trend emerges: the device internal bandwidth, parallelism, and access latencies are significantly better than the external ones (device-to-host). This is due to various reasons: interfaces, interconnect, physical design, and architectures.

Active Storage is a concept that targets the execution data processing operations (fully or partially) *in situ*: within the compute elements on the respective level of the storage hierarchy, close to where data is physically stored and transfer the results back, without moving the raw data. The underlying assumptions are: (a) the result size is much smaller than the raw data, hence less frequent and smaller-sized data transfers; or (b) the *in situ* computation is faster and more efficient than on the host, thus higher performance and scalability or better efficiency. Related concepts are *in situ processing*, *In-Storage Processing*, *smart storage*, and *Near-Data Processing* (Balasubramonian et al. 2014). The *Active Storage* paradigms have profound impact on multiple aspects:

1. *Interfaces*: hardware and software interfaces need to be extended, and new abstractions need to be introduced. This includes device and storage interfaces and operating systems and I/O abstractions: operations and conditions, records/objects vs. blocks, atomic primitives, and transactional support.

2. *Heterogeneity* in terms of storage and computer hardware interfaces is to be addressed.
3. *Toolchain*: extensive tool support is necessary to utilize Active Storage: compilers, hardware generators, debugging and monitoring tools, and advisors.
4. *Placement* of data and computation across the hierarchy is crucial to efficiency.
5. *Workload adaptivity* is a major goal as static assignments lower the placement and collocation effects.

These challenges already attract research focus, as todays accelerators exhibit Active Storage alike characteristics in a simplistic manner, i.e., GPUs and FPGAs are defined by a considerably higher level of internal parallelism and bandwidth in contrast to their connection to the host system. Specialized computation already uses hardware programmable with high-level synthesis toolchains like TaPaSCo (Korinth et al. 2015) and co-location with storage elements and often necessitate for shared virtual memory. Classical research questions, e.g., about a dynamic workload distribution, data dependence, and flexible data placement are approached by Fan et al. (2016), Hsieh et al. (2016), and Chen and Chen (2012), respectively. The significant potential arising with Near-Data Processing is investigated under perfect conditions by Kotra et al. (2017) stating performance boosts of about 75%.

Key Research Findings

Storage

The concept of *Active Storage* is not new. Historically it is deeply rooted in the concept of *database machines* (DeWitt and Gray 1992; Boral and DeWitt 1983) developed in the 1970s and 1980s. Boral and DeWitt (1983) discusses approaches such as processor-per-track or processor-per-head as an early attempt to combine storage and simple computing elements to accelerate data processing. Existing I/O bandwidth and parallelism are claimed to be the limiting factor to justify parallel DBMS. While this conclusion is not surprising given the characteristics of magnetic/mechanical storage

combined with Amdahl's balanced systems law, it is revised with modern technologies. Modern semiconductor storage technologies (NVM, Flash) are offering high raw bandwidth and levels of parallelism. Boral and DeWitt (1983) also raises the issue of temporal locality in database applications, which has been questioned back then and is considered to be low in modern workloads, causing unnecessary data transfers. Near-Data Processing and Active Storage present an opportunity to address it.

The concept of *Active Disk* emerged toward the end of the 1990s and early 2000s. It is most prominently represented by systems such as Active Disk (Acharya et al. 1998), IDISK (Keeton et al. 1998), and Active Storage/Disk (Riedel et al. 1998). While database machines attempted to execute fixed primitive access operations, *Active Disk* targets executing application-specific code on the drive. Active Storage/Disk (Riedel et al. 1998) relies on processor-per-disk architecture. It yields significant performance benefits for I/O-bound scans in terms of bandwidth, parallelism, and reduction of data transfers. IDISK (Keeton et al. 1998) assumed a higher complexity of data processing operations compared to Riedel et al. (1998) and targeted mainly analytical workloads and business intelligence and DSS systems. Active Disk (Acharya et al. 1998) targets an architecture based on on-device processors and pushdown of custom data processing operations. Acharya et al. (1998) focusses on programming models and explores a streaming programming model, expressing data-intensive operations as so-called disklets, which are pushed down and executed on the disk processor.

An extension of the above ideas (Sivathanu et al. 2005) investigates executing operations on the RAID controller. Yet, classical RAID technologies rely on general-purpose CPUs that operate well with slow mechanical HDDs, are easily overloaded, and turn into a bottleneck with modern storage technologies (Petrov et al. 2010).

Although in the Active Disk, concept increases the scope and applicability, it is equally impacted by bandwidth limitations and high manufacturing costs. Nowadays two

trends have important impact. On the one hand, semiconductor storage technologies (NVM, Flash) offer significantly higher bandwidths, lower latencies, and levels of parallelism. On the other hand, hardware vendors are able to fabricate economically combinations of storage and compute units and package them on storage devices. Both combined the result in new generation of Active Storage devices.

Smart SSDs (Do et al. 2013) or multi-stream SSDs aim to achieve better data processing performance by utilizing on device resources and pushing down data processing operations close to the data. Programming models such as *SSDlets* are being proposed. One trend is *In-Storage Processing* (Jo et al. 2016; Kim et al. 2016) that presents significant performance increase on embedded CPUs for standard DBMS operators. Combinations of storage and GPGPUs demonstrate an increase of up to 40x (Cho et al. 2013a). IBEX (Woods et al. 2013, 2014) is a system demonstrating operator pushdown on FPGA-based storage.

Do et al. (2013) is one of the first works to explore offloading parts of data processing on Smart SSDs, indicating potential of significant performance improvements (up to 2.7x) and energy savings (up to 3x). Do et al. (2013) defines a new session-based communication protocol (DBMS-SmartSSD) comprising three operations: OPEN, CLOSE, and GET. In addition they define a set of APIs for on-device functionality: Command API, Thread API, Data API, and Memory API. It does not only enable pushdown but also workload-dependent, cooperative processing. In addition, Do et al. Do et al. (2013) identify two research questions: (i) How can *Active Storage* handle the problem of on-device processing at the presence of a more recent version of the data in the buffer? (ii) What is the efficiency of operation pushdown at the presence of large main memories? The latter becomes obvious in the context of large data sets (Big Data) and computationally intensive operations.

Similarly, Seshadri et al. (2014) propose and describe a user-programmable SSD called Willow, which allows the users to augment the storage device with the application-specific logic.

In order to provide the new functionality of the SSD for a certain application, three subsystems must be appropriately modified to support a new set of RPC commands: the application, the kernel driver, and the operating system running on each storage processing unit inside the Flash SSD.

The initial ideas of Do et al. (2013) have been recently extended in Kim et al. (2016), Jo et al. (2016), and Samsung (2015). Kim et al. (2016) demonstrate between 5x and 47x performance improvement for scans and joins. Jo et al. (2016) describe a similar approach for In-Storage Computing based on the Samsung PM1725 SSD with ISC option (Samsung 2015) integrated in MariaDB. Other approaches (Cho et al. 2013b; Tiwari et al. 2013). Tiwari et al. (2013) stress the importance of in situ processing.

Woods et al. (2014, 2013) demonstrate with Ibex an intelligent storage engine for commodity-relational databases. By off-loading complex queries operators, they tackle the bandwidth bottlenecks arising when moving large amounts of data from storage to processing nodes. In addition, the energy consumption is reduced due to the usage of FPGAs rather than general-purpose processors. Ibex supports aggregation (GROUP BY), projection, and selection. Najafi et al. (2013) and Sadoghi et al. (2012) explore approaches for flexible query processing on FPGAs.

JAFAR is an *Active Storage* approach for column stores by Xi et al. (2015) and Babarinsa and Idreos (2015). JAFAR is based on MonetDB and aims at reducing data transfers, hence pushing size reducing DB operators such as selections; joins are not considered. Xi et al. (2015) stress the importance of on-chip accelerators but do not consider *Active Storage* and accelerators for complex computations in situ.

Memory: Processing-In-Memory (PIM)

Manufacturing costs of DRAM decrease, and memory volume increases steadily, while access latencies improve at a significantly lower rate yielding the so-called Memory Wall (Wulf and McKee 1995). On the one hand, technologies such as Hybrid Memory Cube (HMC) attempt to address this issue by locating processing units

close to memory and by utilizing novel interfaces alike. On the other hand, new types of memory are introduced, characterized by an even higher density and therefore larger volumes, shorter latencies, and higher bandwidth and internal parallelism, as well as non-volatile persistence behavior.

Balasubramonian (2016) discusses in his article the features that can be meaningfully added to memory devices. Not only do these features execute parts of an application, but they may also take care of auxiliary operations that maintain high efficiency, reliability, and security. Research combining memory technologies with the Active Storage concept in general, often referred to as Processing-In-Memory (PIM), is very versatile. In the late 1990 (Patterson et al. 1997), proposed IRAM as a first attempt to address the Memory Wall, by unifying processing logic and DRAM, starting with general research question of the computer science like communication, interfaces, cache coherence, or address schemes. Hall et al. (1999) purpose combining their Data-IntensiVe Architecture (DIVA) PIM memories with external host processors and defining a PIM-to-PIM interconnect; Vermij et al. (2017) present an extension to the CPU architecture to enable NDP capabilities close to the main memory by introducing a new component attached to the system bus responsible for the communication; Boroumand et al. (2017) propose a new hardware cache coherence mechanism designed specifically for PIM; Picorel et al. (2017) show that the historically important flexibility to map any virtual page to any page frame is unnecessary regarding NDP and introduce Distributed Inverted Page Table (DIPTA) as an alternative near-memory structure.

Studying the upcomming new interface HMC, Azarkhish et al. (2017) analyzed its support for NDP in a modular and flexible fashion. The authors propose a fully backward compatible extension to the standard HMC called smart memory cube and design a high-bandwidth, low-latency, and AXI(4)-compatible logic base interconnect, featuring a novel address scrambling mechanism for the reduction in

vault/bank conflicts. A completely different approach to tackle Active Storage in today's memory is presented in Gao et al. (2016b). It introduces DRAF, an architecture for bit-level reconfigurable logic that uses DRAM subarrays to implement dense lookup tables because FPGAs introduce significant area and power overheads, making it difficult to use them in datacenter servers. Leaving the existing sequential programming models in touch by extending the instruction set architecture, Ahn et al. (2015) proposes new PIM-enabled instructions. Firstly, the proposed instruction set is interoperable with existing programming models, cache coherence protocols, and virtual memory mechanisms. Secondly, the instructions can be executed either in-memory or on the processors depending on the data locality. A conceptual near-memory acceleration architecture is presented by Kim et al. (2017b) claiming the need for adopting a high-level synthesis approach. In Lim and Park (2017), kernel operations that can greatly improve with PIM are analyzed resulting in the necessity of three categories of processing engines for NDP logic – in-order core, a coarse-grain reconfigurable processor (CGRA), and dedicated hardware.

Proposing Caribou, an intelligent distributed storage layer, István et al. (2017) target NDP on DRAM/NVRAM storage over the network through a simple key-value store interface. Utilizing FPGAs, each storage node provides high-bandwidth NDP capabilities and fault tolerance through replication by Zookeeper's atomic broadcasts.

The application of the Active Storage concept on memories besides data management is often based on analytical scenarios or neural networks but comprises a variety of different approaches. Gao et al. (2016a) develop hardware and software for an NDP architecture for in-memory analytic frameworks, including MapReduce, graph processing, and deep neural networks. One year later, Gao et al. (2017) presents the hardware architecture and software scheduling and partitioning techniques for TETRIS, a scalable neural network accelerator using 3D memory. For a similar use case, (Chi et al. 2016) proposes

PRIME, providing microarchitecture and circuit designs for a ReRAM-based PIM architecture enabling morphable functions with insignificant area overhead. A compiler-based allocation strategy approach for PIM architectures is proposed by Memoultion Wang et al. (2017). Focusing on convolutional neural networks, it offers thread-level parallelism that can fully exploit the computational power-embedded processors. Another hardware/software co-design for data analytics is presented by the Mondrian Data Engine (Drummond et al. 2017). It focuses on sequential access patterns to enable simple hardware that access memory in streams. A standardization of NDP architecture, in order for PIM stacks to be used for different GPU architectures is proposed by Kim et al. (2017a). Their approach intend to allow data to be spread across multiple memory stacks as is the norm in high-performance systems.

Active Network

Having only the slight variation that data is not persisted at any time but rather streamed through, active networks are another very widespread application of the Active Storage concept. Powerful processing elements near the network adapters or often integrated to the network controller itself as a System-on-Chip (SoC) is not solely responsible for the conventional protocol interpretation anymore but also take over further tasks like security verifications and scheduling of in-transit services and data processing or simply improving the network performance.

Tennenhouse and Wetherall (1996) first introduced the term Active Network as an approach for performing sophisticated computation within the network. By injecting customized program features into the nodes of the network, it is possible to execute these at each traversed network router/switch. Continuing the research of Tennenhouse and Wetherall (1996) and Sykora and Koutny (2010) present an Active Network node called Smart Active Node (SAN). Thereby, they focus on its ability to translate data flow transparently between IP network and active network to further improve performance of IP applications.

Often Active Network is also referred as software-defined network (SDN) and comprises

already an advanced state of research. Especially the area around security comprises progressive research in authentication and authorization, access control, threats, and DoS attacks as summarized by Ahmad et al. (2015). But also the utilization of RDMA-capable network became a trend since the demand on higher bandwidth arose with the introduction of dedicated GPUs in the computation. Ren et al. (2017) propose iRDMA, an RDMA-based parameter server architecture optimized for high-performance network environment supporting both GPU- and CPU-based training.

Definitions

Adaptive Windowing is a technique used for the online analysis of data streams to manage changes in the distribution of the data. It uses the standard idea of sliding window over the data, but, unlike other approaches, the size of the window is not fixed and set a priori but changed dynamically as a function of the data. The window is maintained at all times to the maximum length consistent with the assumption that there is no change in the data contained in it.

Context

Many modern sources of data are best viewed as data streams: a potentially infinite sequence

of data items that arrive one at a time, usually at high and uncontrollable speed. One wants to perform various analysis tasks on the stream in an online, rather than batch, fashion. Among these tasks, many consist of building models such as creating a predictor, forming clusters, or discovering frequent patterns. The source of data may evolve over time, that is, its statistical properties may vary, and often one is interested in keeping the model accurate with respect to the current distribution of the data, rather than that of the past data.

The ability of model-building methods to handle evolving data streams is one of the distinctive concerns of data stream mining, compared to batch data mining (Gama et al. 2014; Ditzler et al. 2015; Bifet et al. 2018). Most of the approaches to this problem in the literature fall into one of the following three patterns or a combination thereof.

One, the algorithm keeps a sliding window over the stream that stores a certain quantity of the most recently seen items. The algorithm then is in charge of keeping the model accurate with respect to the items in the window. *Sliding* means that every newly arrived item is added to the front of the window and that the oldest elements are dropped from the tail of the window. Dropping policies may vary. To keep a window of a constant size (denoted W hereafter), one stores the first W elements and then drops exactly one element for each one that is added.

Two, each item seen so far is associated with a weight that changes over time. The model-building algorithm takes into account the weight of each element in maintaining its model, so that elements with higher weight influence more the model behavior. One can, for example, fix a constant $\lambda < 1$ called the *decay factor* and establish that the importance of every item gets decreased (multiplied) by λ at each time step; this implies that the importance of the item that arrived t time steps ago is λ^t its initial one, that is, weights decrease exponentially fast. This policy is the basis of the EWMA (Exponentially Weighted Moving Average) estimator for the average of some statistic of the stream.

Three, the model builder monitors the stream with a *change detection* algorithm that raises a

flag when it finds evidence that the distribution of the stream items has changed. When this happens, the model builder revises the current model or discards the model and builds a new one with fresh data. Usually, change detection algorithms monitor one statistic or a small number of statistics of the stream, so they will not detect every possible kind of change, which is in general computationally unfeasible. Two easy-to-implement change detection algorithms for streams of real values are the CUSUM (Cumulative Sum) and Page-Hinkley methods (Basseville and Nikiforov 1993; Gama et al. 2014). Roughly speaking, both methods monitor the average of the items in the stream; when the recent average differs from the historical average by some threshold related to the standard deviation, they declare change.

Methods such as EWMA, CUSUM, and Page-Hinkley store a constant amount of real values, while window-based methods require, if implemented naively, memory linear in W . On the other hand, keeping a window provides more information usable by the model builder, namely, the instances themselves.

A disadvantage of all three methods as described is that they require the user to provide parameters containing assumptions about the magnitude or frequency of changes. Fixing a window size to have size W means that the user expects the last W items to be relevant, so that there is little change within them, but that items older than W are suspect of being irrelevant. Fixing a parameter λ in the EWMA estimator to a value close to 1 indicates that change is expected to be rare or slow, while a value closer to 0 suggests that change may be frequent or abrupt. A similar assumption can be found in the choice of parameters for the CUSUM and Page-Hinkley tests.

In general, these methods face the trade-off between reaction time and variance in the data: The user would like them to react quickly to changes (which happens with, e.g., smaller values of W and λ) but also have a low number of false positives when no change occurs (which is achieved with larger values of W and λ). In the case of sliding windows, in general one wants to have larger values of W when no change occurs, because models built from more data tend to be

more accurate, but smaller values of W when the data is changing, so that the model ignores obsolete data. These trade-offs are investigated by Kuncheva and Žliobaitė (2009).

Methods

Adaptive windowing schemes use sliding windows whose size increases or decreases in response to the change observed in the data. They intend to free the user from having to guess expected rates of change in the data, which may lead to poor performance if the guess is incorrect or if the rate of change is different at different moments. Three methods are reviewed in this section, particularly the ADWIN method.

The Drift Detection Method (DDM) proposed by Gama et al. (2004) applies to the construction of two-class predictive models. It is based on the theoretical and practical observation that the empirical error of a predictive model should decrease or remain stable as the model is built with more and more data from a stationary distribution, assuming one controls overfitting. Therefore, when the empirical error instead increases, this is evidence that the distribution in the data has changed.

More precisely, let p_t denote the error rate of the predictor at time t , and $s_t = \sqrt{p_t(1-p_t)/t}$ its standard deviation. DDM stores the smallest value p_{\min} of the error rates observed up to time t , and the standard deviation s_{\min} at that point. Then at time t :

- If $p_t + s_t \geq p_{\min} + 2 \cdot s_{\min}$, DDM declares a warning. It starts storing examples in anticipation of a possible declaration of change.
- If $p_t + s_t \geq p_{\min} + 3 \cdot s_{\min}$, DDM declares a change. The current predictor is discarded and a new one is built using the stored examples. The values for p_{\min} and s_{\min} are reset as well.

This approach is generic and fast enough for the use in the streaming setting, but it has the drawback that it may be too slow in responding to changes. Indeed, since p_t is computed on the

basis of all examples since the last change, it may take many observations after the change to make p_t significantly larger than p_{\min} . Also, for slow change, the number of examples retained in memory may become large.

An evolution of this method that uses EWMA to estimate the errors is presented and thoroughly analyzed by Ross et al. (2012).

The OLIN method due to Last (2002) and Cohen et al. (2008) also adjusts dynamically the size of the sliding window used to update a predictive model, in order to adapt it to the rate of change in nonstationary data streams. OLIN uses the statistical significance of the difference between the training and the validation accuracy of the current model as an indicator of data stability. Higher stability means that the window can be enlarged to use more data to build a predictor, and lower stability implies shrinking the window to discard stale data. Although described for one specific type of predictor (“Information Networks”) in Last (2002) and Cohen et al. (2008), the technique should apply many other types.

The ADWIN (ADaptive WINdowing) algorithm is due to Bifet and Gavaldà (2007) and Bifet (2010). Its purpose is to be a self-contained module that can be used in the design of data stream algorithms (for prediction or classification, but also for other tasks) to detect and manage change in a well-specified way. In particular, it wants to resolve the trade-off between fast reaction to change and reduced false alarms without relying on the user guessing an ad hoc parameter. Intuitively, the ADWIN algorithm resolves this trade-off by checking change at many scales simultaneously or trying many sliding window sizes simultaneously. It should be used when the scale of change rate is unknown, and this is problematic enough to compensate a moderate increase in computational effort.

More precisely, ADWIN maintains a sliding window of real numbers that are derived from the data stream. For example, elements in the window could be W bits indicating whether the current predictive model was correct on the last W stream items; the window then can be used to estimate the current error rate of the predictor. In a clustering task, it could instead keep track of the

fraction of outliers or cluster quality measures, and in a frequent pattern mining task, the number of frequent patterns that appear in the window. Significant variation inside the window of any of these measures indicates distribution change in the stream. ADWIN is parameterized by a confidence parameter $\delta \in (0, 1)$ and a statistical test $T(W_0, W_1, \delta)$; here W_0 and W_1 are two windows, and T decides whether they are likely to come from the same distribution. A good test should satisfy the following criteria:

- If W_0 and W_1 were generated from the same distribution (no change), then with probability at least $1 - \delta$ the test says “no change.”
- If W_0 and W_1 were generated from two different distributions whose average differs by more than some quantity $\epsilon(W_0, W_1, \delta)$, then with probability at least $1 - \delta$ the test says “change.”

When there has been change in the average but its magnitude is less than $\epsilon(W_0, W_1, \delta)$, no claims can be made on the validity of the test’s answer. Observe that in reasonable tests, ϵ decreases as the sizes of W_0 and W_1 increase, that is, as the test sees larger samples. ADWIN applies the test to a number of partitions of its sliding window into two parts, W_0 containing the oldest elements and W_1 containing the newer ones. Whenever $T(W_0, W_1, \delta)$ returns “change”, ADWIN drops W_0 , so the sliding window becomes W_1 . In this way, at all times, the window is kept of the maximum length such that there is no proof of change within it. In times without change, the window can keep growing indefinitely (up to a maximum size, if desired).

In order to be efficient in time and memory, ADWIN represents its sliding window in a compact way, using the Exponential Histogram data structure due to Datar et al. (2002). This structure maintains a summary of a window by means of a chain of buckets. Older bits are summarized and compressed in coarser buckets with less resolution. A window of length W is stored in only $O(k \log W)$ buckets, each using a constant amount of memory words, and yet

the histogram returns an approximation of the average of the window values that is correct up to a factor of $1/k$. ADWIN does not check all partitions of its window into pairs (W_0, W_1), but only those at bucket boundaries. Therefore, it performs $O(k \log W)$ tests on the sliding window for each stream item. The standard implementation of ADWIN uses $k = 5$ and may add the rule that checks are only performed only every t number of items for efficiency – at the price of a delay of up to t time steps in detecting a change.

In Bifet and Gavaldà (2007) and Bifet (2010), a test based on the so-called Hoeffding bound is proposed, which can be rigorously proved to satisfy the conditions above for a “good test.” Based on this, rigorous guarantees on the false positive rate and false negative rate of ADWIN are proved in Bifet and Gavaldà (2007) and Bifet (2010). However, this test is quite conservative and will be slow to detect change. In practice, tests based on the normal approximation of a binomial distribution should be used, obtaining faster reaction time for a desired false positive rate.

Algorithms for mining data streams will probably store their own sliding window of examples to revise/rebuild their models. One or several instances of ADWIN can be used to inform the algorithm of the occurrence of change and the optimal window size it should use. The time and memory overhead is moderate (logarithmic in the size of the window) and often negligible compared with the cost of the main algorithm itself.

Several change detection methods for streams were evaluated by Gama et al. (2009). The conclusions were that Page-Hinkley and ADWIN were the most appropriate. Page-Hinkley exhibited a high rate of false alarms, and ADWIN used more resources, as expected.

Examples of Application

ADWIN has been applied in the design of streaming algorithms and in applications that need to deal with nonstationary streams.

At the level of algorithm design, it was used by Bifet and Gavaldà (2009) to give a more adaptive version of the well-known CVFDT algorithm for building decision trees from streams due to Hulten et al. (2001); ADWIN improves it by replacing hard-coded constants in CVFDT for the sizes of sliding windows and the duration of testing and training phases with data-adaptive conditions. A similar approach was used by Bifet et al. (2010b) for regression trees using perceptrons at the leaves. In Bifet et al. (2009a,b, 2010a, 2012), ADWIN was used in the context of ensemble classifiers to detect when a member of the ensemble is underperforming and needs to be replaced. In the context of pattern mining, ADWIN was used to detect change and maintain the appropriate sliding window size in algorithms that extract frequent graphs and frequent trees from streams of graphs and XML trees (Bifet et al. 2011b; Bifet and Gavaldà 2011). In the context of process mining, ADWIN is used by Carmona and Gavaldà (2012) to propose a mechanism that helps in detecting changes in the process, localize and characterize the change once it has occurred, and unravel process evolution.

ADWIN is a very generic, domain-independent mechanism that can be plugged into a large variety of applications. Some examples include the following:

- Bakker et al. (2011) in an application to detect stress situations in the data from wearable sensors
- Bifet et al. (2011a) in application to detect sentiment change in Twitter streaming data
- Pechenizkiy et al. (2009) as the basic detection mechanism in a system to control the stability and efficiency of industrial fuel boilers
- Talavera et al. (2015) in an application to segmentation of video streams

Future Research

A main research problem continues to be the efficient detection of change in multidimensional data. Algorithms as described above (OLIN,

DDM, and ADWIN) deal, strictly speaking, with the detection of change in a unidimensional stream of real values; it is assumed that this stream of real values, derived from the real stream, will change significantly when there is significant change in the multidimensional stream.

Several instances of these detectors can be created to monitor different parts of the data space or to monitor different summaries or projections thereof, as in, e.g., Carmona and Gavaldà (2012). However, there is no guarantee that all real changes will be detected in this way. Papapetrou et al. (2015) and Muthukrishnan et al. (2007) among others have proposed efficient schemes to directly monitor change in change in multidimensional data. However, the problem in its full generality is difficult to scale to high dimensions and arbitrary change, and research in more efficient mechanisms usable in streaming scenarios is highly desirable.

Cluster scheduling; Job scheduling; Resource management

Definitions

YARN is currently one of the most popular frameworks for scheduling jobs and managing resources in shared clusters. In this entry, we focus on the new features introduced in YARN since its initial version.

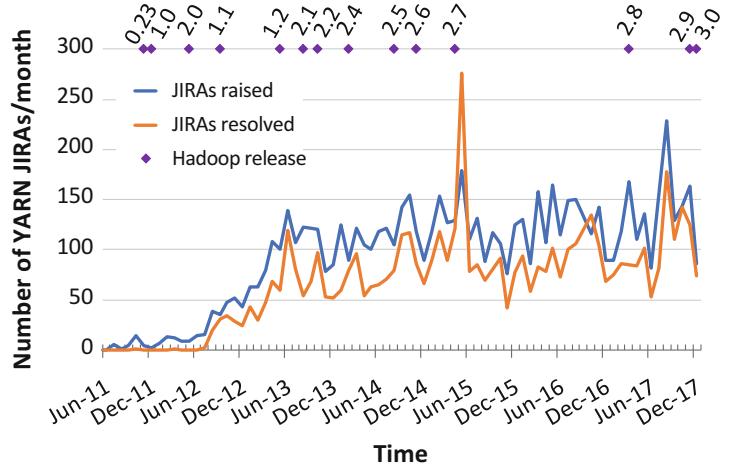

Overview

Apache Hadoop (2017), one of the most widely adopted implementations of MapReduce (Dean and Ghemawat 2004), revolutionized the way that companies perform analytics over vast amounts of data. It enables parallel data processing over clusters comprised of thousands of machines while alleviating the user from implementing complex communication patterns and fault tolerance mechanisms.

With its rise in popularity, came the realization that Hadoop's resource model for MapReduce, albeit flexible, is not suitable for every application, especially those relying on low-latency

Advancements in YARN Resource Manager, Fig. 1

Timeline of Apache Hadoop releases (on top) and number of raised and resolved tickets (JIRAs) per month on YARN

or iterative computations. This motivated decoupling the cluster resource management infrastructure from specific programming models and led to the birth of YARN (Vavilapalli et al. 2013). YARN manages cluster resources and exposes a generic interface for applications to request resources. This allows several applications, including MapReduce, to be deployed on a single cluster and share the same resource management layer.

YARN is a community-driven effort that was first introduced in Apache Hadoop in November 2011, as part of the 0.23 release. Since then, the interest of the community has continued unabated. Figure 1 shows that more than 100 tickets, i.e., JIRAs (YARN JIRA 2017), related to YARN are raised every month. A steady portion of these JIRAs are resolved, which shows the continuous community engagement. In the past year alone, 160 individuals have contributed code to YARN.

Moreover, YARN has been widely deployed across hundreds of companies for production purposes, including Yahoo! (Oath), Microsoft, Twitter, LinkedIn, Hortonworks, Cloudera, eBay, and Alibaba.

Since YARN's inception, we observe the following trends in modern clusters:

Application variety Users' interest has expanded from batch analytics applications (e.g., MapReduce) to include streaming, iterative

(e.g., machine learning), and interactive computations.

Large shared clusters Instead of using dedicated clusters for each application, diverse workloads are consolidated on clusters of thousands or even tens of thousands of machines. This consolidation avoids unnecessary data movement, allows for better resource utilization, and enables pipelines with different application classes.

High resource utilization Operating large clusters involves a significant cost of ownership. Hence, cluster operators rely on resource managers to achieve high cluster utilization and improve their return on investment.

Predictable execution Production jobs typically come with Service Level Objectives (SLOs), such as completion deadlines, which have to be met in order for the output of the jobs to be consumed by downstream services. Execution predictability is often more important than pure application performance when it comes to business-critical jobs.

This diverse set of requirements has introduced new challenges to the resource management layer. To address these new demands, YARN has evolved from a platform for batch analytics workloads to a production-ready, general-purpose resource manager that can support a wide range of applications and user requirements over large shared clusters. In the

remainder of this entry, we first give a brief overview of YARN’s architecture and dedicate the rest of the paper to the new functionality that was added to YARN these last years.

YARN Architecture

YARN follows a centralized architecture in which a single logical component, the resource manager (RM), allocates resources to jobs submitted to the cluster. The resource requests handled by the RM are intentionally generic, while specific scheduling logic required by each application is encapsulated in the application master (AM) that any framework can implement. This allows YARN to support a wide range of applications using the same RM component. YARN’s architecture is depicted in Fig. 2. Below we describe its main components. The new features, which appear in orange, are discussed in the following sections.

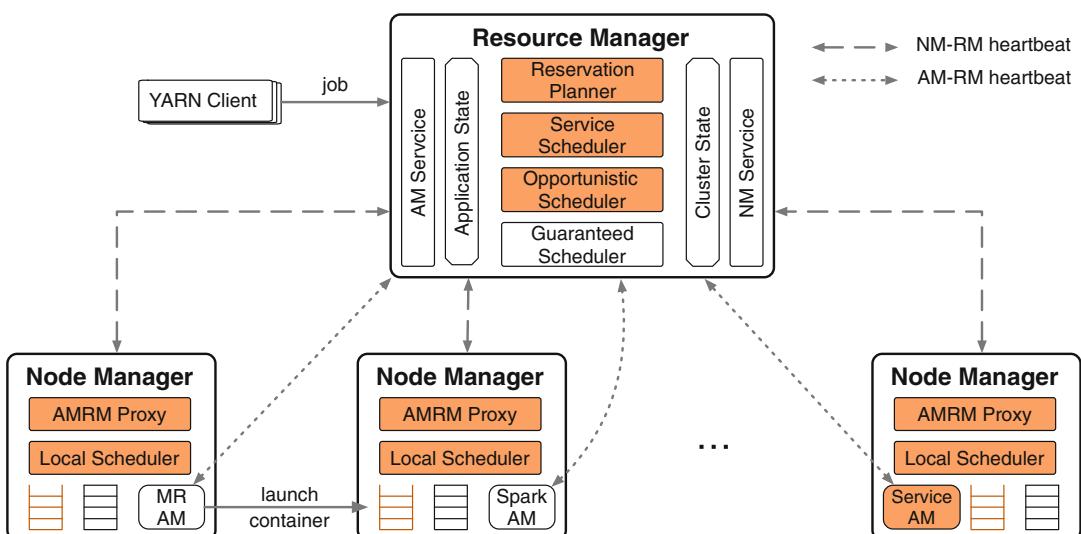

Node Manager (NM) The NM is a daemon running at each of the cluster’s worker nodes. NMs are responsible for monitoring resource availability at the host node, reporting faults,

and managing containers’ life cycle (e.g., start, monitor, pause, and kill containers).

Resource Manager (RM) The RM runs on a dedicated machine, arbitrating resources among various competing applications. Multiple RMs can be used for high availability, with one of them being the master. The NMs periodically inform the RM of their status, which is stored at the *cluster state*. The RM-NM communication is heartbeat-based for scalability. The RM also maintains the resource requests of all applications (*application state*). Given its global view of the cluster and based on application demand, resource availability, scheduling priorities, and sharing policies (e.g., fairness), the *scheduler* performs the matchmaking between application requests and machines and hands leases, called *containers*, to applications. A container is a logical resource bundle (e.g., 2 GB RAM, 1 CPU) bound to a specific node.

YARN includes two scheduler implementations, namely, the Fair and Capacity Schedulers. The former imposes fairness between applications, while the latter dedicates a share of the cluster resources to groups of users.

Jobs are submitted to the RM via the *YARN Client* protocol and go through an

Advancements in YARN Resource Manager, Fig. 2 YARN architecture and overview of new features (in orange)

admission control phase, during which security credentials are validated and various operational and administrative checks are performed.

Application Master (AM) The AM is the job orchestrator (one AM is instantiated per submitted job), managing all its life cycle aspects, including dynamically increasing and decreasing resource consumption, managing the execution flow (e.g., running reducers against the output of mappers), and handling faults. The AM can run arbitrary user code, written in any programming language. By delegating all these functions to AMs, YARN’s architecture achieves significant scalability, programming model flexibility, and improved upgrading/testing.

An AM will typically need to harness resources from multiple nodes to complete a job. To obtain containers, the AM issues resource requests to the RM via heartbeats, using the *AM Service* interface. When the scheduler assigns a resource to the AM, the RM generates a lease for that resource. The AM is then notified and presents the container lease to the NM for launching the container at that node. The NM checks the authenticity of the lease and then initiates the container execution.

In the following sections, we present the main advancements made in YARN, in particular with respect to resource utilization, scalability, support for services, and execution predictability.

Resource Utilization

In the initial versions of YARN, the RM would assign containers to a node only if there were unallocated resources on that node. This **guaranteed** type of allocation ensures that once an AM dispatches a container to a node, there will be sufficient resources for its execution to start immediately.

Despite the predictable access to resources that this design offers, it has the following shortcomings that can lead to suboptimal resource utilization:

Feedback delays The heartbeat-based AM-RM and NM-RM communications can cause idle node resources from the moment a container finishes its execution on a node to the moment an AM gets notified through the RM to launch a new container on that node.

Underutilized resources The RM assigns containers based on the allocated resources at each node, which might be significantly higher than the actually utilized ones (e.g., a 4GB container using only 2 GB of its memory).

In a typical YARN cluster, NM-RM heartbeat intervals are set to 3 s, while AM-RM intervals vary but are typically up to a few seconds. Therefore, feedback delays are more pronounced for workloads with short tasks.

Below we describe the new mechanisms that were introduced in YARN to improve cluster resource utilization. These ideas first appeared in the Mercury and Yaq systems (Karanasos et al. 2015; Rasley et al. 2016) and are part of Apache Hadoop as of version 2.9 (Opportunistic scheduling 2017; Distributed scheduling 2017).

Opportunistic containers Unlike guaranteed containers, opportunistic ones are dispatched to an NM, even if there are no available resources on that node. In such a case, the opportunistic containers will be placed in a newly introduced **NM queue** (see Fig. 2). When resources become available, an opportunistic container will be picked from the queue, and its execution will start immediately, avoiding any feedback delays.

These containers run with lower priority in YARN and will be preempted in case of resource contention for guaranteed containers to start their execution. Hence, opportunistic containers improve cluster resource utilization without impacting the execution of guaranteed containers. Moreover, whereas the original NM passively executes conflict-free commands from the RM, a modern NM uses these two-level priorities as inputs to local scheduling decisions. For instance, low-priority jobs with non-strict execution guarantees or tasks off the critical path of a DAG, are good candidates for opportunistic containers.

The AMs currently determine the execution type for each container, but the system could use automated policies instead. The AM can also request promotion of opportunistic containers to guarantee to protect them from preemption.

Hybrid scheduling Opportunistic containers can be allocated centrally by the RM or in a distributed fashion through a local scheduler that runs at each NM and leases containers on other NMs without contacting the RM. Centralized allocation allows for higher-quality placement decisions and sharing policies. Distributed allocation offers lower allocation latencies, which can be beneficial for short-lived containers. To prevent conflicts, guaranteed containers are always assigned by the RM.

To determine the least-loaded nodes for placing opportunistic containers, the RM periodically gathers information about the running and queued containers at each node and propagates this information to the local schedulers too. To account for occasional load imbalance across nodes, YARN performs dynamic rebalancing of queued containers.

Resource overcommitment Currently, opportunistic containers can be employed to avoid feedback delays. Ongoing development also focuses on overcommitting resources using opportunistic containers (Utilization-based scheduling 2017). In this scenario, opportunistic containers facilitate reclaiming overcommitted resources on demand, without affecting the performance and predictability of jobs that opt out of overcommitted resources.

Cluster Scalability

A single YARN RM can manage a few thousands of nodes. However, production analytics clusters at big cloud companies are often comprised of tens of thousands of machines, crossing YARN’s limits (Burd et al. 2017).

YARN’s scalability is constrained by the resource manager, as load increases proportionally to the number of cluster nodes and the appli-

cation demands (e.g., active containers, resource requests per second). Increasing the heartbeat intervals could improve scalability in terms of number of nodes, but would be detrimental to utilization (Vavilapalli et al. 2013) and would still pose problems as the number of applications increases.

Instead, as of Apache Hadoop 2.9 (YARN Federation 2017), a **federation-based** approach scales a single YARN cluster to tens of thousands of nodes. This approach divides the cluster into smaller units, called **subclusters**, each with its own YARN RM and NMs. The federation system negotiates with subcluster RMs to give applications the experience of a single large cluster, allowing applications to schedule their tasks to any node of the federated cluster.

The state of the federated cluster is coordinated through the **State Store**, a central component that holds information about (1) subcluster liveliness and resource availability via heartbeats sent by each subcluster RM, (2) the YARN subcluster at which each AM is being deployed, and (3) policies used to impose global cluster invariants and perform load rebalancing.

To allow jobs to seamlessly span subclusters, the federated cluster relies on the following components:

Router A federated YARN cluster is equipped with a set of routers, which hide the presence of multiple RMs from applications. Each application gets submitted to a router, which, based on a policy, determines the subcluster for the AM to be executed, gets the subcluster URL from the State Store, and redirects the application submission request to the appropriate subcluster RM.

AMRM Proxy This component runs as a service at each NM of the cluster and acts as a proxy for every AM-RM communication. Instead of directly contacting the RM, applications are forced by the system to access their local AMRM Proxy. By dynamically routing the AM-RM messages, the AMRM Proxy provides the applications with transparent access to multiple YARN RMs. Note that the AMRM Proxy is also used to implement the

local scheduler for opportunistic containers and could be used to protect the system against misbehaving AMs.

This federated design is scalable, as the number of nodes each RM is responsible for is bounded. Moreover, through appropriate policies, the majority of applications will be executed within a single subcluster; thus the number of applications that are present at each RM is also bounded. As the coordination between subclusters is minimal, the cluster's size can be scaled almost linearly by adding more subclusters. This architecture can provide tight enforcement of scheduling invariants within a subcluster, while continuous rebalancing across subclusters enforces invariants in the whole cluster.

A similar federated design has been followed to scale the underlying store (HDFS Federation 2017).

Long-Running Services

As already discussed, YARN's target applications were originally batch analytics jobs, such as MapReduce. However, a significant share of today's clusters is dedicated to workloads that include stream processing, iterative computations, data-intensive interactive jobs, and latency-sensitive online applications. Unlike batch jobs, these applications benefit from long-lived containers (from hours to months) to amortize container initialization costs, reduce scheduling load, or maintain state across computations. Here we use the term *services* for all such applications.

Given their long-running nature, these applications have additional demands, such as support for restart, in-place upgrade, monitoring, and discovery of their components. To avoid using YARN's low-level API for enabling such operations, users have so far resorted to AM libraries such as Slider (Apache Slider 2017). Unfortunately, these external libraries only partially solve the problem, e.g., due to lack of common standards for YARN to optimize resource demands

across libraries or version incompatibilities between the libraries and YARN.

To this end, the upcoming Apache Hadoop 3.1 release adds first-class support for long-running services in YARN, allowing for both traditional process-based and Docker-based containers. This service framework allows users to deploy existing services on YARN, simply by providing a JSON file with their service specifications, without having to translate those requirements into low-level resource requests at runtime.

The main component of YARN's service framework is the **container orchestrator**, which facilitates service deployment. It is an AM that, based on the service specification, configures the required requests for the RM and launches the corresponding containers. It deals with various service operations, such as starting components given specified dependencies, monitoring their health and restarting failed ones, scaling up and down component resources, upgrading components, and aggregating logs.

A **RESTful API server** is developed to allow users to manage the life cycle of services on YARN via simple commands, using framework-independent APIs. Moreover, a **DNS server** enables service discovery via standard DNS lookups and greatly simplifies service failovers.

Scheduling services Apart from the aforementioned support for service deployment and management, service owners also demand precise control of container placement to optimize the performance and resilience of their applications. For instance, containers of services are often required to be collocated (affinity) to reduce network costs or separated (anti-affinity) to minimize resource interference and correlated failures. For optimal service performance, even more powerful constraints are useful, such as complex intra- and inter-application constraints that collocate services with one another or put limits in the number of specific containers per node or rack.

When placing containers of services, cluster operators have their own, potentially conflicting, global optimization objectives. Examples include minimizing the violation of placement constraints, the resource fragmentation, the load

imbalance, or the number of machines used. Due to their long lifetimes, services can tolerate longer scheduling latencies than batch jobs, but their placement should not impact the scheduling latencies of the latter.

To enable high-quality placement of services in YARN, Apache Hadoop 3.1 introduces support for rich placement constraints (Placement constraints 2017).

Jobs with SLOs

In production analytics clusters, the majority of cluster resources is usually consumed by **production jobs**. These jobs must meet strict Service Level Objectives (SLOs), such as completion deadlines, for their results to be consumed by downstream services. At the same time, a large number of smaller **best-effort jobs** are submitted to the same clusters in an ad hoc manner for exploratory purposes. These jobs lack SLOs, but they are sensitive to completion latencies.

Resource managers typically allocate resources to jobs based on *instantaneous* enforcement of job priorities and sharing invariants. Although simpler to implement and impose, this instantaneous resource provisioning makes it challenging to meet job SLOs without sacrificing low latency for best-effort jobs.

To ensure that important production jobs will have predictable access to resources, YARN was extended with the notion of *reservations*, which provide users with the ability to reserve resources over (and ahead of) time. The ideas around reservations first appeared in Rayon (Curino et al. 2014) and are part of YARN as of Apache Hadoop 2.6.

Reservations This is a construct that determines the resource needs and temporal requirements of a job and translates the job's completion deadline into an SLO over predictable resource allocations. This is done ahead of the job's execution, aimed at ensuring a predictable and timely execution. To this end, YARN introduced a reservation definition language (RDL) to express a rich class of time-aware resource requirements, including

deadlines, malleable and gang parallelism, and inter-job dependencies.

Reservation planning and scheduling RDL provides a uniform and abstract representation of jobs' needs. Reservation requests are received ahead of a job's submission by the **reservation planner**, which performs online admission control. It accepts all jobs that can fit in the cluster agenda over time and rejects those that cannot be satisfied. Once a reservation is accepted by the planner, the scheduler is used to dynamically assign cluster resources to the corresponding job.

Periodic reservations Given that a high percentage of production jobs are recurring (e.g., hourly, daily, or monthly), YARN allows users to define periodic reservations, starting with Apache Hadoop 2.9. A key property of recurring reservations is that once a periodic job is admitted, each of its instantiations will have a predictable resource allocation. This isolates periodic production jobs from the noisiness of sharing.

Toward predictable execution The idea of recurring reservations was first exposed as part of the Morpheus system (Jyothi et al. 2016). Morpheus analyzes inter-job data dependencies and ingress/egress operations to automatically derive SLOs. It uses a resource estimator tool, which is also part of Apache Hadoop as of version 2.9, to estimate jobs' resource requirements based on historic runs. Based on the derived SLOs and resource demands, the system generates recurring reservations and submits them for planning. This guarantees that periodic production jobs will have guaranteed access to resources and thus predictable execution.

Further Improvements

In this section, we discuss some additional improvements made to YARN.

Generic resources As more heterogeneous applications with varying resource demands are deployed to YARN clusters, there is an increasing

need for finer control of resource types other than memory and CPU. Examples include disk bandwidth, network I/O, GPUs, and FPGAs.

Adding new resource types in YARN used to be cumbersome, as it required extensive code changes. The upcoming Apache Hadoop 3.1 release (Resource profiles 2017) follows a more flexible resource model, allowing users to add new resources with minimal effort. In fact, users can define their resources in a configuration file, eliminating the need for code changes or recompilation. The Dominant Resource Fairness (Ghodsi et al. 2011) scheduling algorithm at the RM has also been adapted to account for generic resource types, while *resource profiles* can be used for AMs to request containers specifying predefined resource sets. Ongoing work focuses on the isolation of resources such as disk, network, and GPUs.

Node labels Cluster operators can group nodes with similar characteristics, e.g., nodes with public IPs or nodes used for development or testing. Applications can then request containers on nodes with specific labels. This feature is supported by YARN’s Capacity Scheduler from Apache Hadoop 2.6 on (Node labels 2017) and allows at most one label to be specified per node, thus creating nonoverlapping node partitions in the cluster. The cluster administrator can specify the portion of a partition that a queue of the scheduler can access, as well as the portion of a queue’s capacity that is dedicated to a specific node partition. For instance, queue A might be restricted to access no more than 30% of the nodes with public IPs, and 40% of queue A has to be on `dev` machines.

Changing queue configuration Several companies use YARN’s Capacity Scheduler to share clusters across non-coordinating user groups. A hierarchy of queues isolates jobs from each department of the organization. Due to changes in the resource demands of each department, the queue hierarchy or the cluster condition, operators modify the amount of resources assigned to each organization’s queue and to the sub-queues used within that department.

However, queue reconfiguration has two main drawbacks: (1) setting and changing configurations is a tedious process that can only be performed by modifying XML files; (2) queue owners cannot perform any modifications to their sub-queues; the cluster admin must do it on their behalf.

To address these shortcomings, Apache Hadoop 2.9 (OrgQueue 2017) allows configurations to be stored in an in-memory database instead of XML files. It adds a RESTful API to programmatically modify the queues. This has the additional benefit that queues can be dynamically reconfigured by automated services, based on the cluster conditions or on organization-specific criteria. Queue ACLs allow queue owners to perform modifications on their part of the queue structure.

Timeline server Information about current and previous jobs submitted in the cluster is key for debugging, capacity planning, and performance tuning. Most importantly, observing historic data enables us to better understand the cluster and jobs’ behavior in aggregate to holistically improve the system’s operation.

The first incarnation of this effort was the application history server (AHS), which supported only MapReduce jobs. The AHS was superseded by the timeline server (TS), which can deal with generic YARN applications. In its first version, the TS was limited to a single writer and reader that resided at the RM. Its applicability was therefore limited to small clusters.

Apache Hadoop 2.9 includes a major redesign of TS (YARN TS v2 2017), which separates the collection (writes) from the serving (reads) of data, and performs both operations in a distributed manner. This brings several scalability and flexibility improvements.

The new TS collects metrics at various granularities, ranging from *flows* (i.e., sets of YARN applications logically grouped together) to jobs, job attempts, and containers. It also collects cluster-wide data, such as user and queue information, as well as configuration data.

The data collection is performed by collectors that run as services at the RM and at every NM.

The AM of each job publishes data to the collector of the host NM. Similarly, each container pushes data to its local NM collector, while the RM publishes data to its dedicated collector. The readers are separate instances that are dedicated to serving queries via a REST API. By default Apache HBase (Apache HBase 2017) is used as the backing storage, which is known to scale to large amounts of data and read/write operations.

Conclusion

YARN was introduced in Apache Hadoop at the end of 2011 as an effort to break the strong ties between Hadoop and MapReduce and to allow generic applications to be deployed over a common resource management fabric. Since then, YARN has evolved to a fully fledged production-ready resource manager, which has been deployed on shared clusters comprising tens of thousands of machines. It handles applications ranging from batch analytics to streaming and machine learning workloads to low-latency services while achieving high resource utilization and supporting SLOs and predictability for production workloads. YARN enjoys a vital community with hundreds of monthly contributions.

Definitions

The meaning of the word benchmark is (Andersen and Pettersen [1995](#)) *A predefined position, used as a reference point for taking measures against.* There is no clear formal definition of analytics benchmarks.

Jim Gray ([1992](#)) describes the benchmarking as follows: “This quantitative comparison starts

with the definition of a benchmark or workload. The benchmark is run on several different systems, and the performance and price of each system is measured and recorded. Performance is typically a throughput metric (work/second) and price is typically a five-year cost-of-ownership metric. Together, they give a price/performance ratio.” In short, we define that a software benchmark is a program used for comparison of software products/tools executing on a pre-configured hardware environment.

Analytics benchmarks are a type of domain-specific benchmark targeting analytics for databases, transaction processing, and big data systems. Originally, the TPC (Transaction Processing Performance Council) ([TPC 2018](#)) defined online transaction processing (OLTP) (TPC-A and TPC-B) and decision support (DS) benchmarks (TPC-D and TPC-H). The DS systems can be seen as some sort of special online analytical processing (OLAP) system with an example of the TPC-DS benchmark, which is a successor of TPC-H (Nambiar and Poess [2006](#)) and specifies many OLAP and data mining queries, which are the predecessors of the current analytics benchmarks. However, due to the many new emerging data platforms like hybrid transaction/analytical processing (HTAP) (Kemper and Neumann [2011](#); Özcan et al. [2017](#)), distributed parallel processing engines (Sakr et al. [2013](#); Hadoop [2018](#); Spark [2018](#); Flink [2018](#); Carbone et al. [2015](#), etc.), Big data management (AsterixDB [2018](#); Alsubaiee et al. [2014](#)), SQL-on-Hadoop-alike (Abadi et al. [2015](#); Hive [2018](#); Thusoo et al. [2009](#); SparkSQL [2018](#); Armbrust et al. [2015](#); Impala [2018](#); Kornacker et al. [2015](#), etc.), and analytics systems (Hu et al. [2014](#)) integrating machine learning (MLlib [2018](#); Meng et al. [2016](#); MADlib [2018](#); Hellerstein et al. [2012](#)), Deep Learning (Tensorflow [2018](#)) and more, the emerging benchmarks try to follow the trend to stress these new system features. This makes the currently standardized benchmarks (such as TPC-C, TPC-H, etc.) only partially relevant for the emerging big data management systems as they offer new features that require new analytics benchmarks.

Overview

This chapter reviews the evolution of the analytics benchmarks and their current state today (as of 2017). It starts overview of the most relevant benchmarking organizations their benchmark standards and outlines the latest benchmark development and initiatives targeting the emerging Big Data Analytics systems. Last but not least the typical benchmark components are described as well as the different goals that these benchmarks try to achieve.

Historical Background

OLTP and DSS/OLAP

In the end of the 1970s, many businesses started implementing transaction-based systems (Rockart et al. 1982), which later became known as the term online transaction processing (OLTP) systems and represent the instant interaction between the user and the data management system. This type of transaction processing systems became a key part of the companies' operational infrastructure and motivated TPC (TPC 2018) to target these systems in their first formal benchmark specification. At the same time, the decision support systems (DSS) evolved significantly and became a standard tool for the enterprises that assisted in the human decision-making (Shim et al. 2002).

In the early 1990s, a different type of system, called online analytical processing (OLAP) systems by Codd et al. (1993), was used by the enterprises to dynamically manipulate and synthesize historic information. The historic data was aggregated from the OLTP systems, and through the application of dynamic analysis, the users were able to gain important knowledge for the operational activities over longer periods of time.

Over the years, the DS systems were enhanced by the use of the OLAP systems (Shim et al. 2002). They became an essential decision-making tool for the enterprise management and a core element of the company infrastructure. With the wide adaption of multipurpose database

systems to build both an OLTP and DS system, the need for standardized database benchmarks arose. This resulted in an intense competition between database vendors to dominate the market, which leads to the need of domain-specific benchmarks to stress the database software. The use of sample workloads together with a bunch of metrics was not enough to guarantee the product capabilities in a transparent way. Another arising issue was the use of benchmarks for benchmarketing. It happens when a company uses a particular benchmark to highlight the strengths of its product and hide its weaknesses and then promotes the benchmark as a "standard," often without disclosing the details of the benchmark (Gray 1992). All of these opened the gap for standardized benchmarks that are formally specified by recognized expert organizations. Therefore, a growing number of organizations are working on defining and standardizing of benchmarks. They operate as consortia of public and private organizations and define domain-specific benchmarks, price, and performance metrics, measuring and reporting rules as well as formal validation and auditing rules.

TPC

The TPC (Transaction Processing Performance Council) (TPC 2018) is a nonprofit corporation operating as an industry consortium of vendors that define transaction processing, database, and big data system benchmarks. TPC was formed on August 10, 1988, by eight companies convinced by Omri Serlin (TPC 2018). In November 1989 was published the first standard benchmark TPC-A with 42-page specification (Gray 1992). By late 1990, there were 35 member companies. As of 2017, TPC has 21 company members and 3 associate members. There are 6 obsolete benchmarks (TPC-A, TPC-App, TPC-B, TPC-D, TPC-R, and TPC-W), 14 active benchmarks (TPC-C (Raab 1993), TPC-E (Hogan 2009), TPC-H (Pöss and Floyd 2000), TPC-DS (Poess et al. 2017; Pöss et al. 2007; Nambiar and Poess 2006), TPC-DI (Poess et al. 2014), TPC-V (Sethuraman and Taheri 2010), TPCx-HS (Nambiar 2014),

Analytics Benchmarks, Table 1 Active TPC benchmarks (TPC 2018)

Benchmark domain	Specification name
Transaction processing (OLTP)	TPC-C, TPC-E
Decision support (OLAP)	TPC-H, TPC-DS, TPC-DI
Virtualization	TPC-VMS, TPCx-V, TPCx-HCI
Big data	TPCx-HS V1, TPCx-HS V2, TPCx-BB, TPC-DS V2
IoT	TPCx-IoT
Common specifications	TPC-pricing, TPC-energy

Storage	SPEC SFS2014
Power	SPECpower ssj2008
Virtualization	SPEC VIRT SC 2013

TPCx-BB (Ghazal et al. 2013)), and 2 common specifications (pricing and energy) used across all benchmarks. Table 1 lists the active TPC benchmarks grouped by domain.

SPEC

The SPEC (Standard Performance Evaluation Corporation) (SPEC 2018) is a nonprofit corporation formed to establish, maintain, and endorse standardized benchmarks and tools to evaluate performance and energy efficiency for the newest generation of computing systems. It was founded in 1988 by a small number of workstation vendors. The SPEC organization is an umbrella organization that covers four groups (each with their own benchmark suites, rules, and dues structure): the Open Systems Group (OSG), the High-Performance Group (HPG), the Graphics and Workstation Performance Group (GWPG), and the SPEC Research Group (RG). As of 2017, there are around 19 active SPEC benchmarks listed in Table 2.

STAC

The STAC Benchmark Council (STAC 2018) consists of over 300 financial institutions and more than 50 vendor organizations whose purpose is to explore technical challenges and solutions in financial services and to develop technology benchmark standards that are useful to financial organizations. Since 2007, the council is working on benchmarks targeting fast data, big data, and big compute workloads in the finance industry. As of 2017, there are around 11 active benchmarks listed in Table 3.

Other historical benchmark organizations and consortia are The Perfect Club (Gray 1992; Hockney 1996) and the Parkbench Committee (Hockney 1996).

Big Data Technologies

In the recent years, many emerging data technologies have become popular, trying to solve the challenges posed by the new big data and Internet of things application scenarios. In a historical

overview of the trends in data management technologies, Nambiar et al. (2012) highlight the role of big data technologies and how they are currently changing the industry. One such technology is the NoSQL storage engines (Cattell 2011) which relax the ACID (atomicity, consistency, isolation, durability) guarantees but offer faster data access via distributed and fault-tolerant architecture. There are different types of NoSQL engines (key value, column, graph, and documents stores) covering different data representations.

In the meantime, many new big data technologies such as (1) Apache Hadoop (2018) with HDFS and MapReduce; (2) general parallel processing engines like Spark (2018) and Flink (2018); (3) SQL-on-Hadoop systems like Hive (2018) and Spark SQL (2018); (4) real-time stream processing engines like Storm (2018), Spark Streaming (2018) and Flink; and (5) graph engines on top of Hadoop like GraphX (2018) and Flink Gelly (2015) have emerged. All these tools enabled advanced analytical techniques from data science, machine learning, data mining, and deep learning to become common practices in many big data domains. Because of all these analytical techniques, which are currently integrated in many different ways in both traditional database and new big data management systems, it is hard to define the exact features that a successor of the DS/OLAP systems should have.

Big Data Analytics Benchmarks

Following the big data technology trends, many new benchmarks for big data analytics have emerged. Good examples for OLTP benchmarks targeting the NoSQL engines are the Yahoo! Cloud Serving Benchmark (short YCSB), developed by Yahoo, and LinkBench developed by Facebook, described in Table 4. However, most big data benchmarks stress the capabilities of Hadoop as the major big data platform, as listed in Table 5. Others like BigFUN (Pirzadeh et al. 2015) and BigBench (Ghazal et al. 2013) are technology-independent. For example, BigBench (standardized as TPCx-BB) addresses the Big Data 3V's characteristics and relies on workloads which can be implemented by different SQL-on-Hadoop systems and parallel processing engines supporting advanced analytics and machine learning libraries. Since there are no clear boundaries for the analytical capabilities of the new big data systems, it is also hard to formally specify what is an analytics benchmark.

A different type of benchmark, called benchmark suites, has become very popular. Their goal is to package a number of micro-benchmarks or representative domain workloads together and in this way enable the users to easily test the systems for the different functionalities. Some of these suites target one technology like SparkBench (Li et al. 2015; Agrawal et al. 2015), which stresses only Spark, while others like HiBench offer implementations for multiple processing engines. Table 6 lists some popular big data benchmarking suites.

A more detailed overview of the current big data benchmarks is provided in a SPEC Big Data Research Group survey by Ivanov et al. (2015) and a journal publication by Han et al. (2018).

Foundations

In the last 40 years, the OLTP and DS/OLAP systems have been the industry standard systems for data storage and management. Therefore, all popular TPC benchmarks were specified in these areas. The majority TPC benchmark specifications (Poess 2012) have the following main components:

Analytics Benchmarks, Table 4 OLTP benchmarks

Name	Benchmark description
YCSB (Cooper et al. 2010; Patil et al. 2011)	A benchmark designed to compare emerging cloud serving systems like Cassandra, HBase, MongoDB, Riak, and many more, which do not support ACID. It provides a core package of six predefined workloads A–F, which simulate a cloud OLTP application
LinkBench (Armstrong et al. 2013)	A benchmark, developed by Facebook, using synthetic social graph to emulate social graph workload on top of databases such as MySQL and MongoDB

Analytics Benchmarks, Table 5 DS/OLAP/Analytics benchmarks

Name	Benchmark description
MRBench (Kim et al. 2008)	Implementing the TPC-H benchmark queries directly in map and reduce operations
CALDA (Pavlo et al. 2009)	It consists of five tasks defined as SQL queries among which is the original MR Grep task, which is a representative for most real user MapReduce programs
AMP lab big data benchmark (AMPLab 2013)	A benchmark based on CALDA and HiBench, implemented on five SQL-on-Hadoop engines (RedShift, Hive, Stinger/Tez, Shark, and Impala)
BigBench (Ghazal et al. 2013)	An end-to-end big data benchmark that represents a data model simulating the volume, velocity, and variety characteristics of a big data system, together with a synthetic data generator for structured, semi-structured, and unstructured data, consisting of 30 queries
BigFrame (BigFrame 2013)	BigFrame is a benchmark generator offering a benchmarking-as-a-service solution for big data analytics
PRIMEBALL (Ferrarons et al. 2013)	A novel and unified benchmark specification for comparing the parallel processing frameworks in the context of big data applications hosted in the cloud. It is implementation- and technology-agnostic, using a fictional news hub called New York Times, based on a popular real-life news site
BigFUN (Pirzadeh et al. 2015)	It is based on a social network use case with synthetic semi-structured data in JSON format. The benchmark focuses exclusively on micro-operation level and consists of queries with various operations such as simple retrieves, range scans, aggregations, and joins, as well as inserts and updates
BigBench V2 (Ghazal et al. 2017)	BigBench V2 separates from TPC-DS with a simple data model, consisting only of six tables. The new data model still has the variety of structured, semi-structured, and unstructured data as the original BigBench data model. The semi-structured data (weblogs) are generated in JSON logs. New queries replace all the TPC-DS queries and preserve the initial number of 30 queries

- Preamble – Defines the benchmark domain and the high level requirements.
- Database Design – Defines the requirements and restrictions for implementing the database schema.
- Workload – Characterizes the simulated workload.
- ACID – Atomicity, consistency, isolation, and durability requirements.
- Workload scaling – Defines tools and methodology on how to scale the workloads.
- Metric/Execution rules – Defines how to execute the benchmark and how to calculate and derive the metrics.

Analytics Benchmarks, Table 6 Big data benchmark suites

Name	Benchmark description
MRBS (Sangroya et al. 2012)	A comprehensive benchmark suite for evaluating the performance of MapReduce systems in five areas: recommendations, BI (TPC-H), bioinformatics, text processing, and data mining
HiBench (Huang et al. 2010)	A comprehensive benchmark suite consisting of multiple workloads including both synthetic micro-benchmarks and real-world applications. It features several ready-to-use benchmarks from 4 categories: micro benchmarks, Web search, machine learning, and HDFS benchmarks
CloudSuite (Ferdman et al. 2012)	A benchmark suite consisting of both emerging scale-out workloads and traditional benchmarks. The goal of the benchmark suite is to analyze and identify key inefficiencies in the processors core micro-architecture and memory system organization when running todays cloud workloads
CloudRank-D (Luo et al. 2012)	A benchmark suite for evaluating the performance of cloud computing systems running big data applications. The suite consists of 13 representative data analysis tools, which are designed to address a diverse set of workload data and computation characteristics (i.e., data semantics, data models and data sizes, the ratio of the size of data input to that of data output)
BigDataBench (Wang et al. 2014)	An open-source big data benchmark suite consisting of 15 data sets (of different types) and more than 33 workloads. It is a large effort organized in China available with a toolkit that adopts different other benchmarks
SparkBench (Li et al. 2015; Agrawal et al. 2015)	SparkBench, developed by IBM, is a comprehensive Spark-specific benchmark suite that comprises of four main workload categories: machine learning, graph processing, streaming, and SQL queries.

- Benchmark driver – Defines the requirements for implementing the benchmark driver/program.
- Full disclosure report – Defines what needs to be reported and how to organize the disclosure report.
- Audit requirements – Defines the requirements for performing a successful auditing process.

The above structure was typical for the OLTP and DS/OLAP benchmarks defined by TPC, but due to the emerging hybrid OLTP/OLAP systems and big data technologies, these trends have changed (Bog 2013) adapting the new system features. For example, the database schema and ACID properties are not anymore a key requirement in the NoSQL and big data management systems

and are replaced by more general one like system under test (SUT). For example, new categories in TPCx-BB are:

- System under test – Describes the system architecture with its hardware and software components and their configuration requirements.
- Pricing – Defines the pricing of the components in the system under test including the system maintenance.
- Energy – Defines the methodology, rules, and metrics to measure the energy consumption of the system under test in the TPC benchmarks.

The above components are part of the standard TPC benchmark specifications and are not representative for the entire analytics benchmarks

spectrum. Many of the newly defined big data benchmarks are open-source programs. However, the main characteristics of a good domain-specific benchmark are still the same. Jim Gray (1992) defined four important criteria that domain-specific benchmarks must meet:

- Relevant: It must measure the peak performance and price/performance of systems when performing typical operations within that problem domain.
- Portable: It should be easy to implement the benchmark on many different systems and architectures.
- Scalable: The benchmark should apply to small and large computer systems. It should be possible to scale the benchmark up to larger systems and to parallel computer systems as computer performance and architecture evolve.
- The benchmark must be understandable/interpretable; otherwise it will lack credibility.

Similarly, Karl Huppler (2009) outlines five key characteristics that all good benchmarks have:

- Relevant – A reader of the result believes the benchmark reflects something important.
- Repeatable – There is confidence that the benchmark can be run a second time with the same result.
- Fair – All systems and/or software being compared can participate equally.
- Verifiable – There is confidence that the documented result is real.
- Economical – The test sponsors can afford to run the benchmark.

In reality, many of the new benchmarks (in Tables 4, 5 and 6) do not have clear specifications and do not follow the practices defined by Gray (1992) and Huppler (2009) but just provide a workload implementation that can be used in many scenarios. This opens the challenge that the reported benchmark results are not really compa-

rable and strictly depend on the environment in which they were obtained.

In terms of component specification, the situation looks similar. All TPC benchmarks use synthetic data generators, which allow for scalable and deterministic workload generation. However, many new benchmarks use open data sets or real workload traces like BigDataBench (Wang et al. 2014) or a mix between real data and synthetically generated data. This influences also the metrics reported by these benchmarks. They are often not clearly specified or very simplistic (like execution time) and cannot be used for an accurate comparison between different environments.

The ongoing evolution in the big data systems and the data science, machine learning, and deep learning tools and techniques will open many new challenges and questions in the design and specification of standardized analytics benchmarks. There is a growing need for new standardized big data analytics benchmarks and metrics.

Key Applications

The analytics benchmarks can be used for multiple purposes and in different environments. For example, vendors of database-related products can use them to test the features of their data products both in the process of development and after it is released, to position them in the market. The final benchmarking of a data product is usually done by an accredited organization. For example, TPC and SPEC have certified auditors that perform transparent auditing of the complete benchmarking process. The database and big data system administrators can regularly run benchmarks to ensure that the systems are properly configured and perform as expected. Similarly, system architects and application developers use benchmarks to test and compare the performance of different data storage technologies in the process of choosing the best tool for their requirements. Furthermore, benchmarks can be used for different comparisons as in the four categories defined by Jim Gray 1992:

- **To compare different software and hardware systems:** The goal is to use metric reported by the benchmark as a comparable unit for evaluating the performance of different data technologies on different hardware running the same application. This case represents classical competitive situation between hardware vendors.
 - **To compare different software on one machine:** The goal is to use the benchmark to evaluate the performance of two different software products running on the same hardware environment. This case represents classical competitive situation between software vendors.
 - **To compare different machines in a comparable family:** The objective is to compare similar hardware environments by running the same software product and application benchmark on each of them. This case represents a comparison of different generations of vendor hardware or for a case comparing of different hardware vendors.
 - **To compare different releases of a product on one machine:** The objective is to compare different releases of a software product by running benchmark experiments on the same hardware. Ideally the new releases should perform faster (based on the benchmark metric) than its predecessors. This can be also seen as performance regression tests that can assure the new release support all previous system features.

Apache Apex

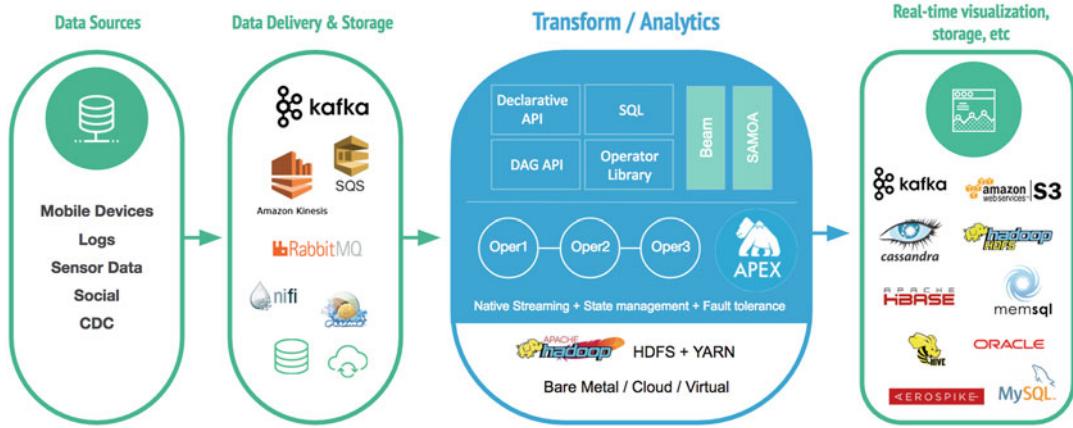

Ananth Gundabattula¹ and Thomas Weise²

¹Commonwealth Bank of Australia, Sydney, NSW, Australia

²Atrato Inc., San Francisco, CA, USA

Introduction

Apache Apex (2018; Weise et al. 2017) is a large-scale stream-first big data processing framework that can be used for low-latency, high-throughput, and fault-tolerant processing of unbounded (or bounded) datasets on clusters. Apex development started in 2012, and it became a project at the Apache Software Foundation in 2015. Apex can be used for real-time and batch processing, based

Apache Apex, Fig. 1 Apex as distributed stream processor

on a unified stateful streaming architecture, with support for event-time windowing and exactly-once processing semantics (Fig. 1).

Application Model and APIs

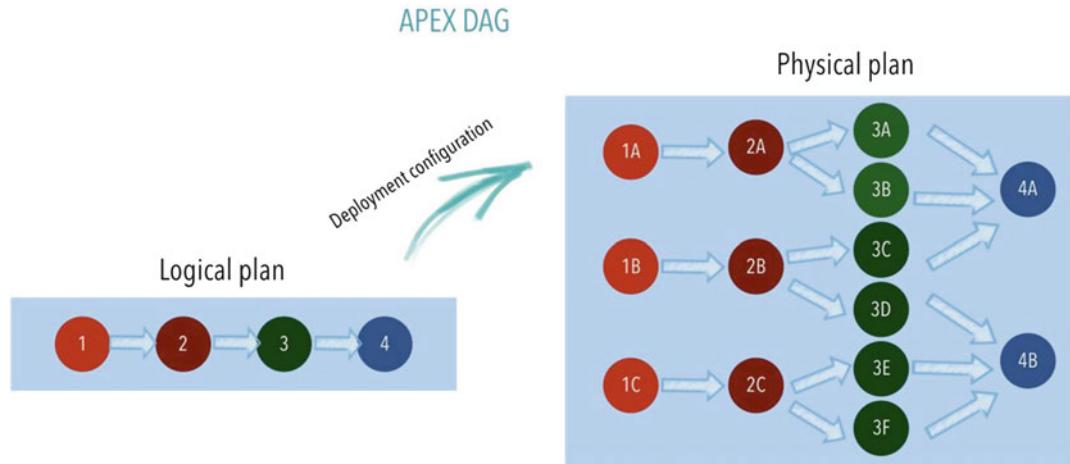

DAG: The processing logic of an Apex application is represented by a directed acyclic graph (DAG) of operators and streams. Streams are unbounded sequences of events (or tuples), and operators are the atomic functional building blocks for sources, sinks, and transformations. With the DAG, arbitrary complex processing logic can be arranged in sequence or in parallel. With an acyclic graph, the output of an operator can only be transmitted to downstream operators. For pipelines that require a loop (or iteration), a special delay operator is supported that allows the output of an operator to be passed back as input to upstream operators (often required in machine learning). The engine also defines a module interface, which can be used to define composite operators that represent a reusable DAG fragment (Fig. 2).

The user-defined DAG is referred to as the logical plan. The Apex engine will expand it into the physical plan, where operators are partitioned (for parallelism) and grouped into containers for deployment. Attributes in the logical plan can

influence these translations, such as the affinity to control which operators should be deployed into the same thread, process, or host.

Low-level, compositional API: The Apex engine defines the low-level API, which can be used to assemble a pipeline by composing operators and streams into a DAG. The API offers a high degree of flexibility and control: Individual operators are directly specified by the developer, and attributes can be used to control details such as resource constraints, affinity, stream encoding, and more. On the other hand, the API tends to be more verbose for those use cases that don't require such flexibility. That's why Apex, as part of the library, offers higher-level constructs, which are based on the DAG API.

High-level, declarative API: The Apex library provides the high-level stream API, which allows the application developer to specify the application through a declarative, fluent style API (similar to API found in Apache Spark and Apache Flink). Instead of identifying individual operators, the developer specifies sources, transformations, and sinks by chaining method calls on the stream interface. The API internally keeps track of operator(s) and streams for eventual expansion into the lower-level DAG. The stream API does not require knowledge of individual operator classes and more concise for use cases that don't require advanced constructs.

Apache Apex, Fig. 2 Apex converts a logical plan into a physical execution model by means of configuration

It is still possible to add customizations as the needs of the application evolve.

SQL: SQL is important for analytics and widely used in the big data ecosystem, with BI tools that can connect to engines such as Apache Hive, Apache Impala, Apache Drill, and others, besides the traditional database systems. SQL isn't limited to querying data; it can also be used to specify transformations. Recent efforts to bring SQL to stream processing like Apache Calcite (2018), Flink (Carbone et al. 2015a), Beam (Akidau et al. 2015), and KSQL (Confluent blog 2018) promise to target a wider audience without lower-level programming expertise, for use cases including ad hoc data exploration, ETL, and more. Apex provides a SQL API that is implemented based on Calcite. It currently covers select, insert, where clause, inner join, and scalar functions. Supported endpoints (read and write) can be file, Kafka, or any other stream defined with the DAG API.

Operators

Operators are Java classes that implement the *Operator* interface and other optional interfaces that are defined in the Apex API and recognized by the engine.

Operators have *ports* (type-safe connection points for the streams) to receive input and emit

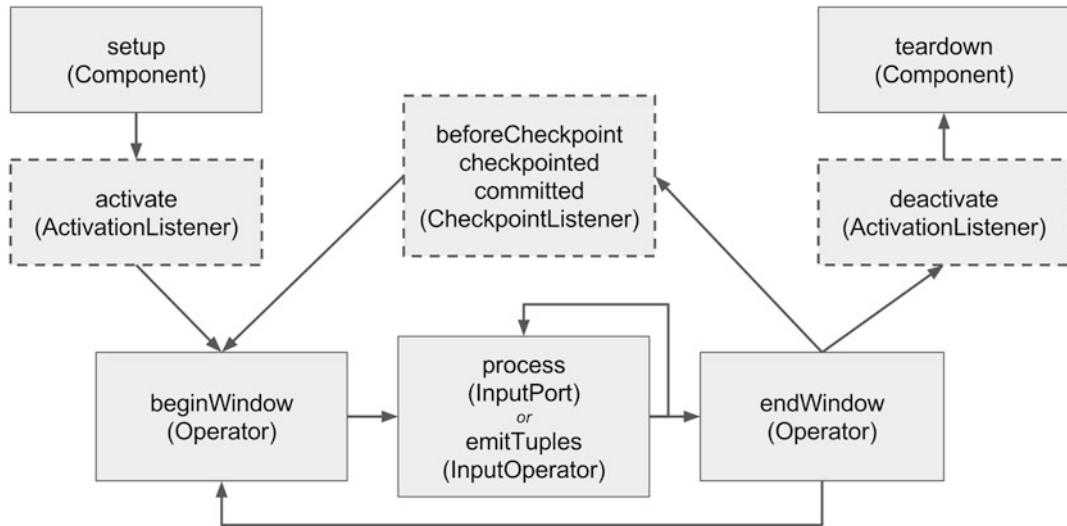

output. Each operator can have multiple ports. Operators that don't have input ports are sources, and operators that don't emit output are sinks. These operators interface with external systems. Operators that have both types of ports typically transform data.

The operator interfaces inform how the engine will interact with the operator at execution time, once it is deployed into a container (Fig. 3).

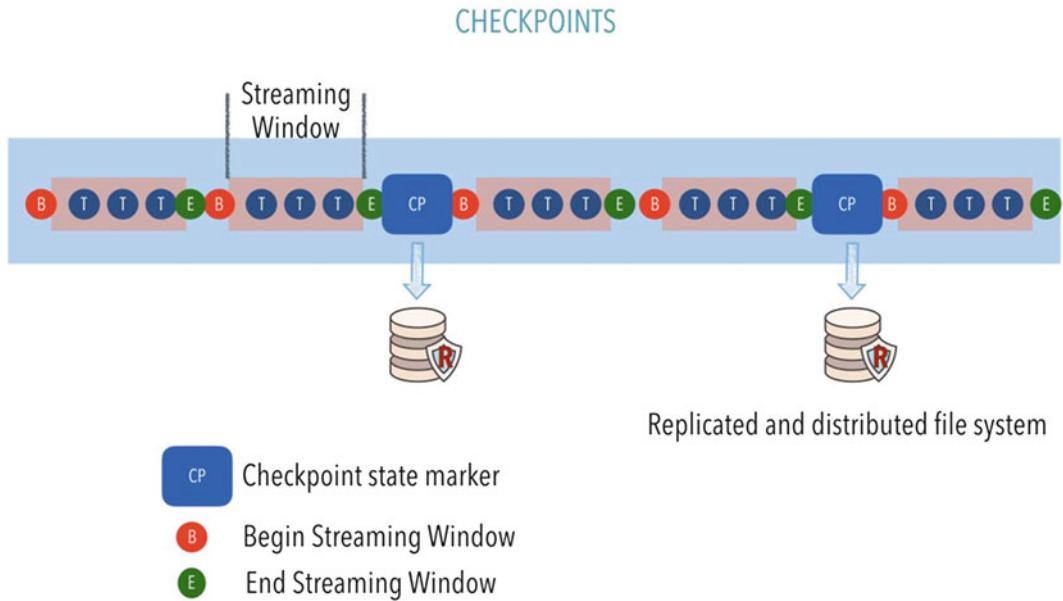

Apex has a continuous operator model; the operator, once deployed, will process data until the pipeline is terminated. The *setup* and *activate* calls can be used for initialization. From then on, data (individual events) will be processed. Periodically the engine will call *begin/endWindow* to demarcate streaming intervals (processing time). This presents an opportunity to perform work that is less suitable for every event. The operator can also implement the optional *CheckpointListener* interface to perform work at checkpoint boundaries.

Checkpointing

Checkpointing in Apex is the foundation for failure handling as well as on-demand parallelism a.k.a. dynamic partitioning. Checkpointing enables application recovery in case of failure by storing the state of the DAG at configurable units

Apache Apex, Fig. 3 Operator lifecycle and interfaces

Apache Apex, Fig. 4 Checkpoint markers injected into the tuple stream at streaming window boundaries

of processing time windows. In case of partitioning (described in the next section), checkpointing allows for resharding the operator states for existing as well as newly spawned operators for elastic scaling (Fig. 4).

Asynchronous and decentralized: Checkpointing is enabled by the framework injecting checkpoint markers into the stream at configured

intervals of ingress/arrival time. An operator instance on the arrival of this marker triggers the checkpointing mechanism. Saving of the state itself is executed asynchronously, without blocking the operator. Completed checkpoints are reported to the application master, which has a view of the entire DAG and can mark a checkpoint as “committed” when it was reported by all operators.

Checkpointing in Apex is thus an asynchronous, lightweight, and decentralized approach.

Idempotency for resumption from checkpoint: Introduction of checkpoint markers into the stream in Apex is a slight variation from Carbone et al. (2015b). The checkpoint markers are introduced at the input operator (source) and traverse the entire DAG. Upon resumption from failure, the stream needs to be replayed in the exact same sequence to enable the entire application as a reproducible state machine. Apex provides the necessary building blocks to achieve idempotency. Individual operators in the DAG ensure idempotency is maintained in their processing logic. For each stream that crosses a container/process boundary, Apex provides a buffer server like (Lin et al. 2016) that can be used by a downstream operator to start consumption from a specific position. This enables fine-grained recovery and dynamic partitioning without a full DAG reset. In case of an input operator, idempotency of replay is either backed by capabilities of the source (in cases like Kafka and files by offset tracking and sequential scan) or the input operator can record the source data for replay by using a write-ahead log (WAL) implementation that is provided by the Apex library.

Opt-in independence: Operators in Apex can choose to opt out of checkpointing cycles to avoid serialization overhead. As an example, an operator that is representing a matrix transpose operation can choose to not be part of the checkpointing process as it does not need a state to be accumulated across tuples or across streaming windows. On the other hand, an operator which is computing a cumulative sum or part of sort, join logic in SQL DAG needs the state to be handed from one streaming window to another and hence needs to be stateful. Stateless operators can be enabled either by an annotation marker on the operator implementation or declaring it in the configuration provided as input to the application launch. For stateful operators, Apex ensures that the state is serialized at checkpoint intervals. The default serialization mechanism allows the operator implementation to decide (and optimize) which fields are serialized (or skipped by marking

them transient) and also how fields are serialized through optional annotations.

Exactly-once state and exactly-once processing: Exactly-once processing is the holy grail of distributed stream processing engines. In reality though, reprocessing cannot be avoided in a distributed system, and therefore exactly-once refers to the effect on the state, which is also why it is alternatively referred to as “effectively once.” While some engines define exactly-once semantics purely from internal state persistence point of view, others aim to provide constructs for exactly-once processing in addition to state with varying degrees of implementation complexity as given in Kulkarni et al. (2015), Noghabi et al. (2017), and Jacques-Silva et al. (2016). Exactly-once state management in Apex is a distributed process by the virtue of each operator triggering its own state passivation when the checkpoint tuple is processed. While some streaming systems only focus on exactly-once semantics for internal state, the Apex library provides support for end-to-end exactly-once for many of its connectors, thereby also covering the effect of processing on the state in respective external systems. This is possible through interface contracts in the low-level API and idempotency and by utilizing capabilities that are specific to the integrated system, such as transactions, atomic renames, etc.

At-most-once and at-least-once processing semantics: It is not atypical for at-least-once processing semantics for use cases like finding a max value in a given stream, while at-most-once processing is required for use cases where recency of data processing state matters the most. At-least-once semantics is achieved by the upstream operator replaying the tuples from the checkpoint and the downstream operator not implementing any lightweight checkpoint state-based checks. For at-most-once semantics, the upstream operator needs to just stream tuples to downstream without starting from a checkpoint.

Low-level API for processing semantics: As described in the Operator section, the operator is given a chance to perform business logic-specific process at streaming window boundaries as well as checkpoint boundaries. Several operators in Apex implement incremental lightweight state

saving at window boundaries and a complete operator state at checkpointing boundaries. Utilities exist in the framework to get/set data structures that represent state using a window ID marker as input thus allowing for a lightweight state passivation. Since a checkpoint resumption can result in reprocessing multiple windows, this incremental state can come in handy to completely skip windows that are processed from a certain checkpoint. Let us consider how this approach provides for exactly-once processing semantics in systems that do not provide two-phase commit transaction support. Until the last streaming window before a crash (referred to as orphaned window hereafter), state can be passivated incrementally at streaming window boundaries. For the orphaned window, for which neither a lightweight state has been persisted nor a full checkpoint cycle is complete, custom business logic can be invoked using a “check/read and then process” pattern. This “check and process along with a business helper function” is only executed for the orphaned window reprocessing. Processing resumes a normal pattern beyond this orphaned window processing. Thus a combination of lightweight checkpointing at window boundaries, full checkpointing at checkpoint boundaries, and the check and process pattern can achieve exactly-once processing semantics in Apex for this class of systems.

Managed state and spillable data structures: State saving at checkpointing boundary may be sub-optimal when the state is really large (Del Monte 2017). Incremental state persistence at smaller intervals and/or spillable state can be effective patterns to mitigate this (To et al. 2017; Fernandez et al. 2013; Akidau et al. 2013; Sebepou and Magoutis 2011). Apex supports both. To handle very large state, the Apex library provides for spillable data structures similar to Carbone et al. (2017). Instead of a full copy local store like RocksDB, spillable data structures in Apex are block structured and by default backed by the distributed file system (DFS), allowing for delta writes and on-demand load (from DFS) when operators are restored.

Flexibility, ease of use, and efficiency have been core design principles for Apex, and checkpointing is no exception. When desired, the user

has complete control to define the data structures that represent the operator state. For recovery, Apex will only reset to checkpoint the part of the DAG that is actually affected by a failure. These are examples of features that set Apex apart from other streaming frameworks like Zaharia et al. (2012) and Carbone et al. (2015b). With flexibility at the lower level, higher-level abstractions are provided as part of the library that optimize for specific use cases.

High Availability

High availability in Apex is achieved by extending two primary constructs. Leverage YARN as cluster manager to handle process and node failure scenarios and use the distributed file system to recover the state. An Apex application is associated with an application ID and is either given a new ID or resume from a previous application identity as identified by an ID given as a startup parameter. Apex being a YARN native application utilizes the YARN Resource manager to allocate the application master (AM) at the time of launch. AM either instantiates a new physical deployment plan using the logical plan or reuses an existing physical plan if an existing application ID is passed at startup. As the DAG is physicalized and starts executing, each of the JVM operators sends heartbeats to the AM using a separate thread. Subsequent to this, there are many scenarios that can result in a fault scenario and recovery options possible as given in Nasir (2016).

Worker container failure: In case of a container JVM crashing or stalling for a long time due to a GC pause, AM detects the absence of the heartbeat and initiates a kill (if applicable) and redeploy sequence. AM would negotiate with YARN for the replacement container and request to kill the old container (if it was stalled). The new instance would then resume from a checkpointed state. It may be noted that the entire sub-DAG downstream to the failed operator will be redeployed as well to ensure the semantics of processing are upheld especially for cases when the

downstream operators are implementing exactly-once semantics.

AM failure: During an AM crash, the individual worker containers continue processing the tuples albeit without any process taking care of the recovery and monitoring. In the meantime, YARN would detect that AM container has gone down and redeploy a new instance of it and pass the previous application ID as part of the restart process. This new instance would then resume from its checkpointed state. The checkpointed state of AM is more related to the execution state of the DAG. This new AM container would update its metadata in the distributed file system representing the application ID which in turn would be picked up by the worker containers to reestablish their heartbeat cycles.

Machine failures: In the event of a physical node failure, YARN resource manager (RM) would be notified of the node manager (NM) death. This would result in RM deploying all containers currently running on that NM. It is possible that there are multiple containers of the application on the failed host, and all of these would be migrated to new host(s) using the process described before.

Resource Management

Apex is a YARN native application that follows the YARN principles of resource request and grant model. The application master upon launch generates a physical execution plan from the DAG logical representation. The application master itself is a YARN container. The application master then spawns the operator instances by negotiating operator containers from the YARN resource manager, taking into account

the memory and compute resource settings in the DAG (Fig. 5).

Deployment models: The Apex operator deployment model allows for four different patterns:

1. Thread – Operator logic is invoked by a single thread in the same JVM.
2. Container – Operators coexist in the same JVM.
3. Host – Operators are available on the same node.
4. Default – Highest cost in terms of serialization and IPC.

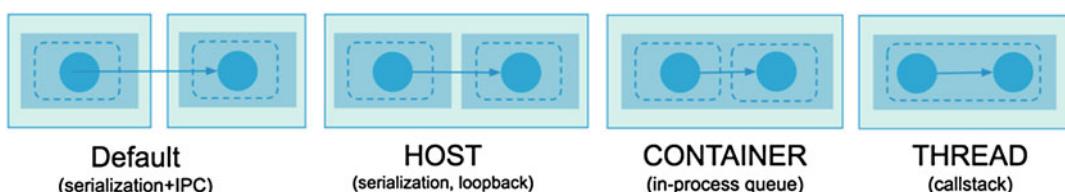

Affinity or anti-affinity patterns further allow for customized location preferences while deploying the operators by the application master. Affinity allows for multiple operators to be located on the same host or share the same container or thread.

Partitioning/Scaling

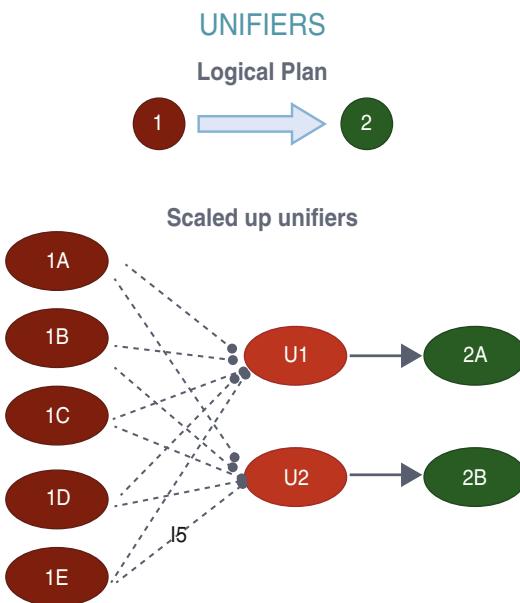

Operator parallelism a.k.a partitioning helps in dealing with latency and throughput trade-off aspects of a streaming application design. Apex enables developers to concentrate on the business logic and enable a configuration-based approach to scale a logical implementation to a scalable physical deployment model. This approach is referred to as partitioning and is enabled by configuring a partitioner for an operator.

Partitioners

A partitioner implementation can be specified how to partition the operator instances. While use case like specifying a fixed number of partitions

Apache Apex, Fig. 5 Operator deployment models

Apache Apex, Fig. 6 Unifiers allow for varying parallelism between operators. U1 and U2 unifiers are automatically injected into the DAG at deployment time

at startup can be met by using one of the partitioners available as part of the framework, Apex allows for custom implementation as well.

Such custom implementations can cater to many use cases like deciding partitions on the input source system characteristics. As an example, the Kafka partitioners as part of the Apex library have the capability to scale to as many Kafka partitions that each of the configured Kafka topics have or alternatively support mapping multiple Kafka partitions to one Apex operator partition. A partitioner can be stateful; it can re-shard the state of the old partitions (Fig. 6).

Unifiers

While partitioning allows for scalability of the operator business logic, it invariably results in an impedance mismatch if the downstream operator is not at the right scaling factor. Apex allows parallelism to vary between operators. In such cases, unifiers are automatically injected into the physical plan and define how the upstream results are shuffled to the new parallelism level. The user can customize the unifier implementation, which

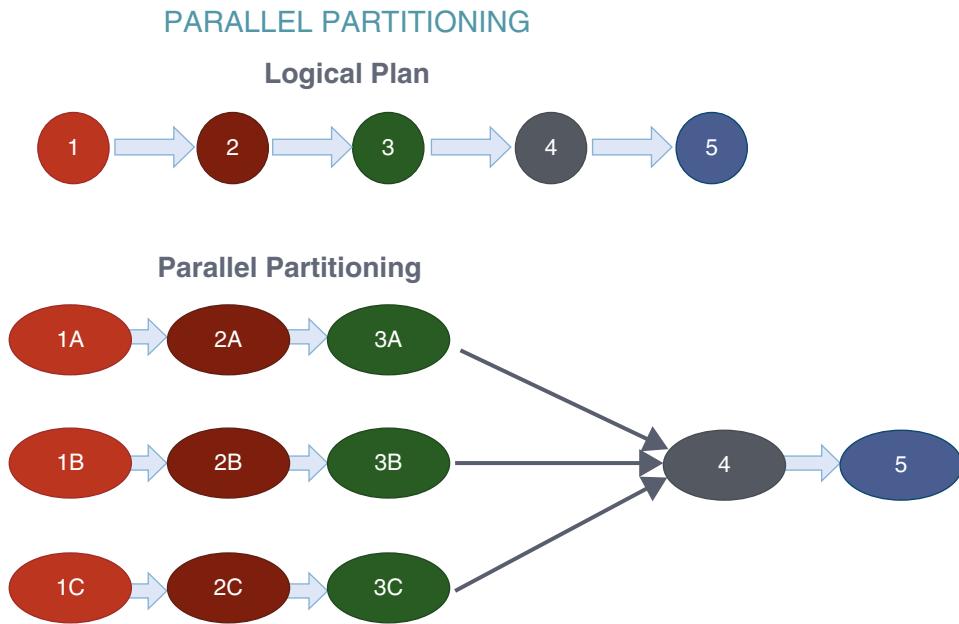

typically depends on the operator logic. A unifier is an operator without input port that is set on the output port of the partitioned operator. Cascading unifier patterns can also be implemented wherein the partitioned operator output can itself be shuffled in stages before streaming the merged result to the downstream operator. For a reduce operation, this can be used to overcome resource limits (network, CPU, etc.) for a latency trade-off (Fig. 7).

Parallel Partitioning

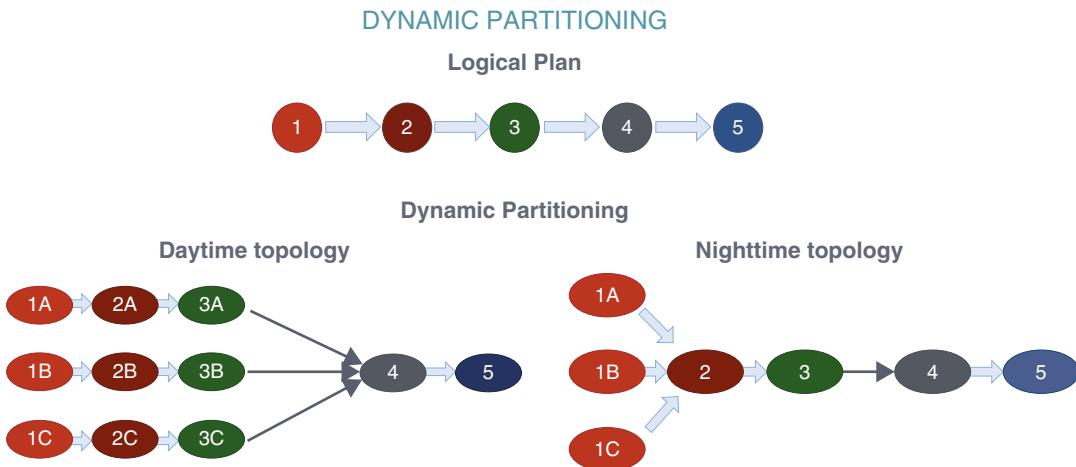

While partitioners and unifiers allow for independent scaling of each operator of an application, there will be use cases where downstream operators can align with the upstream operators' level of parallelism and avoid a unifier, thus further decreasing the overall latencies due to decreased network hops (in some systems, this also referred to as chaining). This is enabled via a configuration parameter set on the downstream operator, and this parallel partitioning can be configured for as many downstream operators as the application design mandates it to be (Fig. 8).

Dynamic Partitioning

Load variation is a common pattern across many streaming systems, and some of these engines provide for dynamic scaling as given in Floratou et al. (2017) and Bertolucci et al. (2015). Also the advent of cloud computing where cost is based on resource consumption models as given in Hummer et al. (2013) and Sattler and Beier (2013) makes compelling case for the need to dynamically adjust resources based on context. Static partitioning may not be sufficient to achieve latency SLAs or optimize resource consumption. Apex allows partitions to be scaled or contracted dynamically at checkpointing boundaries. A partitioner implementation can use the operational metrics of the physical operator instances to decide on the optimal scaling configuration. Unlike other streaming engines like Spark which need stand-alone shuffle service, Apex dynamic partitioning can be aligned with the application patterns.

Apache Apex, Fig. 7 Parallel partitioning can avoid shuffling overheads when it is not necessary

Apache Apex, Fig. 8 Dynamic partitioning allows for scale-up and scale-down strategies at runtime. Example above has different topologies at daytime and nighttime allowing for efficient use of hardware

Integration Using Apex Library

Apex enables a faster time to market model by shipping many connectors to external systems that can act as a source or a sink or both. The Apex library is also referred to as Malhar. Some of the common integrations include JDBC driver-enabled databases like Oracle, MySQL, and Postgres; replayable sources like Kafka and files;

NOSQL databases like Cassandra and HBase; and JMS-enabled systems like MQ besides many others. The library implementations provide value add by not only implementing read/write patterns to these systems but also aiming to provide exactly-once processing.

File systems: Apex operators bring in lot more to the maturity of the implementation by enabling enterprise patterns like polling directories for new

file arrivals, offset tracking backed sequential scanning approach, resumption from checkpoints in case of failures, handling of varied formats of the file contents, and compression formats while writing contents and even splitting very large files into blocks while reading to enable efficient partitioning strategies.

Kafka: Kafka integration is one of the battle-tested integrations of Apex. Kafka operators allow for flexible mapping of operators wherein the mapping configuration can map “m” Kafka partitions across “n” Apex operators. It may be noted that m can represent partitions that may span across multiple Kafka clusters and multiple Kafka topics spread across these Kafka topics. Apex Kafka operators also support exactly-once semantics for Kafka versions prior to 0.11 version thus taking the burden of a transaction to Apex processing layer as opposed to relying on Kafka. The integration in Apex thus can be considered far richer as compared to the other systems.

Non-replayable sources like JMS: Exactly-once semantics at input sources is a bit more involved in case of systems like JMS wherein the source does not have a contract to replay a data point once a handover handshake is complete. Apex provides for a WAL implementation which is used by the JMS operator to replay a series of previously acknowledged messages when restarting from a checkpoint.

JDBC-enabled databases: JDBC-enabled databases like Oracle, Postgres, and MySQL allow for an exactly-once write pattern through transactions. The Apex connector can use this to commit transactions at streaming windows or checkpoint boundaries. The JDBC source supports idempotent read by tracking the offset (for a query with order by clause).

Conclusion

Apex is an enterprise-grade distributed streaming engine that comes with many foundational constructs as well as connectors that help in faster time to market as compared to some similar systems. Dockerized containers and support for next-generation container orchestration are some

of the features that would benefit Apex in the near future.

Definitions

Apache Flink is a system for distributed batch and stream processing. It addresses many challenges related to the processing of bounded and unbounded data. Among other things, Flink provides flexible windowing support, exactly-once state consistency, event-time semantics, and stateful stream processing. It offers abstractions for complex event processing and continuous queries.

Overview

Today, virtually all data is continuously generated as streams of events. This includes business transactions, interactions with web or mobile application, sensor or device logs, and database modifications. There are two ways to process continuously produced data, namely batch and stream processing. For stream processing, the data is immediately ingested and processed by a continuously running application as it arrives. For batch processing, the data is first recorded and persisted in a storage system, such as a file system or database system, before it is (periodically) processed by an application that processes a bounded data set. While stream processing

typically achieves lower latencies to produce results, it induces operational challenges because streaming applications which run 24×7 make high demands on failure recovery and consistency guarantees.

The most fundamental difference between batch and stream processing applications is that stream processing applications process continuously arriving data. The two core building blocks when processing streaming data are state and time. Applications require state for every non-trivial computation that involves more than a single event. For example, state is required to collect multiple events before performing a computation or to hold the result of partial computations. Time on the other hand is important to determine when all relevant data was received and a computation can be performed. Having good control over time enables applications to treat result completeness for latency. Time is not relevant in batch processing because all input data is known and present when the processing starts.

Stateful stream processing is a very versatile architectural pattern that can be applied to a wide spectrum of data-related use cases. Besides providing better latency than batch processing solutions, stateful stream processing applications can also address use cases that are not suitable for batch processing approaches at all. Event-driven applications are stateful stream processing applications that ingest continuous streams of events, apply business logic to them, and emit new events or trigger external actions. These applications share more characteristics with transactional workloads than analytical applications. Another common use case for stateful stream processing is complex event processing (CEP), which is applied to evaluate patterns over event streams.

Historical Background

Apache Flink originates from an academic research project. In 2010, the Stratosphere project was started by five research groups from Technische Universität Berlin, Humboldt

Universität zu Berlin, and Hasso Plattner Institute Potsdam (<http://gepris.dfg.de/gepris/projekt/132320961?language=en>. Visited on 22 Dec 2017). The goal of the project was to develop novel approaches for large-scale distributed data processing. In the course of the project, the researchers developed the prototype of a data processing system to evaluate the new approaches and released the software as open source under the Apache software license (Alexandrov et al. 2014).

When the project started in 2010, the Apache Hadoop project (<https://hadoop.apache.org>. Visited on 22 Dec 2017), an open-source implementation of Google’s MapReduce (Dean and Ghemawat 2008) and GFS (Ghemawat et al. 2003) publications, had gained a lot of interest in research and industry. MapReduce’s strong points were its ability to scale data processing tasks to a large number of commodity machines and its excellent tolerance for hardware and software failures. However, the database research community had also realized that MapReduce was neither the most user-friendly nor most efficient approach to define complex data analysis applications. Therefore, the Stratosphere project aimed to build a system that combined the advantages of MapReduce and relational database systems. The first result was a system consisting of the PACT programming model, the distributed dataflow processing engine Nephele, and an optimizer that translated PACT programs into Nephele dataflows (Battre et al. 2010). The PACT programming model generalized the MapReduce programming model by providing more parallelizable operator primitives and defining programs as directed acyclic dataflows. Hence, specifying complex analytical applications became much easier (Alexandrov et al. 2011). The runtime operators to execute PACT programs were implemented based on well-known algorithms from database system literature, such as external merge-sort, block-nested loop join, hybrid-hash join, and sort-merge join. Having a choice in runtime operators and data distribution strategies due to the flexibility of the distributed dataflow execution engine Nephele resulted in different alternatives of how a PACT program could be executed. Similar to physical optimization in re-

lational database systems, a cost-based optimizer enumerated execution plans under consideration of interesting and existing physical properties (such as partitioning, sorting, and grouping) and chose the least expensive plan for execution. Compared to the MapReduce programming and execution model, the Stratosphere research prototype provided a programming API that was as versatile as MapReduce but eased the definition of advanced data analysis applications, an efficient runtime based on concepts and algorithms of relational database systems, and a database-style optimizer to automatically choose efficient execution plans. At the same time, the prototype had similar hardware requirements and offered similar scalability as MapReduce. Based on the initial Stratosphere prototype, further research was conducted on leveraging static code analysis of user-defined function for logical program optimization (Hueske et al. 2012) and the definition and execution of iterative programs to support machine learning and graph analysis applications (Ewen et al. 2012).

In May 2014, the developers of the Stratosphere prototype decided to donate the source code of the prototype to the Apache Software Foundation (ASF) (<https://wiki.apache.org/incubator/StratosphereProposal>. Visited on 22 Dec 2017). Due to trademark issues, the project was renamed to Apache Flink. Flink is the German word for “nimble” or “swift.” The initial group of committers consisted of the eight Stratosphere contributors and six members of the Apache Incubator to teach the Flink community the Apache Way. In August 2014, version 0.6 of Apache Flink was released as the first release under the new name Apache Flink (<http://flink.apache.org/news/2014/08/26/release-0.6.html>. Visited on 22 Dec 2017). Three months later in November 2014, version 0.7 was released. This release included a first version of Flink’s DataStream API. With this addition, Flink was able to address stream as well as batch processing use cases with a single processing engine (Carbone et al. 2015a). Because the distributed dataflow processor (formerly known as Nephele) had always supported pipelined data transfers, the new stream processing capabilities did not require major changes

to the engine. In January 2015, 9 months after the start of the incubation, Flink left the incubator and became a top-level project of the Apache Software Foundation (https://blogs.apache.org/foundation/entry/the_apache_software_foundation_announces69). Visited 22 Dec 2017).

While until Flink’s graduation the community was mostly working on batch processing features, stream processing slowly became the new focus of the community. Over the next couple of releases, features such as windowing support, exactly-once state consistency, event-time semantics, stateful stream processing, and high availability for worker and master processes were added. Moreover, the DataStream API was declared stable and support for persisting application state in savepoints, and restarting applications from savepoints as well as maintaining very large operator state in RocksDB were implemented. When version 1.0.0 was released in March 2016 (<https://flink.apache.org/news/2016/03/08/release-1.0.0.html>. Visited on 22 Dec 2017), Flink had become a fully fleshed stream processor with a feature set that was unique among other open-source stream processors.

Since Flink’s 1.0.0 release until today (December 2017, version 1.4.0), many more new significant features were added, such as SQL support for unified batch and streaming queries (<https://flink.apache.org/news/2017/04/04/dynamic-tables.html>. Visited on 22 Dec 2017), a complex event processing (CEP) library to identify and react on patterns in event streams (<https://data-artisans.com/blog/complex-event-processing-flink-cep-update>. Visited 22 Dec 2017), support for scaling applications in and out (Carbone et al. 2017), and support for querying operator state from external applications. By now, the Flink community has grown to 34 committers, and more than 350 individuals have contributed to Flink. Apache Flink is used in production at very large scale by enterprises around the world and across various industries, such as Alibaba, DellEMC, ING, King, Netflix, and Uber. Some of these users have built services for internal users or even expose these services to paying customers.

Foundations

Apache Flink is a system for batch and stream processing use cases (Carbone et al. 2015b). The main APIs, namely, the *DataSet API* for batch and *DataStream API* for streaming programs, allow to fluently specify a data processing plan by using first-order and second-order functions known from functional programming. *Second-order functions* give certain guarantees about the distributed execution. *First-order functions* implement custom business logic within the provided guarantees. For example, the map operator guarantees to apply a first-order function to every record, and keyBy partitions and distributes the stream by using a key specified in the first-order function. In the following, the discussion focuses on the DataStream API and Flink’s stream processing capabilities since this reflects the current evolution of the system and the majority of its production use cases.

Figure 1 shows an example of a Flink DataStream API program that reads from a publish-subscribe messaging system. The program transforms the input by applying a user-defined map function to every record. Afterward, it partitions the records by a key and aggregates multiple records over a window of 5 seconds that discretizes the stream. The result is written into a continuous single log file. Flink automatically gathers information about the return type of each operator and generates appropriate record serializers for the network shipping. The API calls only construct a logical representation and are translated into a directed acyclic job graph that is submitted to the cluster for execution.

Figure 2 illustrates the distributed execution of the example program. A Flink setup consists of two types of processes: the *JobManager* and the *TaskManagers*. For high availability, there might be multiple standby JobManagers. The JobManager is the master that is responsible for cluster coordination, metrics collection, and monitoring. It receives a job graph and constructs an execution graph with knowledge of the available TaskManagers and their allocation. The execution graph is deployed on the TaskManagers. The TaskManagers are the workers that are

```

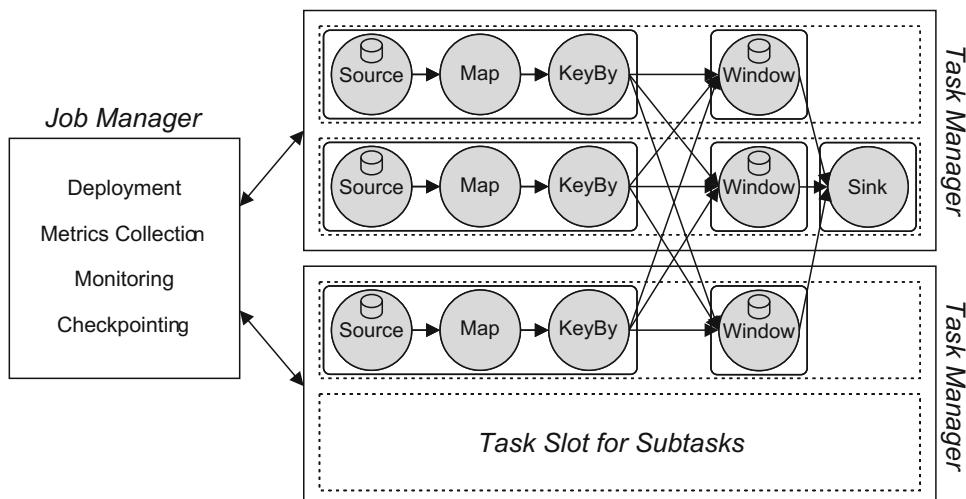

// setup the environment
StreamExecutionEnvironment env =
    StreamExecutionEnvironment.getExecutionEnvironment();

// define a streaming pipeline
env.addSource(new FlinkKafkaConsumer011<>(...))
    .map(new UserDefinedMapFunction())
    .keyBy("userId")
    .window(TumblingProcessingTimeWindows.of(Time.seconds(5)))
    .apply(new UserDefinedWindowFunction())
    .writeAsText("/file.log").setParallelism(1);

// execute the constructed plan
env.execute();

```

Apache Flink, Fig. 1 Apache Flink DataStream API program

Apache Flink, Fig. 2 Flink distributed execution model

responsible for executing operator pipelines and exchanging data streams.

The example from Fig. 2 is executed with a degree of parallelism equal to 3 and thus occupies three task slots. *Task slots* split the resources of a TaskManager into a finer granularity and define how many slices of a program can be executed concurrently by a TaskManager; the dotted lines

in Fig. 2 highlight the task slots. Each pipeline is independently evaluated. Once an operator's result is ready, it will be forwarded immediately to the next operator without additional synchronization steps. A pipeline consists of one or more subtasks. Depending on the operations, a *subtask* executes only one operator, such as the window operator, or multiple operators that are

concatenated by so-called operator chaining. In the example, the reading of a record from the source, its transformation, and the extraction of a key are performed in a chain without having to serialize intermediate data. Both the `keyBy` and the sink operation break the chain, because `keyBy` requires a shuffling step and the sink has a lower parallelism than its predecessor.

Operators in Flink DataStream programs can be stateful. In our example, the sources need to store the current read offset in the log of the publish-subscribe system to remember which records have been consumed so far. Window operators need to buffer records until the final aggregation at the end of a window can be triggered. The JobManager is responsible for coordinating the creation of consistent checkpoints of a program's state, i.e., the state of all operators, and restarting the program in case of failures by loading the latest complete checkpoint and replaying parts of a stream. Flink's checkpoint and recovery mechanism will be covered later in more detail.

Time Handling

The handling of *time* receives special attention in Flink's DataStream API. Most streaming applications need a notion of time to define operations on conceptually never-ending inputs. The previous example included a *tumbling time window* to discretize the stream into segments containing the records received within an interval of 5 seconds. Similarly, *sliding windows* allow for similar fixed-length windows but with a possible overlap, e.g., a window of 1 minute length that is evaluated every 10 seconds. *Session windows* have a variable length and are evaluated depending on a gap of inactivity. These window types as well as several other operations on data streams depend on a notion of time to specify an interval of the stream that they interact with. Time-based operators need to be able to look up the “current time” while processing a record of a stream. Flink supports two time modes.

Processing time is defined by the local clock of the machine that processes an operator. Perform-

ing operations based on the wall-clock time is the easiest notion of time with little overhead. However, it assumes a perfect environment where all records arrive in a strict order, can be processed on time without any side effects, and do not need to be reprocessed. In the real world, events might arrive in the wrong order, or large amounts of events might arrive at the same time and, thus, logically belong to the same window but do not reach the window operator punctually. Moreover, the amount of hardware resource available for processing can affect which records are grouped together. Hence, processing time is not applicable if quality-of-service specifications require that results, which are computed from a log of events, and must be reproducible.

Event time addresses the issues above by relying on a timestamp that is associated with every record and by defining a strategy to make progress that guarantees consistent results. Flink adopts the *dataflow model* (Akidau et al. 2015). In addition to timestamped records, data streams need to be enriched with *watermarks* in order to leverage event time. Watermarks are metadata records with a timestamp that indicate that no record with a timestamp lower than the watermark's timestamp will be received from a connection in the future. Every operator in Flink contains logic to compute a new watermark from the watermarks it receives via its incoming connections. The watermark of an operator acts as its internal clock and triggers computations, such as the computation of a window when the watermark passes its end time. An operator tracks for each incoming connection the highest observed watermark and computes its own watermark as the smallest watermark across the current watermarks of its incoming connections. Whenever an operator advances its own watermark, it performs all computations that are triggered by the new watermark, emits the resulting records, and subsequently broadcasts its new watermark across all its outgoing connections. This mechanism ensures that watermarks are strictly increasing and that emitted records remain aligned with the emitted watermarks.

State and Fault Tolerance

The ability to memorize information that was received or computed for future computations is another crucial feature in streaming applications. *State* can be used to buffer records until a certain event occurs, to maintain (partial) aggregates based on incoming events, or to train and store machine learning models. From a user’s point of view, state can be considered as a set of member variables in each operator. A member variable is empty at the beginning and can be accessed and modified depending on its data type. Since the values in state variables affect the computed result, state must be resilient to failures, recoverable, and flexible enough for rescaling.

Flink takes care of snapshotting the content of state variables by performing so-called Checkpoints in regular intervals (e.g., every minute). Flink employs *lightweight asynchronous snapshots* (Carbone et al. 2015c) based on the *Chandy-Lamport algorithm* (Mani Chandy and Lamport 1985) for distributed snapshots. When a snapshot is triggered, *checkpoint barriers* with a specific checkpoint ID are inserted at each source task and broadcasted across all outgoing connections. When an operator received a checkpoint barrier with the same checkpoint ID from all incoming connections, it draws a snapshot of its current state, starts to write it out asynchronously, and broadcasts the checkpoint barrier to all outgoing connections. A checkpoint is completed once all operators finished persisting their state. An important property of checkpoints is that they are consistent, i.e., the snapshotted state of all operators depends on the same set of input records, i.e., all records that were ingested before the checkpoint barriers were injected by the source tasks. In case of a failure, Flink restores the state of all operators from the most recent completed checkpoint. Many source operators persist the read positions (or offsets) on their input streams as regular state, such that read positions and operator states are consistently restored in case of a failure which results in exactly-once state consistency.

Usually, checkpoints are continuously replaced by newer ones. Flink allows for creating

special persistent checkpoints, called *savepoints*. Savepoints can be created at any time and hold the complete state of an application. An application can be restarted from a savepoint, which means its internal state, usually including read positions on input streams, is completely restored. Savepoints make it possible to save multiple versions of a streaming application, recover state, or perform A/B testing with modified business logic but same state in a test environment.

State management also affects whether and how the parallelism of stateful operators can be changed, a feature that is important to support scale out of streaming applications during peak times or increasing loads and scale in afterward to save resources and money. Adjusting the parallelism of a stateful operator requires to redistribute its state to fewer or more parallel tasks. Flink provides mechanisms for scaling operators and applications by taking a savepoint from a running job and restarting it with a different parallelism from the savepoint.

Flink distinguishes between two types of state, *operator state* and *keyed state*. Operator state maintains state that is scoped to the parallel task of an operator. Operator state needs to be splittable and mergeable to support operator rescaling. Keyed state is scoped to a key of the data and requires a keyed stream, i.e., a stream partitioned on a key attribute. When processing a record, an operator with keyed state can only access the state that corresponds to the key of the current record. Operators with keyed state are rescaled by reassigning key ranges and redistributing the corresponding state to fewer or more operator tasks.

Flink maintains the state of operators in a so-called state backend. A state backend implements the internal data structures to hold the data and logic to checkpoint the state. Heap-based state backends use regular Java data structures to store the state. They are limited by the size of the JVM heap of the TaskManagers. Heap-based state backends can checkpoint to the JVM heap of the JobManager or to a remotely accessible file system, such as HDFS, NFS, or S3. The RocksDB-based state backend writes state to disk and therefore allows for state that exceeds the size of available memory. Flink exploits

many RocksDB features for checkpointing to a remote file system, and maintaining state that becomes very large (on the order of multiple terabytes). When using the RocksDB state backend, Flink can not only create checkpoints asynchronously but also incrementally which speeds up the checkpointing operation.

Key Applications

In the past, analytical data was commonly dumped into database systems or distributed file systems and, if at all, processed in nightly or monthly batch jobs. Nowadays, in a globalized, faster-moving world, reacting to events quickly is crucial for economic success. For Flink, processing of unbounded data means handling events when they occur in a non-approximated but accurate fashion. This requires support for event-time processing, exactly-once state consistency, and fault tolerance capabilities. Applications must be scalable to handle both current and increasing data volumes in the future, leading to a parallelized and distributed execution. Moreover, Flink applications can consume data from a variety of sources such as publish-subscribe message queues, file systems, databases, and sockets.

However, the use cases for Flink are not limited to faster data analytics. Its flexibility to model arbitrary dataflows and its precise control over state and time allow a variety of new applications. So-called event-driven applications are becoming more and more popular as part of an overall *event-driven architecture*. Such applications trigger computations based on incoming events and might store an accumulated history of events to relate it to newly arrived events. Applications can output their result to a database or key-value store, trigger an immediate reaction via an RPC call, or emit a new event which might trigger subsequent actions. In contrast to traditional two-tier architectures where application and database system separate business logic and data from each other, event-driven applications own computation and state and keep them close together. The benefits of

this approach are that (1) state access is always local instead of accessing a remote database, (2) state and computation are scaled together, and (3) applications define the schema of their own state, similar to microservices.

Entire social networks have been built with Flink (Koliopoulos 2017) following the event-driven approach. Incoming user requests are written to a distributed log that acts as the single source of truth. The log is consumed by multiple distributed stateful applications which build up their state independently from each other for aggregated post views, like counts, and statistics. Finally, the updated results are stored in a materialized view that web servers can return to the user.

In addition, Flink offers a domain-specific API for complex event processing to detect and react on user-defined patterns in event streams. CEP is useful for fraud or intrusion detection scenarios or to monitor and validate business processes. Furthermore, Flink provides relational APIs to unify queries on bounded and unbounded data streams. With its Table and SQL APIs, Flink can continuously update a result table which is defined by query on one or more input streams, similar to a materialized view as known from relational database systems.

Apache Kafka

Matthias J. Sax
Confluent Inc., Palo Alto, CA, USA

Definitions

Apache Kafka (Apache Software Foundation 2017b; Kreps et al. 2011; Goodhope et al. 2012; Wang et al. 2015; Kleppmann and Kreps 2015) is a scalable, fault-tolerant, and highly available distributed streaming platform that can be used to store and process data streams.

Kafka consists of three main components:

- the Kafka cluster,
- the Connect framework (Connect API),
- and the Streams programming library (Streams API).

The Kafka cluster stores data streams, which are sequences of messages/events continuously produced by applications and sequentially and incrementally consumed by other applications. The Connect API is used to ingest data into Kafka and export data streams to external systems like distributed file systems, databases, and others. For data stream processing, the Streams API allows developers to specify sophisticated stream processing pipelines that read input streams from the Kafka cluster and write results back to Kafka.

Kafka supports many different use cases categories such as traditional publish-subscribe

messaging, streaming ETL, and data stream processing.

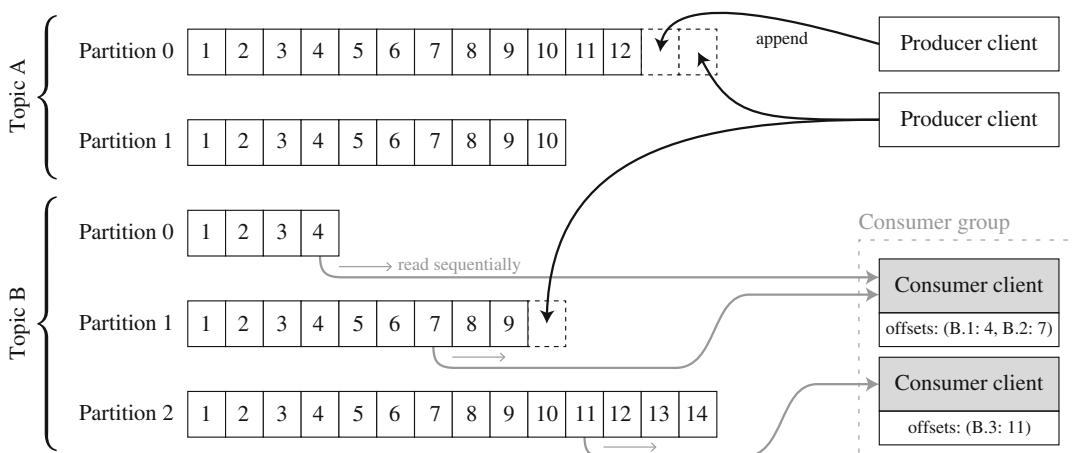

Overview

A Kafka cluster provides a publish-subscribe messaging service (Fig. 1). Producer clients (publishers) write messages into Kafka, and consumer clients (subscribers) read those messages from Kafka. *Messages* are stored in Kafka servers called *brokers* and organized in named *topics*. A topic is an append-only sequence of messages, also called a log. Thus, each time a message is written to a topic, it is appended to the end of the log. A Kafka message is a key-value pair where key and value are variable-length byte arrays. Additionally, each message has a time stamp that is stored as 64-bit integer.

Topics are divided into *partitions*. When a message is written to a topic, the producer must specify the partition for the message. Producers can use any partitioning strategy for the messages they write. By default, messages are hash-partitioned by key, and thus all messages with the same key are written to the same partition. Each message has an associated *offset* that is the message's position within the partition, i.e., a monotonically increasing sequence number. The mes-

sage's offset is implicitly determined by the order in which messages are appended to a partition. Hence, each message within a topic is uniquely identified by its partition and offset. Kafka guarantees strict message ordering within a single partition, i.e., it guarantees that all consumers reading a partition receive all messages in the exact same order as they were appended to the partition. There is no ordering guarantee between messages in different partitions or different topics.

Topics can be written by multiple producers at the same time. If multiple producers write to the same partition, their messages are interleaved. If consumers read from the same topic, they can form a so-called consumer group. Within a consumer group, each individual consumer reads data from a subset of partitions. Kafka ensures that each partition is assigned to exactly one consumer within a group. Different consumer groups or consumers that don't belong to any consumer group are independent from each other. Thus, if two consumer groups read the same topic, all messages are delivered to both groups. Because consumers are independent from each other, each consumer can read messages at its own pace. This results in decoupling—a desirable property for a distributed system—and makes the system robust against stragglers. In summary, Kafka supports

Apache Kafka, Fig. 1 Kafka topics are divided into partitions that are ordered sequences of messages. Multiple producers can write simultaneously into the same topic. Consumers track their read progress and can form

a consumer group to share the read workload over all consumers within the group (Source: Kleppmann and Kreps 2015)

multiple producers and can deliver the same data to multiple consumers.

Kafka Brokers

Kafka brokers store messages reliably on disk. In contrast to traditional messaging/publish-subscribe systems, Kafka can be used for long-term storage of messages, because Kafka does not delete messages after delivery. Topics are configured with a so-called *retention time* that specifies how long a message should be stored. Topic retention can also be specified in bytes instead of time, to apply an upper bound on disk space. If the retention boundaries are reached, Kafka truncates partitions at the end of the log.

From a semantic point of view, messages are immutable facts, and thus it is not reasonable to support deleting individual messages from a topic. Users can only apply a “time-to-live” via topic retention to truncate old data.

Log Compaction

Kafka also supports so-called *compacted* topics. If a topic is configured for log compaction, users apply different *semantics* to the stored messages. While regular topics store *immutable facts*, a compacted topic can be used to store *updates*. Note that a compacted topic is still an append-only sequence of messages, and there are no in-place updates. Appending an update message to a compacted topic implies that a newer messages “replaces” older messages with the same key. The difference of compacted topics to topics with log retention is that Kafka guarantees that the latest update of a key is never deleted, while older updates can be garbage collected.

Log compaction is applied on a per-partition basis; thus updates for the same key should be written to the same partition. For performance reasons, brokers don’t delete older messages immediately, but compaction is triggered as background process in regular intervals. In contrast to “regular” topics, compacted topics also support delete semantics for individual record via so-called *tombstone* messages. A tombstone is a

message with a null value, and it indicates that all previous updates for the corresponding key can be deleted (including the tombstone itself).

Scaling and Load Balancing

As described in section “[Overview](#),” messages are stored in topics, and topics are divided into partitions. Partitions allow brokers to scale out horizontally and to balance load within the cluster, because partitions are independent units within a topic. Even if partitions of the same topic are stored at different brokers, there is no need for broker synchronization, and thus a Kafka cluster scales linearly with the number of brokers. A single broker only limits the capacity of a single partition, but because topics can be created with an arbitrary number of partitions, this is not a limitation in practice. Overall the read/write throughput and storage requirements of topics are not limited by the size of a single server, and the cluster capacity can be increased by adding new brokers to the system. Last but not least, partitions can be reassigned from one broker to another to balance load within a cluster.

There is no master node in a Kafka cluster: all brokers are able to perform all services provided by the cluster. This design supports linear scale-out, as a master node could become a bottleneck. For broker coordination, Kafka uses Apache ZooKeeper (Apache Software Foundation [2017d](#); Hunt et al. [2010](#)), a scalable, fault-tolerant, and highly available distributed coordination service. Kafka uses ZooKeeper to store all cluster metadata about topics, partitions, partition-to-broker mapping, etc., in a reliable and highly available manner.

Fault Tolerance and High Availability

To ensure fault tolerance and high availability, partitions can be replicated to multiple brokers. Each topic can be configured with an individual replication factor that indicates how many copies of a partition should be maintained. To ensure strict message ordering guarantees per partitions, replication uses a *leader-follower* pattern. Each partition has a single leader and a configurable number of followers. All read and write requests are handled by the leader, while the followers

replicate all writes to the leader in the background. If the broker hosting the leader fails, Kafka initiates a leader election via ZooKeeper, and one of the followers becomes the new leader. All clients will be updated with the new leader information and send all their read/write request to the new leader. If the failed broker recovers, it will rejoin the cluster, and all hosted partitions become followers.

Message Delivery

Reading data from Kafka works somewhat differently compared to traditional messaging/publish-subscribe systems. As mentioned in section “[Kafka Brokers](#),” brokers do not delete messages after delivery. This design decision has multiple advantages:

- Brokers do not need to track the reading progress of consumers. This allows for an increased read throughput, as there is no progress tracking overhead for the brokers.
- It allows for in-order message delivery. If brokers track read progress, consumers need to acknowledge which messages they have processed successfully. This is usually done on a per-message basis. Thus, if an earlier message is not processed successfully, but a later message is processed successfully, re-delivery of the first message happens out of order.
- Because brokers don’t track progress and don’t delete data after delivery, consumers can go back in time and reprocess old data again. Also, newly created consumers can retrieve older data.

The disadvantage of this approach is that consumer clients need to track their progress themselves. This happens by storing the offset of the next message a consumer wants to read. This offset is included in the read request to the broker, and the broker will deliver consecutive messages starting at the requested offset to the consumer. After processing all received messages, the consumer updates its offset accordingly and sends the next read request to the cluster.

If a consumer is stopped and restarted later on, it usually should continue reading where it left off. To this end, the consumer is responsible for storing its offset reliably so it can retrieve it on restart. In Kafka, consumers can commit their offsets to the brokers. On offset commit brokers store consumer offsets reliably in a special topic called *offset topic*. As offset topic is also partitioned and replicated and is thus scalable, fault-tolerant, and highly available. This allows Kafka to manage a large number of consumers at the same time. The offset topic is configured with log compaction enabled (cf. section “[Log Compaction](#)”) to guarantee that offsets are never lost.

Delivery Semantics

Kafka supports multiple delivery semantics, namely, *at-most-once*, *at-least-once*, and *exactly once*. What semantics a user gets depends on multiple factors like cluster/topic configuration as well as client configuration and user code.

It is important to distinguish between the write and read path when discussing delivery semantics. Furthermore, there is the concept of end-to-end processing semantics that applies to Kafka’s Streams API. In this section, we will only cover the read and write path and refer to section “[Kafka Streams](#)” for end-to-end processing semantics.

Writing to Kafka

When a producer writes data into a topic, brokers acknowledge a successful write to the producer. If a producer doesn’t receive an acknowledgement, it can ignore this and follow at-most-once semantics, as the message might not have been written to the topic and thus could be lost. Alternatively, a producer can retry the write resulting in at-least-once semantics. The first write could have been successful, but the acknowledgement might be lost. Kafka also supports exactly once writes by exploiting idempotence. For this, each message is internally assigned a unique identifier. The producer attaches this identifier to each message it writes, and the broker stores the identifier as metadata of each message in the topic. In case of a producer write retry, the broker can detect the

duplicate write by comparing the message identifiers. This deduplication mechanism is internal to producer and broker and does not guard against application-level duplicates.

Atomic Multi-partition Writes Kafka also support atomic multi-partition writes that are called *transactions*. A Kafka transaction is different to a database transaction, and there is no notion of ACID guarantees. A transaction in Kafka is similar to an atomic write of multiple messages that can span different topics and/or partitions. Due to space limitations, we cannot cover the details of transactional writes and can only give a brief overview. A transactional producer is first initialized for transactions by performing a corresponding API call. The broker is now ready to accept transactional writes for this producer. All messages sent by the producer belong to the current transaction and won't be delivered to any consumer as long as the transaction is not completed. Messages within a transaction can be sent to any topic/partition within the cluster. When all messages of a transaction have been sent, the producer commits the transaction. The broker implements a two-phase commit protocol to commit a transaction, and it either successfully "writes" all or none of the messages belonging to a transaction. A producer can also abort a transaction; in this case, none of the messages will be deleted from the log, but all messages will be marked as aborted.

Reading from Kafka

As discussed in section "[Message Delivery](#)," consumers need to track their read progress themselves. For fault-tolerance reasons, consumers commit their offsets regularly to Kafka. Consumers can apply two strategies for this: after receiving a message, they can either first commit the offset and process the message afterwards, or they do it in reverse order and first process the message and commit the offset at the end. The commit-first strategy provides at-most-once semantics. If a message is received and the offset is committed before the message is processed, this message would not be redelivered in case of failure: after a failure, the consumer would

recover its offsets as the last committed offset and thus would resume reading after the failed message.

In contrast, the process-first strategy provides at-least-once semantics. Because the consumer doesn't update its offsets after processing the receive message successfully, it would always fall back to the old offset after recovering from an error. Thus, it would reread the processed message, resulting in potential duplicates in the output.

Transactional Consumers Consumers can be configured to read all (including aborted messages) or only committed messages (cf. paragraph *Atomic multi-partition writes* in section "[Writing to Kafka](#)"). This corresponds to a read uncommitted and read committed mode similar to other transactional systems. Note that aborted messages are not deleted from the topics and will be delivered to all consumers. Thus, consumers in read committed mode will filter/drop aborted messages and not deliver them to the application.

Kafka Connect Framework

Kafka Connect—or the Connect API—is a framework for integrating Kafka with external systems like distributed file systems, databases, key-value stores, and others. Internally, Kafka Connect uses producer/consumer clients as described in section "[Kafka Brokers](#)," but the framework implements much of the functionality and best practices that would otherwise have to be implemented for each system. It also allows running in a fully managed, fault-tolerant, and highly available manner.

The Connect API uses a *connector* to communicate with each type of external system. A *source connector* continuously reads data from an external source system and writes the records into Kafka, while a *sink connector* continuously consumes data from Kafka and sends the records to the external system. Many connectors are available for a wide variety of systems, including HDFS, S3, relational databases, document database systems, other messaging systems, file

systems, metric systems, analytic systems, and so on. Developers can create connectors for other systems.

Kafka Connect can be either used as stand-alone or deployed to a cluster of machines. To connect with an external system, a user creates a configuration for a connector that defines the specifics of the external system and the desired behavior, and the user uploads this configuration to one of the Connect workers. The worker, which is running in a JVM, deploys the connector and distributes the connector's *tasks* across the cluster. Source connector tasks load data from the external system and generate records, which Connect then writes to the corresponding Kafka topics. For sink connector tasks, Connect consumes the specified topics and passes these records to the task, which then is responsible for sending the records to the external system.

Single-Message Transforms

The Connect API allows to specify simple transformation—so-called single-message transforms, SMT—for individual messages that are imported/exported into/from Kafka. Those transformations are independent of the connector and allow for stateless operations. Standard transformation functions are already provided by Kafka, but it is also possible to implement custom transformations to perform initial data cleaning. If SMTs are not sufficient because a more complex transformation is required, the Streams API (described in the next section) can be used instead.

Kafka Streams

Kafka Streams—or the Streams API—is the stream processing library of Apache Kafka. It provides a high-level DSL that supports stateless as well as stateful stream processing operators like joins, aggregations, and windowing. The Streams API also supports exactly once processing guarantees and event-time semantics and handles out-of-order and late-arriving data. Additionally, the Streams API introduces *tables*

as a first-class abstraction next to data *streams*. It shares a few ideas with Apache Samza (cf. article on “► [Apache Samza](#)”) (Apache Software Foundation 2017c; Noghabi et al. 2017; Kleppmann and Kreps 2015) such as building on top of Kafka's primitives for fault tolerance and scaling. However, there are many notable differences to Samza: for example, Kafka Streams is implemented as a library and can run in any environment, unlike Samza, which is coupled to Apache Hadoop's resource manager YARN (Apache Software Foundation 2017a; Vavilapalli et al. 2013); it also provides stronger processing guarantees and supports both streams and tables as core data abstractions.

Streams and Tables

Most stream processing frameworks provide the abstraction of a *record stream* that is an append-only sequence of immutable facts. Kafka Streams also introduces the notion of a *changelog stream*, a mutable collection of data items. A changelog stream can also be described as a continuously updating table. The analogy between a changelog and a table is called the *stream-table duality* (Kleppmann 2016, 2017). Supporting tables as first-class citizens allow to enrich data streams via stream-table joints or populate tables as self-updating caches for an application.

The concept of changelogs aligns with the concept of compacted topics (cf. section “[Log Compaction](#)”). A changelog can be stored in a compacted topic, and the corresponding table can be recreated by reading the compacted topic without data loss as guaranteed by the compaction contract.

Kafka Streams also uses the idea of a changelog stream for (windowed) aggregations. An aggregation of a record stream yields both a table and a changelog stream as a result—not a record stream. Thus, the table always contains the current aggregation result that is updated for each incoming record. Furthermore, each update to the result table is propagated downstream as a changelog record that is appended to the changelog stream.

State Management

Operator state is a first-class citizen in Kafka's Streams API similar to Samza and uses the aforementioned table abstraction. For high performance, state is kept local to the stream processing operators using a RocksDB (Facebook Inc. 2017) store. Local state is not fault-tolerant, and thus state is additionally backed by a topic in the Kafka cluster. Those topics have log compaction (cf. section “[Log Compaction](#)”) enabled and are called *changelog topics*. Using log compaction ensures that the size of the changelog topic is linear in the size of the state. Each update to the store is written to the changelog topic; thus, the persistent changelog topic is the source of truth, while the local RocksDB store is an ephemeral materialized view of the state.

If an application instance fails, another instance can recreate the state by reading the changelog topic. For fast fail-over, Kafka Streams also support *standby replicas*, the hold hot standbys of state store. Standby replicas can be maintained by continuously reading all changes to the primary store from the underlying changelog topic.

Fault Tolerance and Scaling

Kafka Streams uses the same scaling/parallelism abstraction as Samza, namely, partitions. This is a natural choice as Kafka Streams reads input data from partitioned topics. Each input topic partition is mapped to a *task* that processes the records of this partition. Tasks are independent units of parallelism and thus can be executed by different threads that might run on different machines. This allows to scale out a Kafka Streams application by starting multiple instances on different machines. All application instances form a consumer group, and thus Kafka assigns topic partitions in a load balanced manner to all application instances (cf. section “[Kafka Brokers](#)”).

Because Kafka Streams is a library, it cannot rely on automatic application restarts of failed instances. Hence, it relies on the Kafka cluster to detect failures. As mentioned above, a Streams application forms a consumer group, and the Kafka cluster monitors the liveness of

all members of the group. In case of a failure, the cluster detects a dead group member and reassigns the corresponding input topic partitions of the failed application instance to the remaining instances. This process is called an consumer group *rebalance*. During a rebalance, Kafka Streams also ensures that operator state is migrated from the failing instance (cf. section “[State Management](#)”). Kafka's consumer group management mechanism also allows for fully elastic deployments. Application instances can be added or removed during runtime without any downtime: the cluster detects joining/leaving instances and rebalances the consumer group automatically. If new instances are joining, partitions are *revoked* from existing members of the groups and assigned to the new members to achieve load balancing. If members are leaving a consumer group, this is just a special case of fail-over, and the partitions of the leaving instance are assigned to the remaining ones. Note that in contrast to a fail-over rebalance, a scaling rebalance guarantees a clean hand over of partitions, and thus each record is processed exactly once.

Time Semantics

Time is a core concept in stream processing, and the operators in Kafka's stream processing DSL are based on time: for example, windowed aggregations require record time stamps to assign records to the correct time windows. Handling time also requires to handle late-arriving data, as record might be written to a topic out of order (note: Kafka guarantees offset based in-order delivery; there is no time stamp-based delivery guarantee).

Stream processing with Kafka supports three different time semantics: event time, ingestion time, and processing time. From a Streams API point of view, there are only two different semantics though: *event time* and *processing time*.

Processing time semantics are provided when there is no record time stamp, and thus Streams needs to use wall clock time when processing data for any time-based operation like windowing. Processing time has the disadvantage that there is no relationship between the time when data was created and when data gets processed.

Furthermore, processing time semantics is inherently non-deterministic.

Event time semantics are provided when the record contains a time stamp in its payload or metadata. This time-stamp is assigned when a record is created and thus allows for deterministic data reprocessing. Applications may include a time stamp in the payload of the message, but the processing of such time stamps is then application-dependent. For this reason, Kafka supports record metadata time stamps that are stored in topics and automatically set by the producer when a new record is created.

Additionally, Kafka topics can be configured to support *ingestion time* for time-based operations: ingestion time is the time when data is appended to the topic, i.e., the current broker wall clock time on write. Ingestion time is an approximation of event time, assuming that data is written to a topic shortly after it was created. It can be used if producer applications don't provide a record metadata time stamp. As ingestion time is an approximation of event time, the Streams API is agnostic to ingestion time (it is treated as a special case of event time).

Exactly Once Processing Semantics

Processing an input record can be divided into three parts: first, the actual processing including any state updates; second, writing the result records to the output topics; third, recording the progress by committing the consumer offset. To provide exactly once processing semantics, all three parts must be performed “all or nothing.”

As described in section “[State Management](#),” updating operator state is actually a write to a changelog topic that is the source of truth (the local state is only a materialized view). Furthermore, committing input offsets is a write to the special *offset topic* as discussed in section “[Message Delivery](#).“ Hence, all three parts use the same underlying operation: writing to a topic.

This allows the Streams API to leverage Kafka's transactions (cf. section “[Writing to Kafka](#)”) to provide end-to-end exactly once stream processing semantics. All writes that happen during the processing of a record are part of the same transaction. As a transaction is

an atomic multi-partition write, it ensures that either all writes are committed or all changes are aborted together.

Summary

Apache Kafka is a scalable, fault-tolerant, and highly available distributed streaming platform. It allows fact and changelog streams to be stored and processed, and it exploits the stream-table duality in stream processing. Kafka's transactions allow for exactly once stream processing semantics and simplify exactly once end-to-end data pipelines. Furthermore, Kafka can be connected to other systems via its Connect API and can thus be used as the central data hub in an organization.

Apache Mahout

Andrew Musselman
Apache Software Foundation, Seattle, WA, USA

Definitions

Apache Mahout (<http://mahout.apache.org>) is a distributed linear algebra framework that includes a mathematically expressive domain-specific language (DSL). It is designed to aid mathematicians, statisticians, and data scientists to quickly implement numerical algorithms while focusing on the mathematical concepts in their work, rather than on code syntax. Mahout uses an extensible plug-in interface to systems such as Apache Spark and Apache Flink.

Historical Background

Mahout was founded as a sub-project of Apache Lucene in late 2007 and was promoted to a top-

level Apache Software Foundation (ASF) (ASF 2017) project in 2010 (Khudairi 2010). The goal of the project from the outset has been to provide a machine learning framework that was both accessible to practitioners and able to perform sophisticated numerical computation on large data sets.

Mahout has undergone two major stages of architecture design. The first versions relied on the Apache Hadoop MapReduce framework, a popular tool for orchestrating large-scale data flow and computation. Hadoop, while flexible enough to handle many typical workflows, has severe limitations when applied to highly iterative processes, like those used in most machine learning methods.

The Hadoop implementation of MapReduce does not allow for caching of intermediate results across steps of a long computation. This means that algorithms that iteratively use the same data many times are at a severe disadvantage – the framework must read data from disk every iteration rather than hold it in memory. This type of algorithm is common in data science and machine learning: examples include k -means clustering (which has to compute distances for all points in each iteration) and stochastic gradient descent (which has to compute gradients for the same points over many iterations).

Since enabling iterative work on large data sets is a core requirement of a machine learning library geared toward big data, Mahout moved away from Hadoop in its second design phase. Starting with release 0.10.0 (PMC 2015), Mahout switched its computation engine to Apache Spark, a framework designed specifically to facilitate distributed in-memory computation. At the same time, Mahout jobs built using Hadoop MapReduce were deprecated to discourage users from relying on them long-term, and a new interface on the front end was released, named “Samsara,” after the Hindu and Buddhist concept of rebirth. This new front end has a simple syntax for matrix math modeled after other systems such as MATLAB and R, to allow maximal readability and quick prototyping. Samsara can be run in an interactive shell where results are displayed inline, enabling a live back-and-forth with code and

results, much like an interactive SQL or other interpreted environment familiar to many users.

As an example of the Samsara DSL syntax for calculating, for instance, the transpose of a matrix

A multiplied with A itself, a common operation in machine learning jobs, can be written in Scala code as

```
val C = A.t %*% A.
```

Note the declaration of the resulting matrix C , the transpose operator t , and the matrix multiplication operator $\%*\%$. Behind the scenes, the right-hand side of the statement is parsed and the back end takes an optimal approach when physically performing the multiplication.

More recently, beginning in early 2017 with version 0.13.0 (PMC 2017), Mahout added the capability to perform computation directly on hardware, outside the Java Virtual Machine (JVM), using operation solvers written specifically to optimize performance according to native processor and memory architecture. This allows for speed gains from using all cores of all CPUs on the host and the option to leverage matrix-math-specific instruction sets built into graphics processing units (GPUs).

Foundations

The motivation for the Mahout project is to bring large-scale machine learning to practitioners in real-world environments. This boils down to three concepts: first, providing a convenient syntax for writing programs and doing experimental and exploratory work; second, handling all the nitty-gritty details of distributed matrix arithmetic without requiring the user to understand the low-level implementation; and last, making deployment to production simple and straightforward.

Many machine learning libraries and tools either provide an array of algorithms, but do not operate on very large data sets, or else manage computation at scale but require significant programming experience and skill. Bridging those gaps, Mahout works at scale, is flexible with

regard to hardware and compute engines, and allows data science and machine learning practitioners to focus on the math in their work symbolically.

For example, in the distributed stochastic principal component analysis (dSPCA) job in Mahout, there is a computation that is expressed symbolically as

$$G = BB^T - C - C^T + \xi^T \xi s_q^T s_q.$$

This equation can be expressed in code in Mahout as

```
val G = B %*% B.t - C - C.t
+ (xi dot xi) * (s_q cross s_q),
```

which is readable and compact compared to many alternative representations.

The main reason many machine learning operations need to be distributed in real-world environments is because one of the key strengths of machine learning methods is their ability to build predictions from very large data sets. Data sets at this scale include, for example, HTTP access logs for high-traffic websites, large text corpora consisting of millions of documents, and streaming, high-volume data from sensors in industrial settings. With smaller data sets, the input is often held in memory, and all computation is performed on one host computer. However, as soon as a data set scales beyond the memory on a single host, inefficiency caused by spilling data to storage and re-reading it slows down operations and makes them too costly to be viable.

Distributed computing frameworks that allow computation on large data sets are continuously evolving based on shifting market requirements and ongoing research and development. Mahout takes advantage of many of the abstractions provided by these frameworks and then builds further performance improvements and refinements. Many refinements come from exploiting well-studied properties of matrices and matrix arithmetic and using “tricks” and shortcuts to avoid doing more operations than required,

and others come from solvers purpose-built for specific types of hardware and environments.

Overview of Architecture

The most recent design of Mahout allows for iterative rapid prototyping in the Samsara DSL which can be used directly in production with minimal changes. Computation on the back end is adaptable to varied configurations of compute engine and hardware. For example, an algorithm can be handed off to a Spark or Flink engine for computation, and any required matrix arithmetic can be computed in the JVM, on the CPU (using all available cores), or on compatible GPUs, depending on the shape and characteristics of the vectors and matrices being operated on. All these combinations will work with the same front-end code with minimal changes.

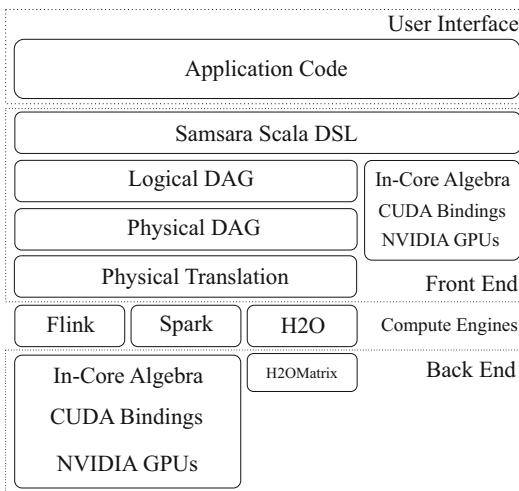

All the moving parts involved are seen in Fig. 1, moving from the top layer where application code is written to the front end which hands off computation to the appropriate engine or to native solvers (which perform the com-

putations), the pluggable compute engine layer, and the back end which handles computation according to instructions from compute engines. Noteworthy for the Mahout user is the Scala DSL layer which allows for interactive, iterative development which can be captured directly into Scala packages and run as application code in production environments with minimal changes.

Also notable is the pluggable compute engine layer, allowing flexibility in deployment as well as future-proofing for when new compute engines become viable and beneficial to users' needs. In fact, code written for the Spark engine, for example, can be directly re-used on Flink with minor changes to import and initialization statements in the code.

Another recent introduction to Mahout is a template that simplifies algorithm contributions from the project's maintainers as well as from its users. The interface is modeled after the machine learning training and evaluation patterns found in many R packages and the Python-based scikit-learn package.

As seen in Fig. 2, a new algorithm need only define a `fit` method in a `Fitter` class, which populates a `Model` class, which contains parameter estimates, statistics about the fit, and an overall summary of performance, and which finally uses its `predict` method to make predictions on new data. The bulk of the work any new algorithm performs is written inside the `fit` method.

Apache Mahout, Fig. 1 Current architecture of Mahout, showing four main components: the user interface where application code is written, the front end which handles which subsystem will perform computation (which could be native and in-core), the pluggable compute engine layer, and the back end which takes instructions from a compute engine and performs mathematical operations

Key Applications

Practical applications of machine learning usually fall into one of three categories, the so-called Three Cs: collaborative filtering (known commonly as “recommender systems,” or “recommenders”), classification, and clustering.

Recommender systems typically come into play in situations where the goal is to present new items to users which they are likely to need or want. These recommendations are based on historical user behavior across all users and across all items they interact with. Examples

Apache Mahout, Fig. 2

Code listing of a skeleton for a new algorithm, showing both the Fitter and Model classes, including their fit and predict methods

```

class Foo[K] extends RegressorFitter[K] {

    def fit(drmX: DrmLike[K],
            drmTarget: DrmLike[K],
            hyperparameters: (Symbol, Any)*): FooModel[K] = {
        /**
         * Normally this section would have more code
         *
         */
        var model = new FooModel[K]
        model.summary = "This model has been fit, etc."
        model
    }
}

class FooModel[K] extends RegressorModel[K] {

    def predict(drmPredictors: DrmLike[K]): DrmLike[K] = {
        drmPredictors.mapBlock(1) {
            case (keys, block: Matrix) => {
                var outputBlock = new DenseMatrix(block.nrow, 1)
                keys -> (outputBlock += 1.0)
            }
        }
    }
}

```

include online retail, where increasing customer spending and site interactions is a key business goal. A common use of a recommender is to present examples of products that other customers have bought, calculated by the similarity between other customers' purchases or between products themselves.

Classifiers cover a broad range of methods which can be summarized as predicting either a categorical value for a user or an item, such as “likely or unlikely to default on a bank loan,” or a numerical value such as age or salary. These methods are used across most scientific fields and industrial sectors, for anything from screening for illnesses in medicine, to determining risk in the financial sector, to predictive plant maintenance in manufacturing operations.

Clustering methods are generally used to make sense of groups of users, documents, or other items. Presented as a whole, a data set can be daunting or even impossible to understand as a pile of records full of numbers and values, and it is often desirable to segment the whole set into smaller pieces, each of which collects most-similar items together for more close analysis and inspection. A common use for clustering is

with a text corpus that contains documents on a variety of subjects. In order to categorize all the documents into one or more relevant topics which could be used for quicker filing and retrieval, the entire corpus can be analyzed by a clustering method which separates documents into groups, members of each being relevant to similar topics or concepts.

In real-world applications, the distinction between these methods can be less clear-cut. Often more than one type of machine learning method will be used in combination to achieve further nuance and improve relevance and effectiveness of predictions. For example, after a corpus of documents is organized into topics, if a new document is added to the corpus, it can effectively be “classified” based on which cluster it is closest to. Similarly, the input to a recommender system in production can be a customer’s recent browsing history on the product website. The customer’s history can be fed into a classifier to determine which cohort of customers they belong to. This information can then be the input to a recommender built specifically per cohort, so that any products recommended are more relevant to that customer.

Apache Samza

Martin Kleppmann
University of Cambridge, Cambridge, UK

Definitions

Apache Samza is an open source framework for distributed processing of high-volume event streams. Its primary design goal is to support high throughput for a wide range of processing patterns, while providing operational robustness at the massive scale required by Internet companies. Samza achieves this goal through a small number of carefully designed abstractions: partitioned

logs for messaging, fault-tolerant local state, and cluster-based task scheduling.

Overview

Stream processing is playing an increasingly important part of the data management needs of many organizations. Event streams can represent many kinds of data, for example, the activity of users on a website, the movement of goods or vehicles, or the writes of records to a database.

Stream processing jobs are long-running processes that continuously consume one or more event streams, invoking some application logic on every event, producing derived output streams, and potentially writing output to databases for subsequent querying. While a batch process or a database query typically reads the state of a dataset at one point in time, and then finishes, a stream processor is never finished: it continually awaits the arrival of new events, and it only shuts down when terminated by an administrator.

Many tasks can be naturally expressed as stream processing jobs, for example:

- aggregating occurrences of events, e.g., counting how many times a particular item has been viewed;
- computing the rate of certain events, e.g., for system diagnostics, reporting, and abuse prevention;
- enriching events with information from a database, e.g., extending user click events with information about the user who performed the action;
- joining related events, e.g., joining an event describing an email that was sent with any events describing the user clicking links in that email;
- updating caches, materialized views, and search indexes, e.g., maintaining an external full-text search index over text in a database;
- using machine learning systems to classify events, e.g., for spam filtering.

Apache Samza, an open source stream processing framework, can be used for any of the above applications (Kleppmann and Kreps 2015; Noghabi et al. 2017). It was originally developed at LinkedIn, then donated to the Apache Software Foundation in 2013, and became a top-level Apache project in 2015. Samza is now used in production at many Internet companies, including LinkedIn (Paramasivam 2016), Netflix (Netflix Technology Blog 2016), Uber (Chen 2016; Hermann and Del Balso 2017), and TripAdvisor (Calisi 2016).

Samza is designed for usage scenarios that require very high throughput: in some production settings, it processes millions of messages per second or trillions of events per day (Feng 2015; Paramasivam 2016; Noghabi et al. 2017). Consequently, the design of Samza prioritizes scalability and operational robustness above most other concerns.

The core of Samza consists of several fairly low-level abstractions, on top of which high-level operators have been built (Pathirage et al. 2016). However, the core abstractions have been carefully designed for operational robustness, and the scalability of Samza is directly attributable to the choice of these foundational abstractions. The remainder of this article provides further detail on

those design decisions and their practical consequences.

Partitioned Log Processing

A Samza job consists of a set of Java Virtual Machine (JVM) instances, called *tasks*, that each processes a subset of the input data. The code running in each JVM comprises the Samza framework and user code that implements the required application-specific functionality. The primary API for user code is the Java interface `StreamTask`, which defines a method `process()`. Figure 1 shows two examples of user classes implementing the `StreamTask` interface.

Once a Samza job is deployed and initialized, the framework calls the `process()` method once for every message in any of the input streams. The execution of this method may have various effects, including querying or updating local state and sending messages to output streams. This model of computation is closely analogous to a map task in the well-known MapReduce programming model (Dean and Ghemawat 2004), with the difference that

```
class SplitWords implements StreamTask {
    static final SystemStream WORD_STREAM =
        new SystemStream("kafka", "words");

    public void process(
        IncomingMessageEnvelope in,
        MessageCollector out,
        TaskCoordinator _) {
        String str = (String) in.getMessage();
        for (String word : str.split(" ")) {
            out.send(
                new OutgoingMessageEnvelope(
                    WORD_STREAM, word, 1));
        }
    }
}
```

```
class CountWords implements StreamTask,
    IitableTask {
    private KeyValueStore<String, Integer> store;

    public void init(Config config,
                     TaskContext context) {
        store = (KeyValueStore<String, Integer>)
            context.getStore("word-counts");
    }

    public void process(
        IncomingMessageEnvelope in,
        MessageCollector out,
        TaskCoordinator _) {
        String word = (String) in.getKey();
        Integer inc = (Integer) in.getMessage();
        Integer count = store.get(word);
        if (count == null) count = 0;
        store.put(word, count + inc);
    }
}
```

Apache Samza, Fig. 1 The two operators of a streaming word-frequency counter using Samza's `StreamTask` API (Image source: Kleppmann and Kreps 2015, © 2015 IEEE, reused with permission)

a Samza job’s input is typically never-ending (*unbounded*).

Similarly to MapReduce, each Samza task is a single-threaded process that iterates over a sequence of input records. The inputs to a Samza job are partitioned into disjoint subsets, and each input partition is assigned to exactly one processing task. More than one partition may be assigned to the same processing task, in which case the processing of those partitions is interleaved on the task thread. However, the number of partitions in the input determines the job’s maximum degree of parallelism.

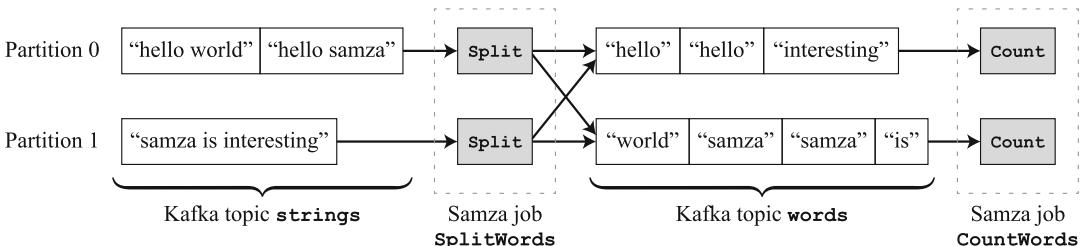

The log interface assumes that each partition of the input is a totally ordered sequence of records and that each record is associated with a monotonically increasing sequence number or identifier (known as *offset*). Since the records in each partition are read sequentially, a job can track its progress by periodically writing the offset of the last read record to durable storage. If a stream processing task is restarted, it resumes consuming the input from the last recorded offset.

Most commonly, Samza is used in conjunction with Apache Kafka (see separate article on Kafka). Kafka provides a partitioned, fault-tolerant log that allows publishers to append messages to a log partition and consumers (subscribers) to sequentially read the messages in a log partition (Wang et al. 2015; Kreps et al. 2011; Goodhope et al. 2012). Kafka also allows stream processing jobs to reprocess previously seen records by resetting the consumer offset to an earlier position, a fact that is useful during recovery from failures.

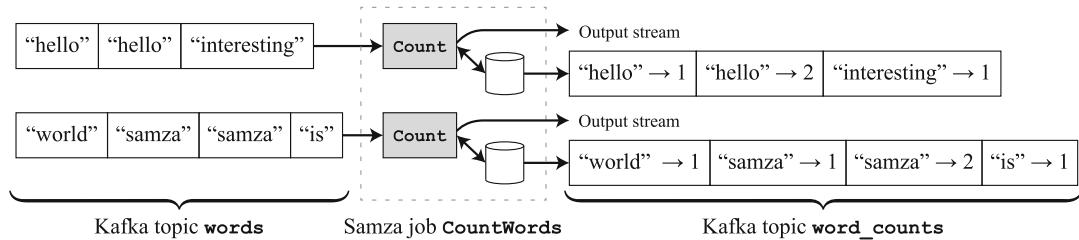

However, Samza’s stream interface is pluggable: besides Kafka, it can use any storage or messaging system as input, provided that the system can adhere to the partitioned log interface. By default, Samza can also read files from the Hadoop Distributed Filesystem (HDFS) as input, in a way that parallels MapReduce jobs, at competitive performance (Noghabi et al. 2017). At LinkedIn, Samza is commonly deployed with *Databus* inputs: Databus is a change data capture technology that records the log of writes to a database and makes this log available for applications to consume (Das et al. 2012; Qiao et al. 2013). Processing the stream of writes to a database enables jobs to maintain external indexes or materialized views onto data in a database and is especially relevant in conjunction with Samza’s support for local state (see section “Fault-Tolerant Local State”) (Fig. 3).

While every partition of an input stream is assigned to one particular task of a Samza job, the output partitions are not bound to tasks. That is, when a `StreamTask` emits output messages, it can assign them to any partition of the output stream. This fact can be used to group related data items into the same partition: for example, in the word-counting application illustrated in Fig. 2, the `SplitWords` task chooses the output partition for each word based on a hash of the word. This ensures that when different tasks encounter occurrences of the same word, they are all written to the same output partition, from where a downstream job can read and aggregate the occurrences.

When stream tasks are composed into multi-stage processing pipelines, the output of one task

Apache Samza, Fig. 2 A Samza task consumes input from one partition, but can send output to any partition (Image source: Kleppmann and Kreps 2015, © 2015 IEEE, reused with permission)

Apache Samza, Fig. 3 A task’s local state is made durable by emitting a changelog of key-value pairs to Kafka (Image source: Kleppmann and Kreps 2015, © 2015 IEEE, reused with permission)

becomes the input to another task. Unlike many other stream processing frameworks, Samza does not implement its own message transport layer to deliver messages between stream operators. Instead, Kafka is used for this purpose; since Kafka writes all messages to disk, it provides a large buffer between stages of the processing pipeline, limited only by the available disk space on the Kafka brokers.

Typically, Kafka is configured to retain several days or weeks worth of messages in each topic. Thus, if one stage of a processing pipeline fails or begins to run slow, Kafka can simply buffer the input to that stage while leaving ample time for the problem to be resolved. Unlike system designs based on backpressure, which require a producer to slow down if the consumer cannot keep up, the failure of one Samza job does not affect any upstream jobs that produce its inputs. This fact is crucial for the robust operation of large-scale systems, since it provides fault containment: as far as possible, a fault in one part of the system does not negatively impact other parts of the system.

Messages are dropped only if the failed or slow processing stage is not repaired within the retention period of the Kafka topic. In this case, dropping messages is desirable because it isolates the fault: the alternative – retaining messages indefinitely until the job is repaired – would lead to resource exhaustion (running out of memory or disk space), which would cause a cascading failure affecting unrelated parts of the system.

Thus, Samza’s design of using Kafka’s on-disk logs for message transport is a crucial factor in its scalability: in a large organization, it is often the case that an event stream produced by

one team’s job is consumed by one or more jobs that are administered by other teams. The jobs may be operating at different levels of maturity: for example, a stream produced by an important production job may be consumed by several unreliable experimental jobs. Using Kafka as a buffer between jobs ensures that adding an unreliable consumer does not negatively impact the more important jobs in the system.

Finally, an additional benefit of using Kafka for message transport is that every message stream in the system is accessible for debugging and monitoring: at any point, an additional consumer can be attached to inspect the message flow.

Fault-Tolerant Local State

Stateless stream processing, in which any message can be processed independently from any other message, is easy to implement and scale. However, many important applications require that stream processing tasks maintain state. For example:

- when performing a join between two streams, a task must maintain an index of messages seen on each input within some time window, in order to find messages matching the join condition when they arrive;
- when computing a rate (number of events per time interval) or aggregation (e.g., sum of a particular field), a task must maintain the current aggregate value and update it based on incoming events;

- when processing an event requires a database query to look up some related data (e.g., looking up a user record for the user who performed the action in the event), the database can also be regarded as stream processor state.

Many stream processing frameworks use transient state that is kept in memory in the processing task, for example, in a hash table. However, such state is lost when a task crashes or when a processing job is restarted (e.g., to deploy a new version). To make the state fault-tolerant, some frameworks such as Apache Flink periodically write checkpoints of the in-memory state to durable storage (Carbone et al. 2015); this approach is reasonable when the state is small, but it becomes expensive as the state grows (Noghabi et al. 2017).

Another approach, used, for example, by Apache Storm, is to use an external database or key-value store for any processor state that needs to be fault-tolerant. This approach carries a severe performance penalty: due to network latency, accessing a database on another node is orders of magnitude slower than accessing local in-process state (Noghabi et al. 2017). Moreover, a high-throughput stream processor can easily overwhelm the external database with queries; if the database is shared with other applications, such overload risks harming the performance of other applications to the point that they become unavailable (Kreps 2014).

In response to these problems, Samza pioneered an approach to managing state in a stream task that avoids the problems of both checkpointing and remote databases. Samza's approach to providing fault-tolerant local state has subsequently been adopted in the Kafka Streams framework (see article on Apache Kafka).

Samza allows each task to maintain state on the local disk of the processing node, with an in-memory cache for frequently accessed items. By default, Samza uses RocksDB, an embedded key-value store that is loaded into the JVM process of the stream task, but other storage engines can also be plugged in its place. In Fig. 1, the CountWords task accesses this managed state

through the `KeyValueStore` interface. For workloads with good locality, Samza's RocksDB with cache provides performance close to in-memory stores; for random-access workloads on large state, it remains significantly faster than accessing a remote database (Noghabi et al. 2017).

If a job is cleanly shut down and restarted, for example, to deploy a new version, Samza's host affinity feature tries to launch each `StreamTask` instance on the machine that has the appropriate RocksDB store on its local disk (subject to available resources). Thus, in most cases the state survives task restart without any further action. However, in some cases – for example, if a processing node suffers a full system failure – the state on the local disk may be lost or rendered inaccessible.

In order to survive the loss of local disk storage, Samza again relies on Kafka. For each store containing state of a stream task, Samza creates a Kafka topic called a *changelog* that serves as a replication log for the store. Every write to the local RocksDB store is also encoded as a message and published to this topic, as illustrated in Fig. 3. These writes can be performed asynchronously in batches, enabling much greater throughput than synchronous random-access requests to a remote data store. The write queue needs to only be flushed when the offsets of input streams are written to durable storage, as described in the last section.

When a Samza task needs to recover its state after the loss of local storage, it reads all messages in the appropriate partition of the changelog topic and applies them to a new RocksDB store. When this process completes, the result is a new copy of the store that contains the same data as the store that was lost. Since Kafka replicates all data across multiple nodes, it is suitable for fault-tolerant durable storage of this changelog.

If a stream task repeatedly writes new values for the same key in its local storage, the changelog contains many redundant messages, since only the most recent value for a given key is required in order to restore local storage. To remove this redundancy, Samza uses a Kafka feature called *log compaction*

on the changelog topic. With log compaction enabled, Kafka runs a background process that searches for messages with the same key and discards all but the most recent of those messages. Thus, whenever a key in the store is overwritten with a new value, the old value is eventually removed from the changelog. However, any key that is not overwritten is retained indefinitely by Kafka. This compaction process, which is very similar to internal processes in log-structured storage engines, ensures that the storage cost and recovery time from a changelog corresponds to the size of the state, independently of the total number of messages ever sent to the changelog (Kleppmann 2017).

Cluster-Based Task Scheduling

When a new stream processing job is started, it must be allocated computing resources: CPU cores, RAM, disk space, and network bandwidth. Those resources may need to be adjusted from time to time as load varies and reclaimed when a job is shut down.

At large organizations, hundreds or thousands of jobs need to run concurrently. At such scale, it is not practical to manually assign resources: task scheduling and resource allocation must be automated. To maximize hardware utilization, many jobs and applications are deployed to a shared pool of machines, with each multi-core machine typically running a mixture of tasks from several different jobs.

This architecture requires infrastructure for managing resources and for deploying the code of processing jobs to the machines on which it is to be run. Some frameworks, such as Storm and Flink, have built-in mechanisms for resource management and deployment. However, frameworks that perform their own task scheduling and cluster management generally require a static assignment of computing resources – potentially even dedicated machines – before any jobs can be deployed to the cluster. This static resource allocation leads to inefficiencies in machine

utilization and limits the ability to scale on demand (Kulkarni et al. 2015).

By contrast, Samza relies on existing cluster management software, which allows Samza jobs to share a pool of machines with non-Samza applications. Samza supports two modes of distributed operation:

- A job can be deployed to a cluster managed by Apache Hadoop YARN (Vavilapalli et al. 2013). YARN is a general-purpose resource scheduler and cluster manager that can run stream processors, MapReduce batch jobs, data analytics engines, and various other applications on a shared cluster. Samza jobs can be deployed to existing YARN clusters without requiring any special cluster-level configuration or resource allocation.
- Samza also supports a *stand-alone* mode in which a job’s JVM instances are deployed and executed through some external process that is not under Samza’s control. In this case, the instances use Apache ZooKeeper (Junqueira et al. 2011) to coordinate their work, such as assigning partitions of the input streams.

The stand-alone mode allows Samza to be integrated with an organization’s existing deployment and cluster management tools or with cloud computing platforms: for example, Netflix runs Samza jobs directly as EC2 instances on Amazon Web Services (AWS), relying on the existing cloud facilities for resource allocation (Paramasivam 2016). Moreover, Samza’s cluster management interface is pluggable, enabling further integrations with other technologies such as Mesos (Hindman et al. 2011).

With large deployments, an important concern is resource isolation, that is, ensuring that each process receives the resources it requested and that a misbehaving process cannot starve colocated processes of resources. When running in YARN, Samza supports the Linux cgroups feature to enforce limits on the CPU and memory use of stream processing tasks. In virtual machine environments such as EC2, resource isolation is enforced by the hypervisor.

Summary

Apache Samza is a stream processing framework that is designed to provide high throughput and operational robustness at very large scale. Efficient resource utilization requires a mixture of different jobs to share a multi-tenant computing infrastructure. In such an environment, the primary challenge in providing robust operation is fault isolation, that is, ensuring that a faulty process cannot disrupt correctly running processes and that a resource-intensive process cannot starve others.

Samza isolates stream processing jobs from each other in several different ways. By using Kafka's on-disk logs as a large buffer between producers and consumers of a stream, instead of backpressure, Samza ensures that a slow or failed consumer does not affect upstream jobs. By providing fault-tolerant local state as a common abstraction, Samza improves performance and avoids reliance on external databases that might be overloaded by high query volume. Finally, by integrating with YARN and other cluster managers, Samza builds upon existing resource scheduling and isolation technology that allows a cluster to be shared between many different applications without risking resource starvation.

Apache Spark

Alexandre da Silva Veith and Marcos Dias de Assuncao
Inria Avalon, LIP Laboratory, ENS Lyon,
University of Lyon, Lyon, France

Definitions

Apache Spark is a cluster computing solution and in-memory processing framework that extends the MapReduce model to support other types of computations such as interactive queries and stream processing (Zaharia et al. 2012). Designed to cover a variety of workloads, Spark introduces an abstraction called Resilient Distributed Datasets (RDDs) that enables running

computations in memory in a fault-tolerant manner. RDDs, which are immutable and partitioned collections of records, provide a programming interface for performing operations, such as map, filter, and join, over multiple data items. For fault-tolerance purposes, Spark records all transformations carried out to build a dataset, thus forming a *lineage graph*.

A

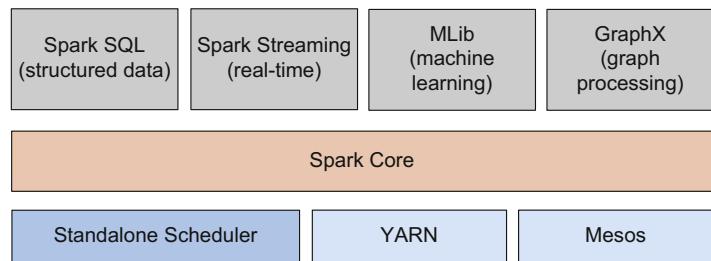

Overview

Spark (Zaharia et al. 2016) is an open-source big data framework originally developed at the University of California at Berkeley and later adopted by the Apache Foundation, which has maintained it ever since. Spark was designed to address some of the limitations of the MapReduce model, especially the need for speed processing of large datasets. By using RDDs, purposely designed to store restricted amounts of data in memory, Spark enables performing computations more efficiently than MapReduce, which runs computations on the disk.

Although the project contains multiple components, at its core (Fig. 1) Spark is a computing engine that schedules, distributes, and monitors applications comprising multiple tasks across nodes of a computing cluster (Karau et al. 2015). For cluster management, Spark supports its native Spark cluster (standalone), Apache YARN (Vavilapalli et al. 2013), or Apache Mesos (Hindman et al. 2011). At the core also lies the RDD abstraction. RDDs are sets of data items distributed across the cluster nodes and that can be manipulated in parallel. At a higher level, it provides support for multiple tightly integrated components for handling various types of workloads such as SQL, streaming, and machine learning.

Figure 2 depicts an example of a word count application using Spark’s Scala API for manipulating datasets. Spark computes RDDs in a lazy fashion, the first time they are used. Hence, the code in the example is evaluated when the counts are saved to disk, in which moment the results of the computation are required. Spark can also read data from

Apache Spark, Fig. 1
The Apache Spark stack
(Karau et al. 2015)

Word count example using
Spark's Scala API (Karau
et al. 2015)

```

// Create a Scala Spark configuration context
val config = new SparkConf().setAppName("WordCount")
val sc = new SparkContext(config)

// Load the input data
val input = sc.textFile(theInputFile)

// Split it into words
val words = input.flatMap(line => line.split(" "))

// Transform into pairs and count
val counts = words.map(word =>
    (word, 1)).reduceByKey{case (x, y) => x + y}

// Save the word count to a text file
counts.saveAsTextFile(theOutputFile)
  
```

various sources, such as Hadoop Distributed File System (HDFS), Cassandra, OpenStack Swift (<https://wiki.openstack.org/wiki/Swift>), and Amazon Simple Storage Service (S3) (<https://aws.amazon.com/s3/>).

Spark SQL

Spark SQL (Armbrust et al. 2015) is a module for processing structured data (<https://spark.apache.org/docs/latest/sql-programming-guide.html>). It builds on the RDD abstraction by providing Spark core engine with more information about the structure of the data and the computation being performed. In addition to enabling users to perform SQL queries, Spark SQL provides the Dataset API, which offers datasets and DataFrames. A dataset can be built using JVM objects that can then be manipulated using functional transformations. A DataFrame can be built from a large number of sources and is analogous to a table in a relational database; it is a dataset organized into named columns.

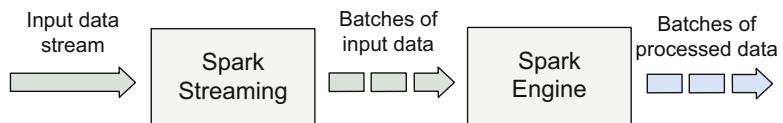

Spark Streaming

Spark Streaming provides a micro-batch-based framework for processing data streams. Data can be ingested from systems such as Apache Kafka (<https://kafka.apache.org/>), Flume, or Amazon Kinesis (<https://aws.amazon.com/kinesis/>). Under the traditional stream processing approach based on a graph of continuous operators that process tuples as they arrive (i.e., the dataflow model), it is arguably difficult to achieve fault tolerance and handle stragglers. As application state is often kept by multiple operators, fault tolerance is achieved either by replicating sections of the processing graph or via upstream backup. The former demands synchronization of operators via a protocol such as Flux (Shah et al. 2003) or other transactional protocols (Wu et al. 2015), whereas the latter, when a node fails, requires parents to replay previously sent messages to rebuild the state.

Spark Streaming uses a high-level abstraction called *discretised stream* or *DStream* (Zaharia et al. 2013). As depicted in Fig. 3, DStreams

Apache Spark, Fig. 3

High-level view of discretized streams

A

follow a micro-batch approach that organizes stream processing as batch computations carried out periodically over small time windows. During a short time interval, DStreams store the received data, which the cluster resources then use as input dataset for performing parallel computations once the interval elapses. These computations produce new datasets that represent an intermediate state or computation outputs. The intermediate state consists of RDDs that DStreams process along with the datasets stored during the next interval. In addition to providing a strong unification with batch processing, this model stores the state in memory as RDDs that DStreams can deterministically recompute. This micro-batch approach, however, sacrifices response time as the delay for processing events is dependent on the length of the micro-batches.

MLlib

Spark contains a library with common machine learning (ML) functionality such as learning algorithms for classification, regression, clustering, and collaborative filtering and featurization including feature extraction, transformation, dimensionality reduction, and selection (Meng et al. 2016). MLlib also enables the creation of ML pipelines and persistence of algorithms, models, and pipelines. These features are designed to scale out across large computing clusters using Spark’s core engine.

GraphX

GraphX (Gonzalez et al. 2014) extends the RDD API by enabling the creation of a multigraph (i.e., the property graph) with arbitrary properties attached to vertices and edges. The library is designed for manipulating graphs, exposing a set of operators (e.g., subgraph, joinVertices), and for carrying out parallel computations. It contains a library of common graph algorithms, such as PageRank and triangle counting.

Examples of Applications

Spark has been used for several data processing and data science tasks, but the range of applications that it enables is endless. Freeman et al. (2014), for instance, designed a library called Thunder on top of Spark for large-scale analysis of neural data. Many machine learning and statistical algorithms have been implemented for MLlib, which simplifies the construction of machine learning pipelines. The source code of Spark has also grown substantially since it became an Apache project. Numerous third-party libraries and packages have been included for performing tasks in certain domains or for simplifying the use of existing APIs.

Spark provides the functionalities that data scientists need to perform data transformation, processing, and analysis. Data scientists often need to perform ad hoc exploration during which they have to test new algorithms or verify the results in the least amount of time. Spark provides APIs, libraries, and shells that allow scientists to perform such tasks while enabling them to test their algorithms on large problem sizes. Once the exploration phase is performed, the solution is productized by engineers who integrate the data analysis tasks into an often more complex business application.

Examples of applications built using Apache Spark include analysis of data from mobile devices (Alsheikh et al. 2016) and Internet of Things (IoT), web-scale graph analytics, anomaly detection of user behavior and network traffic for information security (Ryza et al. 2017), real-time machine learning, data stream processing pipelines, engineering workloads, and geospatial data processing, to cite just a few. New application scenarios are presented each year during Spark’s Summit (<https://spark-summit.org/>), an event that has become a showcase of next-generation big data applications.

Future Directions of Research

Spark APIs shine both during exploratory work and when engineering a solution deployed in production. Over the years, much effort has been paid toward making APIs easier to use and to optimize, for instance, the introduction of the Dataset API to avoid certain performance degradations that could occur if a user did not properly design the chain of operations executed by the Spark engine. As mentioned earlier, considerable work has also focused on creating new libraries and packages, including for processing live streams. The discretized model employed by Spark's stream processing API, however, introduces some delays depending on the time length of micro-batches. More recent and emerging application scenarios, such as analysis of vehicular traffic and networks, monitoring of operational infrastructure, wearable assistance (Ha et al. 2014), and 5G services, require data processing and service response under very short delays. Spark can be used as part of a larger service workflow, but alone it does not provide means to address some of the challenging scenarios that require very short response times. This requires the use of other frameworks such as Apache Storm.

To reduce the latency of applications delivered to users, many service components are also increasingly being deployed at the edges of the Internet (Hu et al. 2015) under a model commonly called edge computing. Some frameworks are available for processing streams of data using resources at the edge (e.g., Apache Edgent (<https://edgent.apache.org/>)), whereas others are emerging. There are also frameworks that aim to provide high-level programming abstractions for creating dataflows (e.g., Apache Beam (<https://beam.apache.org/>)) with underlying execution engines for several processing solutions. There is, however, a lack of unifying solutions on programming models and abstractions for exploring resources from both cloud and edge computing deployments, as well as scheduling and resource management tools for deciding what processing tasks need to be offloaded to the edge.

Apache SystemML

Declarative Large-Scale Machine Learning

Matthias Boehm
IBM Research – Almaden, San Jose, CA, USA

Definitions

Apache SystemML (Ghoting et al. 2011; Boehm et al. 2016) is a system for declarative, large-scale machine learning (ML) that aims to increase the

productivity of data scientists. ML algorithms are expressed in a high-level language with R- or Python-like syntax, and the system automatically generates efficient, hybrid execution plans of single-node CPU or GPU operations, as well as distributed operations using data-parallel frameworks such as MapReduce (Dean and Ghemawat 2004) or Spark (Zaharia et al. 2012). SystemML’s high-level abstraction provides the necessary flexibility to specify custom ML algorithms while ensuring physical data independence, independence of the underlying runtime operations and technology stack, and scalability for large data. Separating the concerns of algorithm semantics and execution plan generation is essential for the automatic optimization of execution plans regarding different data and cluster characteristics, without the need for algorithm modifications in different deployments.

A

Overview

In SystemML (Ghoting et al. 2011; Boehm et al. 2016), data scientists specify their ML algorithms using a language with R- or Python-like syntax. This language supports abstract data types for scalars, matrices and frames, and operations such as linear algebra, element-wise operations, aggregations, indexing, and statistical operations but also control structures such as loops, branches, and functions. These scripts are parsed into a hierarchy of statement blocks and statements, where control flow delineates the individual blocks. For each block of statements, the system then compiles DAGs (directed acyclic graphs) of high-level operators (HOPs), which is the core internal representation of SystemML’s compiler. Size information such as matrix dimensions and sparsity are propagated via intra- and inter-procedural analysis from the inputs through the entire program. This size information is then used to compute memory estimates per operator and accordingly select physical operators resulting in a DAG of low-level operators (LOPs). These LOP DAGs are finally compiled into executable instructions.

Example: As an example, consider the following script for linear regression via a closed-

form method that computes and solves the normal equations:

```

1: X = read($X);
2: y = read($Y);
3: lambda = 0.001;
4: if( $icpt == 1 )
5:     X = cbind(X, matrix(1, nrow(X), 1));
6: I = matrix(1, ncol(X), 1);
7: A = t(X) %*% X + diag(I) * lambda;
8: b = t(X) %*% y;
9: beta = solve(A, b);
10: write(beta, $B);

```

This script reads the feature matrix \mathbf{X} and labels \mathbf{y} , optionally appends a column of 1s to \mathbf{X} for computing the intercept, computes the normal equations, and finally solves the resulting linear system of equations. SystemML then compiles, for example, for lines 6–10, a HOP DAG that contains logical operators such as matrix multiplications for $\mathbf{X}^\top \mathbf{X}$ and $\mathbf{X}^\top \mathbf{y}$. Given input metadata (e.g., let \mathbf{X} be a dense $10^7 \times 10^3$ matrix), the compiler also computes memory estimates for each operation (e.g., 80.08 GB for $\mathbf{X}^\top \mathbf{y}$). If the memory estimate of an operation exceeds the driver memory budget, this operation is scheduled for distributed execution, and appropriate physical operators are selected (e.g., mapmm as a broadcast-based operator for $\mathbf{X}^\top \mathbf{y}$).

Static and Dynamic Rewrites: SystemML’s optimizer applies a broad range of optimizations throughout its compilation chain. An important class of optimizations with high-performance impact are rewrites. SystemML applies static and dynamic rewrites (Boehm et al. 2014a). Static rewrites are size-independent and include traditional programming language techniques – such as common subexpression elimination, constant folding, and branch removal – algebraic simplifications for linear algebra, as well as backend-specific transformations such as caching and partitioning directives for Spark. For instance, in the above example, after constant propagation, constant folding,

and branch removal, the block of lines 4–5 is removed if $\$icpt==0$, which further allows unconditional size propagation and the merge of the entire program into a single HOP DAG. Furthermore, the expression ‘ $\text{diag}(\text{matrix}(1, \text{ncol}(\mathbf{X}), 1)) \odot \lambda$ ’ is simplified to ‘ $\text{diag}(\text{matrix}(\lambda, \text{ncol}(\mathbf{X}), 1))$ ’, which avoids unnecessary operations and intermediates. SystemML’s rewrite system contains hundreds of such rewrites, some of which even change the asymptotic behavior (e.g., $\text{trace}(\mathbf{XY}) \rightarrow \sum(\mathbf{X} \odot \mathbf{Y}^\top)$). Additional dynamic rewrites are size-dependent because they require sizes for cost estimation or validity constraints. Examples are matrix multiplication chain optimization as well as dynamic simplification rewrites such as $\sum(\mathbf{X}^2) \rightarrow \mathbf{X}^\top \mathbf{X} \mid \text{ncol}(\mathbf{X}) = 1$. The former exploits the associativity of matrix multiplications and aims to find an optimal parenthesization for which SystemML applies a textbook dynamic programming algorithm (Boehm et al. 2014a).

Operator Selection and Fused Operators: Another important class of optimizations is the selection of execution types and physical operators (Boehm et al. 2016). SystemML’s optimizer analyzes the memory budgets of the driver and executors and selects – based on worst-case memory estimates (Boehm et al. 2014b) – local or distributed execution types. Besides data and cluster characteristics (e.g., data size/shape, memory,

and parallelism), the compiler also considers matrix and operation properties (e.g., diagonal/symmetric matrices, sparse-safe operations) as well as data flow properties (e.g., co-partitioning and data locality). Depending on the chosen execution types, different physical operators are considered with a selection preference from local or special-purpose to shuffle-based operators. For example, the multiplication $\mathbf{X}^\top \mathbf{X}$ from line 7 allows for a special transpose-self operator (`t smm`), which is an easily parallelizable unary operator that exploits the output symmetry for less computation. For distributed operations, this operator has a block size constraint because it requires access to entire rows. If special-purpose or broadcast-based operators do not apply, the compiler falls back to the shuffle-based `cpmm` and `rmm` operators (Ghoting et al. 2011). Additionally, SystemML replaces special patterns with hand-coded fused operators to avoid unnecessary intermediates (Huang et al. 2015; Elgamal et al. 2017) and unnecessary scans (Boehm et al. 2014a; Ashari et al. 2015; Elgamal et al. 2017), as well as to exploit sparsity across chains of operations (Boehm et al. 2016; Elgamal et al. 2017). For example, computing the weighted squared loss via $\text{sum}(\mathbf{W} \odot (\mathbf{X} - \mathbf{U}\mathbf{V}^\top)^2)$ would create huge dense intermediates. In contrast, sparsity-exploiting operators leverage the sparse driver (i.e., the sparse matrix \mathbf{W} and the sparse-safe multiply \odot) for selective computation that only considers nonzeros in \mathbf{W} .

Dynamic Recompilation: Dynamic rewrites and operator selection rely on size information for memory estimates, cost estimation, and validity constraints. Hence, unknown dimensions or sparsity lead to conservative fallback plans. Example scenarios are complex conditional control flow or function call graphs, user-defined functions, data-dependent operations, computed size expressions, and changing sizes or sparsity as shown in the following example:

```

1: while( continue ) {
2:     parfor( i in 1:n ) {
3:         if( fixed[1,i] == 0 ) {
4:             X = cbind(Xg, Xorig[,i]);
5:             AIC[1,i] = linregDS(X,y);
6:         }
7:         #select & append best to Xg
8:     }
9: }
```

This example originates from a stepwise linear regression algorithm for feature selection that iteratively selects additional features and calls the previously introduced regression algorithm. SystemML addresses this challenge of unknown sizes via dynamic recompilation (Boehm et al. 2014a) that recompiles subplans – at the granularity of HOP DAGs – with exact size information of intermediates during runtime. During initial compilation, operations and DAGs with unknowns are marked for dynamic recompilation, which also includes splitting DAGs after data-dependent operators. During runtime, the recompiler then deep copies the HOP DAG, updates sizes, applies dynamic rewrites, recomputes memory estimates, generates new runtime instructions, and resumes execution with the intermediate results computed so far. This approach yields good plans and performance even in the presence of initial unknowns.

Runtime Integration: At runtime level, SystemML interprets the generated instructions. Single-node and Spark operations directly map to instructions, whereas for the MapReduce backend, instructions are packed into a minimal number of MR jobs. For distributed operations, matrices (and similarly frames) are stored in a blocked representation of pairs of block indexes and blocks with fixed block size, where individual blocks can be dense, sparse, or ultra-sparse. In contrast, for single-node operations, the entire matrix is represented as a single block, which allows reusing the block runtime across backends. Data transfers between the local and distributed backends and driver memory management are handled by a multilevel buffer pool (Boehm et al. 2016) that controls local evictions, parallelizes and collects RDDs, creates broadcasts, and reads/writes data from/to the distributed file system. For example, a single-node instruction first pins its inputs into memory – which triggers reads from HDFS or RDDs if necessary – performs the block operation, registers the output in the buffer pool, and finally unpins its inputs. Many block operations and the I/O system for different formats are multi-threaded to exploit parallelism in scale-up environments. For compute-intensive deep

learning workloads, SystemML further calls native CPU and GPU libraries for BLAS and DNN operations. In contrast to other deep learning frameworks, SystemML also supports sparse neural network operations. Memory management for the GPU device is integrated with the buffer pool allowing for lazy data transfer on demand. Finally, SystemML uses numerically stable operations based on Kahan addition for descriptive statistics and certain aggregation functions (Tian et al. 2012).

Key Research Findings

In addition to the compiler and runtime techniques described so far, there are several advanced techniques with high-performance impact.

Task-Parallel Parfor Loops: SystemML’s primary focus is data parallelism. However, there are many use cases such as ensemble learning, cross validation, hyper-parameter tuning, and complex models with disjoint or overlapping data that are naturally expressed in a task-parallel manner. These scenarios are addressed by SystemML’s `parfor` construct for parallel for loops (Boehm et al. 2014b). In contrast to similar constructs in high-performance computing (HPC), `parfor` only asserts the independence of iterations, and a dedicated `parfor` optimizer reasons about hybrid parallelization strategies that combine data and task parallelism. Reconsider the stepwise linear regression example. Alternative plan choices include (1) a local, i.e., multi-threaded, `parfor` with local operations, (2) a remote `parfor` that runs the entire loop as a distributed Spark job, or (3) a local `parfor` with concurrent data-parallel Spark operations if the data does not fit into the driver.

Resource Optimization: The selection of execution types and operators is strongly influenced by memory budgets of the driver and executor processes. Finding a good static cluster configuration that works well for a broad range of ML algorithms and data sizes is a hard problem.

SystemML addresses this challenge with a dedicated resource optimizer for automatic resource provisioning (Huang et al. 2015) on resource negotiation frameworks such as YARN or Mesos. The key idea is to optimize resource configurations via an online what-if analysis with regard to the given ML program as well as data and cluster characteristics. This framework optimizes performance without unnecessary over-provisioning, which can increase throughout in shared on-premise clusters and save money in cloud environments.

Compressed Linear Algebra: Furthermore, there is a broad class of iterative ML algorithms that use repeated read-only data access and I/O-bound matrix-vector multiplications to converge to an optimal model. For these algorithms, it is crucial for performance to fit the data into available single-node or distributed memory. However, general-purpose, lightweight, and heavyweight compression techniques struggle to achieve both good compression ratios and fast decompression to enable block-wise uncompressed operations. Compressed linear algebra (CLA) (Elgohary et al. 2016) tackles this challenge by applying lightweight database compression techniques – for column-wise compression with heterogeneous encoding formats and co-coding – to matrices and executing linear algebra operations such as matrix-vector multiplications directly on the compressed representation. CLA yields compression ratios similar to heavyweight compression and thus allows fitting large datasets into memory while achieving operation performance close to the uncompressed case.

Automatic Operator Fusion: Similar to query compilation and loop fusion in databases and HPC, the opportunities for fused operators – in terms of fused chains of operations – are ubiquitous. Example benefits are a reduced number of intermediates, reduced number of scans, and sparsity exploitation across operations. Despite their high-performance impact, hand-coded fused operators are usually limited to few operators and incur a large development effort. Automatic operator fusion via code generation (Elgamal et al. 2017) overcomes this challenge

by automatically determining valid fusion plans and generating access-pattern-aware operators in the form of hand-coded skeletons with custom body code. In contrast to existing work on operator fusion, SystemML introduced a cost-based optimizer framework to find optimal fusion plans in DAGs of linear algebra programs for dense, sparse, and compressed data as well as local and distributed operations.

Examples of Application

SystemML has been applied in a variety of ML applications including statistics, classification, regression, clustering, matrix factorization, survival analysis, and deep learning. In contrast to specialized systems for graphs like GraphLab (Low et al. 2012) or deep learning like TensorFlow (Abadi et al. 2016), SystemML provides a unified system for small- to large-scale problems with support for dense, sparse, and ultra-sparse data, as well as local and distributed operations. Accordingly, SystemML’s primary application area is an environment with diverse algorithms, varying data characteristics, or different deployments.

Example deployments include large-scale computation on top of MapReduce or Spark and programmatic APIs for notebook environments or embedded scoring. Thanks to deployment-specific compilation, ML algorithms can be reused without script changes. This flexibility enabled the integration of SystemML into systems with different architectures. For example, SystemML has been shipped as part of the open-source project R4ML and the IBM products BigInsights, Data Science Experience (DSX), and multiple Watson services.

Future Directions for Research

Given the goal of a unified system for ML applications and recent algorithm and hardware trends, there are many directions for future research

throughout the stack of SystemML and similar systems (Kumar et al. 2017):

Specification Languages: SystemML focuses on optimizing fixed algorithm specifications. However, end-to-end applications would further benefit from even higher levels of abstractions for feature engineering, model selection, and life cycle management in general. A promising direction is a stack of declarative languages that allows for reuse and cross-level optimization.

Optimization Techniques: Regarding the automatic optimization of ML programs, further work is required regarding size and sparsity estimates, adaptive query processing and storage (as an extension of dynamic recompilation), and principled approaches to automatic rewrites and automatic operator fusion.

Runtime Techniques: A better support for deep learning and scientific applications requires the extension from matrices to dense/sparse tensors of different data types and their operations. Additionally, further research is required regarding the automatic exploitation of accelerators and heterogenous hardware.

Benchmarks: Finally, SystemML – but also the community at large – would benefit from dedicated benchmarks for the different classes of ML workloads and different levels of specification languages.

Applications

► Big Data in Computer Network Monitoring

Applications of Big Spatial Data: Health

Lance A. Waller

Department of Biostatistics and Bioinformatics,
Rollins School of Public Health, Emory
University, Atlanta, GA, USA

Definitions

The term “big spatial data” encompasses all types of big data with the addition of geographic reference information, typically a location associated with a point in space (e.g., latitude, longitude, and altitude coordinates), an area (e.g., a country, a district, or a census enumeration zone), a line or curve (e.g., a river or a road), or a pixel (e.g., high-resolution satellite images or a biomedical imaging scan). When applied to questions of health, big spatial data can aid in attempts to understand geographic variations in the risks and rates of disease (e.g., is risk here greater than risk there?), to identify local factors driving geographic variations in risks and rates (e.g., does local nutritional status impact local childhood mortality?), and to evaluate the impact of local health policies (e.g., district-specific adjustments to insurance reimbursements).

In addition to defining big spatial data, it is also important to define what is meant by “health.” The World Health Organization defines *health* as “a state of complete physical, mental and social well-being and not merely the absence of disease or infirmity” (Preamble to the WHO Constitution, <http://www.who.int/suggestions/faq/en/>). This can be interpreted at the individual level and at the population level. At the population level, the US Centers for Disease Control and Prevention define *public health* as “the science of protecting and improving the health of people and their communities. This work is achieved by promoting healthy lifestyles, researching disease and injury prevention, and detecting, preventing and responding to

infectious diseases” (<https://www.cdcfoundation.org/what-public-health>). More recently, there has been increasing interest in the concept of *population health*, i.e., “the health outcomes of a group of individuals, including the distribution of such outcomes within the group” (Kindig and Stoddard 2003). Both public and population health focus on measures of health in an overall community with public health typically focusing on health promotion and disease prevention and population health as defining current and target distributions of health outcomes across a population, typically, to evaluate the impact of policy (e.g., government funding or insurance coverage).

Overview

The rapid expansion of measurement technology, data storage, informatics, and analytics feeds rapid growth in applications of big data within the fields of individual, population, and public health. The sequencing of the human genome in 2001 was rapidly followed by the ability to measure multiple aspects of the human metabolome, transcriptome, microbiome, and overall exposure to the environment (the exposome) (Miller and Jones 2014; Wild 2005). These detailed views of the complex world of each individual’s genetic, environmental, and social makeup provide quantitative insight into a more nuanced view of “health” than simply the absence of disease; rather, the measures begin to provide a view into *how* health works at individual, local, societal, and global levels. The measures move from tracking individual biomarkers to panels of biomarkers and toward integration of heterogeneous streaming of information from wearable sensors, local exposure monitors, and georeferenced tracking devices. These heterogeneous data sources enable increasingly detailed exploration of associations between an individual’s location and their phenotype, genotype, and multiple influencing factors relating to diet, activity level, environment, and prevention activities, some of which vary locally themselves. More specifically,

the multiple measures provide insight into aspects of and interactions between the elements of individual, public, and population health, defined above.

Geography provides a key context for all three types of health; specifically, the locations where one lives and works contribute greatly to one’s individual exposome and to the range of environmental and social determinants of disease (and health) associated with the health of the local population. As a result, big spatial data play a key (and expanding) role in the definition, description, and understanding of health.

Key Research Findings

The rapid increase of health-related data and the continued growth of geographic information systems and science (Goodchild 1992) impact both health care and health research. In addition, the ecosocial theory of social determinants of health (Krieger 2001) motivated many health leaders (including the Director of the Robert Wood Johnson Foundation and the Director of the US National Institutes of Health) to comment that an individual’s ZIP code (US postal code) is a more powerful predictor of health than that individual’s genetic code.

Spatial analysis of health traditionally includes geographically referenced, local information on health outcomes, demographics, economics, policies, and potential exposures. Analyses often focus on predicting exposures from a fixed set of observations, assessing of whether point locations of disease occur in geographically concentrated “clusters” or quantifying associations between health outcomes and local measures of potential risk factors (Waller and Gotway 2004). A variety of biostatistical and epidemiologic methods have been extended to allow for potential spatial and spatiotemporal correlations.

The incorporation of big data into a spatial setting provides intriguing opportunities to refine both concepts of health and concepts of location as illustrated below.

Examples of Application

Beginning at the individual patient level, electronic health records (EHRs) contain a potential trove of medical information regarding individual's interaction with the healthcare system, consolidating information invaluable for health care (Murdoch and Detsky 2013). This information typically is stored in multiple, heterogeneous formats designed to allow access by healthcare professionals for determining patient care. Within a given health system, these records are often consolidated into secure data warehouses to allow system-wide assessment of quality of care, monitoring of costs, and reimbursement by health insurance systems. Moving from health care of an individual to research often requires assessing information from multiple systems in different formats. Recent years have seen an increase in explorations of the research potential of EHRs, including (but not limited to) applications of natural language processing of text fields filled by healthcare professionals, development of searchable database of biomedical images, and system-wide assessments of healthcare performance.

In addition to the development of informatics and analytics for EHRs, there is also a rapid increase in applications of informatics and distributed computing services to manage, merge, search, and summarize streaming data from multiple devices within a healthcare setting such as an intensive care unit, emergency department, or surgery facility. Some measures are monitored almost continuously (e.g., blood pressure, blood oxygen levels), while others occur on less frequent timescales (e.g., baseline levels, treatment protocols, caregivers on call). Similar issues arise outside of the healthcare setting in the increasing popularity of wearable monitoring technology providing feedback on activity levels, heart rate, and, in some cases, measures of one's ambient environment. In many cases, such streaming technologies are linked to mobile devices that are also recording location information leading to the development of georeferenced mobile health (mHealth) platforms and analytics (Estrin and Sim 2010; Nilsen et al. 2012).

Recent years have also seen a rise in the amount of, connectivity between, and use of

heterogeneous data from disparate sources to address health questions. Examples include (but again are not limited to) the use of remote sensing data to assess exposure potential for airborne pollutants on local (Liu et al. 2005) and global scales (Shaddick et al. 2017), the use of Internet information in public health surveillance (Brownstein et al. 2009), and the expanded use of administrative data across multiple countries coupled with reported epidemiologic associations to provide assessments of the global burden of disease (Murray and Lopez 1997). The potential is remarkable, but desire for accurate health information can also lead to the temptation to ignore past epidemiologic findings in light of the promise of predictive analytics, a temptation that can lead to gross inaccuracies and potential false alarms (Lazar et al. 2014).

In addition to expanded possibilities of referencing individual-level attributions, volunteered geographic information via location-based apps and related services provide near real-time access to individual-level movement, providing novel opportunities for assessing exposures (Sui et al. 2013). Such information on location and movement provide additional context for moving from maps of local risk (Kitron 1998) to maps of an individual's cumulative experienced risk in moving through such an exposure space. Vazquez-Prokopec et al. (2009) provide a creative example exploring space-time exposures of taxi drivers to mosquitos carrying dengue virus in Iquitos, Peru.

The expanding availabilities of individual-level health and location data raise ongoing discussions of data privacy (determined by an individual's choices of which of their individual data to reveal), data confidentiality (the ability of the data holders to maintain each individual's privacy), and data access (determining which agencies, healthcare systems, physicians can access an individual's personal information). Concepts and comfort levels relating to data privacy vary culturally and between countries leading to differences in regulatory processes to evaluate whether data holders maintain confidentiality. For example, in the United States, the Health Insurance Portability and Accountability Act (HIPAA) of 1996 defines data protection standards for "protected health

information” (PHI) and its use with the healthcare system. HIPAA lists individual location data at a finer resolution than broadscale (3-digit) US ZIP codes among its list of PHI data elements, requiring care and documentation in the collection, storage, visualization, and reporting of geographic information at this and finer resolutions.

The competitive environment of US healthcare systems and the proprietary environment of providers of electronic health record (EHR) systems result in considerable informatics challenges when individual patients interact with multiple providers across different units. Some interesting progress has been made toward informatics solutions (e.g., the Fast Healthcare Interoperability Resources (FHIR)) to address these administrative barriers to data sharing and allow data sharing through app-based platforms (Mandel et al. 2016), but this remains an active area of research in the fields of medical informatics, particularly for FHIR extensions involving geolocation data extensions.

Future Directions for Research

The examples above illustrate that health applications of big spatial data technologies draw from traditional spatial analyses within individual, population, and public health but also illustrate that, to date, such work typically occurs in application-specific settings. The development of cohesive concepts and associated accurate and reliable toolboxes for spatial analytics and their health applications remains an area of active research. These developments include many challenging issues relating to accurate healthcare monitoring, assessment, and provision for each individual patient. Health applications extend well beyond that of individual health, and provide detailed insight into population and public health as well. There is great need for creativity in informatics to allow connection between, linkage across, and searches of elements of spatially referenced health and health-related measurements. As noted above, “health-related” can range from within-individual measures of immune response to satellite-based assessments

of local environmental conditions or global models of climate impact on pollution levels or food sources. Robust and reproducible spatial health analysis requires coordination of expert knowledge across multiple disciplines in order to fully reach its vast potential.

Approximate Computing for Stream Analytics

Do Le Quoc¹, Ruichuan Chen^{2,4}, Pramod Bhatotia³, Christof Fetzer¹, Volker Hilt², and Thorsten Strufe¹

Introduction

Stream analytics systems are extensively used in the context of modern online services to transform continuously arriving raw data streams into useful insights (Foundation 2017a; Murray et al.

2013; Zaharia et al. 2013). These systems target low-latency execution environments with strict service-level agreements (SLAs) for processing the input data streams.

In the current deployments, the low-latency requirement is usually achieved by employing more computing resources. Since most stream processing systems adopt a data-parallel programming model (Dean and Ghemawat 2004), almost linear scalability can be achieved with increased computing resources (Quoc et al. 2013, 2014, 2015a,b). However, this scalability comes at the cost of ineffective utilization of computing resources and reduced throughput of the system. Moreover, in some cases, processing the entire input data stream would require more than the available computing resources to meet the desired latency/throughput guarantees.

To strike a balance between the two desirable, but contradictory design requirements – low latency and efficient utilization of computing resources – there is a surge of *approximate computing* paradigm that explores a novel design point to resolve this tension. In particular, approximate computing is based on the observation that many data analytics jobs are amenable to an approximate rather than the exact output (Doucet et al. 2000; Natarajan 1995). For such workflows, it is possible to trade the output accuracy by computing over a subset instead of the entire data stream. Since computing over a subset of input requires less time and computing resources, approximate computing can achieve desirable latency and computing resource utilization.

Unfortunately, the advancements in approximate computing are primarily geared towards batch analytics (Agarwal et al. 2013; Srikanth et al. 2016), where the input data remains unchanged during the course of computation. In particular, these systems rely on pre-computing a set of samples on the static database, and take an appropriate sample for the query execution based on the user’s requirements (i.e., query execution budget). Therefore, the state-of-the-art systems cannot be deployed in the context of stream processing, where the new data continuously arrives as an unbounded stream.

As an alternative, one could in principle *repurpose* the available sampling mechanisms in well-known big data processing frameworks such as Apache Spark to build an approximate computing system for stream analytics. In fact, as a starting point for this work, based on the available sampling mechanisms, an approximate computing system is designed and implemented for stream processing in Apache Spark. Unfortunately, Spark’s stratified sampling algorithm suffers from three key limitations for approximate computing. First, Spark’s stratified sampling algorithm operates in a “batch” fashion, i.e., all data items are first collected in a batch as Resilient Distributed Datasets (RDDs) (Zaharia et al. 2012), and thereafter, the actual sampling is carried out on the RDDs. Second, it does not handle the case where the arrival rate of sub-streams changes over time because it requires a pre-defined sampling fraction for each stratum. Lastly, the stratified sampling algorithm implemented in Spark requires synchronization among workers for the expensive join operation, which imposes a significant latency overhead.

To address these limitations, this work designed an *online stratified reservoir sampling algorithm* for stream analytics. Unlike existing Spark-based systems, the algorithm performs the sampling process “on-the-fly” to reduce the latency as well as the overheads associated in the process of forming RDDs. Importantly, the algorithm *generalizes* to two prominent types of stream processing models: (1) batched stream processing employed by Apache Spark Streaming (Foundation 2017b), and (2) pipelined stream processing employed by Apache Flink (Foundation 2017a).

More specifically, the proposed sampling algorithm makes use of two techniques: reservoir sampling and stratified sampling. It performs reservoir sampling for each sub-stream by creating a fixed-size reservoir per stratum. Thereafter, it assigns weights to all strata respecting their arrival rates to preserve the statistical quality of the original data stream. The proposed sampling algorithm naturally adapts to varying arrival rates of sub-streams, and requires no synchronization among workers (see section

“[Design](#)”). Based on the proposed sampling algorithm, STREAMAPPROX – an approximate computing system for stream analytics – is designed.

Overview and Background

This section gives an overview of STREAMAPPROX (section “[System Overview](#)”), its computational model (section “[Computational Model](#)”), and its design assumptions (section “[Design Assumptions](#)”).

System Overview

STREAMAPPROX is designed for real-time stream analytics. In this system, the input data stream usually consists of data items arriving from diverse sources. The data items from each source form a *sub-stream*. The system makes use of a stream aggregator (e.g., Apache Kafka Foundation 2017c) to combine the incoming data items from disjoint sub-streams. STREAMAPPROX then takes this combined stream as the input for data analytics.

STREAMAPPROX facilitate data analytics on the input stream by providing an interface for users to specify the streaming query and its corresponding query budget. The query budget can be in the form of expected latency/throughput guarantees, available computing resources, or the accuracy level of query results.

STREAMAPPROX ensures that the input stream is processed within the specified query budget. To achieve this goal, the system makes use of approximate computing by processing only a subset of data items from the input stream, and produce an approximate output with rigorous error bounds. In particular, STREAMAPPROX uses a parallelizable online sampling technique to select and process a subset of data items, where the sample size can be determined based on the query budget.

Computational Model

The state-of-the-art distributed stream processing systems can be classified in two prominent categories: (i) batched stream processing model,

and (ii) pipelined stream processing model. These systems offer three main advantages: (a) efficient fault tolerance, (b) “exactly-once” semantics, and (c) unified programming model for both batch and stream analytics. *The proposed algorithm for approximate computing is generalizable to both stream processing models, and preserves their advantages.*

Batched stream processing model. In this computational model, an input data stream is divided into small batches using a pre-defined batch interval, and each such batch is processed via a distributed data-parallel job. Apache Spark Streaming (Foundation 2017b) adopted this model to process input data streams.

Pipelined stream processing model. In contrast to the batched stream processing model, the pipelined model streams each data item to the next operator as soon as the item is ready to be processed without forming the whole batch. Thus, this model achieves low latency. Apache Flink (Foundation 2017a) implements this model to provide a truly native stream processing engine.

Note that both stream processing models support the time-based sliding window computation (Bhatotia et al. 2014). The processing window slides over the input stream, whereby the newly incoming data items are added to the window and the old data items are removed from the window. The number of data items within a sliding window may vary in accordance to the arrival rate of data items.

Design Assumptions

STREAMAPPROX is based on the following assumptions. The possible means to address these assumptions are discussed in section “[Discussion](#)”.

1. There exists a virtual cost function which translates a given query budget (such as the expected latency guarantees, or the required accuracy level of query results) into the appropriate sample size.

2. The input stream is stratified based on the source of data items, i.e., the data items from each sub-stream follow the same distribution and are mutually independent. Here, a *stratum* refers to one sub-stream. If multiple sub-streams have the same distribution, they are combined to form a stratum.

Design

In this section, first the STREAMAPPROX’s workflow (section “[System Workflow](#)”) is presented. Then, its sampling mechanism (section “[Online Adaptive Stratified Reservoir Sampling](#)”) and its error estimation mechanism (section “[Error Estimation](#)”) are described (see details in Quoc et al. 2017d,c).

System Workflow

This section shows the workflow of STREAMAPPROX. The system takes the user-specified streaming *query* and the query *budget* as the input. Then it executes the query on the input data stream as a sliding window computation (see section “[Computational Model](#)”).

For each time interval, STREAMAPPROX first derives the sample size (*sampleSize*) using a cost function based on the given query budget. Next, the system performs a proposed sampling algorithm (detailed in section “[Online Adaptive Stratified Reservoir Sampling](#)”) to select the appropriate *sample* in an online fashion. This sampling algorithm further ensures that data items from all sub-streams are fairly selected for the sample, and no single sub-stream is overlooked.

Thereafter, the system executes a data-parallel job to process the user-defined *query* on the selected sample. As the last step, the system performs an error estimation mechanism (as described in section “[Error Estimation](#)”) to compute the error bounds for the approximate query result in the form of $output \pm error\ bound$. The whole process repeats for each time interval as the computation window slides (Bhatotia et al. 2012a).

Online Adaptive Stratified Reservoir Sampling

To realize the real-time stream analytics, a novel sampling technique called Online Adaptive Stratified Reservoir Sampling (OASRS) is proposed. It achieves both stratified and reservoir samplings without their drawbacks. Specifically, OASRS does not overlook any sub-streams regardless of their popularity, does not need to know the statistics of sub-streams before the sampling process, and runs efficiently in real time in a distributed manner.

The high-level idea of OASRS is simple. The algorithm first stratifies the input stream into sub-streams according to their sources. The data items from each sub-stream are assumed to follow the same distribution and are mutually independent. (Here, a *stratum* refers to one sub-stream. If multiple sub-streams have the same distribution, they can be combined to form a stratum.) The algorithm then samples each sub-stream independently, and perform the reservoir sampling for each sub-stream individually. To do so, every time a new sub-stream S_i is encountered, its sample size N_i is determined according to an adaptive cost function considering the specified query budget. For each sub-stream S_i , the algorithm performs the traditional reservoir sampling to select items at random from this sub-stream, and ensures that the total number of selected items from S_i does not exceed its sample size N_i . In addition, the algorithm maintains a counter C_i to measure the number of items received from S_i within the concerned time interval.

Applying reservoir sampling to each sub-stream S_i ensures that algorithm can randomly select at most N_i items from each sub-stream. The selected items from different sub-streams, however, should *not* be treated equally. In particular, for a sub-stream S_i , if $C_i > N_i$ (i.e., the sub-stream S_i has more than N_i items in total during the concerned time interval), the algorithm randomly selects N_i items from this sub-stream and each selected item represents C_i/N_i original items on average; otherwise, if $C_i \leq N_i$, the algorithm selects all the received C_i items so that each selected item only represents itself. As a result, in order to statistically recreate

the original items from the selected items, the algorithm assigns a specific weight W_i to the items selected from each sub-stream S_i :

$$W_i = \begin{cases} C_i/N_i & \text{if } C_i > N_i \\ 1 & \text{if } C_i \leq N_i \end{cases} \quad (1)$$

STREAMAPPROX supports *approximate linear queries* which return an approximate weighted sum of all items received from all sub-streams. Though linear queries are simple, they can be extended to support a large range of statistical learning algorithms (Blum et al. 2005, 2008). It is also worth mentioning that, OASRS not only works for a concerned time interval (e.g., a sliding time window), but also works with unbounded data streams.

Distributed execution. OASRS can run in a distributed fashion naturally as it does not require synchronization. One straightforward approach is to make each sub-stream S_i be handled by a set of w worker nodes. Each worker node samples an equal portion of items from this sub-stream and generates a local reservoir of size no larger than N_i/w . In addition, each worker node maintains a local counter to measure the number of its received items within a concerned time interval for weight calculation. The rest of the design remains the same.

Error Estimation

This section describes how to apply OASRS to randomly sample the input data stream to generate the approximate results for linear queries. Next, a method to estimate the accuracy of approximate results via rigorous error bounds is presented.

Similar to section “[Online Adaptive Stratified Reservoir Sampling](#)”, suppose the input data stream contains X sub-streams $\{S_i\}_{i=1}^X$. STREAMAPPROX computes the approximate sum of all items received from all sub-streams by randomly sampling only Y_i items from each sub-stream S_i . As each sub-stream is sampled independently, the variance of the approximate sum is: $\text{Var}(\text{SUM}) = \sum_{i=1}^X \text{Var}(\text{SUM}_i)$.

Further, as items are randomly selected for a sample within each sub-stream, according to the random sampling theory (Thompson 2012), the variance of the approximate sum can be estimated as:

$$\widehat{\text{Var}}(\text{SUM}) = \sum_{i=1}^X \left(C_i \times (C_i - Y_i) \times \frac{s_i^2}{Y_i} \right) \quad (2)$$

Here, C_i denotes the total number of items from the sub-stream S_i , and s_i denotes the standard deviation of the sub-stream S_i 's sampled items:

$$s_i^2 = \frac{1}{Y_i - 1} \times \sum_{j=1}^{Y_i} (I_{i,j} - \bar{I}_i)^2, \text{ where} \\ \bar{I}_i = \frac{1}{Y_i} \times \sum_{j=1}^{Y_i} I_{i,j} \quad (3)$$

Next, the estimation of the variance of the approximate mean value of all items received from all the X sub-streams is described. This approximate mean value can be computed as:

$$\text{MEAN} = \frac{\text{SUM}}{\sum_{i=1}^X C_i} = \frac{\sum_{i=1}^X (C_i \times \text{MEAN}_i)}{\sum_{i=1}^X C_i} \\ = \sum_{i=1}^X (\omega_i \times \text{MEAN}_i) \quad (4)$$

Here, $\omega_i = \frac{C_i}{\sum_{i=1}^X C_i}$. Then, as each sub-stream is sampled independently, according to the random sampling theory (Thompson 2012), the variance of the approximate mean value can be estimated as:

$$\widehat{\text{Var}}(\text{MEAN}) = \sum_{i=1}^X \text{Var}(\omega_i \times \text{MEAN}_i) \\ = \sum_{i=1}^X \left(\omega_i^2 \times \text{Var}(\text{MEAN}_i) \right) \quad (5) \\ = \sum_{i=1}^X \left(\omega_i^2 \times \frac{s_i^2}{Y_i} \times \frac{C_i - Y_i}{C_i} \right)$$

Above, the estimation of the variances of the approximate sum and the approximate mean of the input data stream has been shown. Similarly, the variance of the approximate results of any linear queries also can be estimated by applying the random sampling theory.

Error bound. According to the “68-95-99.7” rule (Wikipedia 2017), approximate result falls within one, two, and three standard deviations away from the true result with probabilities of 68%, 95%, and 99.7%, respectively, where the standard deviation is the square root of the variance as computed above. This error estimation is critical because it gives a quantitative understanding of the accuracy of the proposed sampling technique.

Discussion

The design of STREAMAPPROX is based on the assumptions mentioned in section “[Design Assumptions](#)”. This section discusses some approaches that could be used to meet the assumptions.

I: Virtual cost function. This work currently assumes that there exists a virtual cost function to translate a user-specified query budget into the sample size. The query budget could be specified as either available computing resources, desired accuracy, or latency.

For instance, with an accuracy budget, the sample size for each sub-stream can be determined based on a desired width of the confidence interval using Eq. (5) and the “68-95-99.7” rule. With a desired latency budget, users can specify it by defining the window time interval or the slide interval for the computations over the input data stream. It becomes a bit more challenging to specify a budget for resource utilization. Nevertheless, there are two existing techniques that could be used to implement such a cost function to achieve the desired resource target: (a) virtual data center (Angel et al. 2014), and (b) resource prediction model (Wieder et al. 2012) for latency requirements.

Pulsar (Angel et al. 2014) proposes an abstraction of a virtual data center (VDC) to provide performance guarantees to tenants in the cloud. In particular, Pulsar makes use of a virtual cost function to translate the cost of a request processing into the required computational resources using a multi-resource token algorithm. The cost function could be adapted for STREAMAPPROX as follows: a data item in the input stream is considered as a request and the “amount of resources” required to process it as the cost in tokens. Also, the given resource budget is converted in the form of tokens, using the pre-advertised cost model per resource. This allows computing the sample size that can be processed within the given resource budget.

For any given latency requirement, resource prediction model (Wieder et al. 2010a,b, 2012) could be employed. In particular, the prediction model could be built by analyzing the diurnal patterns in resource usage (Charles et al. 2012) to predict the future resource requirement for the given latency budget. This resource requirement can then be mapped to the desired sample size based on the same approach as described above.

II: Stratified sampling. This work currently assume that the input stream is already stratified based on the source of data items, i.e., the data items within each stratum follow the same distribution – it does not have to be a normal distribution. This assumption ensures that the error estimation mechanism still holds correct since STREAMAPPROX applies the Central Limit Theorem. For example, consider an IoT use-case which analyzes data streams from sensors to measure the temperature of a city. The data stream from each individual sensor follows the same distribution since it measures the temperature at the same location in the city. Therefore, a straightforward way to stratify the input data streams is to consider each sensor’s data stream as a stratum (sub-stream). In more complex cases where STREAMAPPROX cannot classify strata based on the sources, the system needs a pre-processing step to stratify the input data stream. This stratification problem is orthogonal to this work,

nevertheless for completeness, two proposals for the stratification of evolving streams, bootstrap (Dziuda 2010) and semi-supervised learning (Masud et al. 2012), are discussed in this section.

Bootstrap (Dziuda 2010) is a well-studied non-parametric sampling technique in statistics for the estimation of distribution for a given population. In particular, the bootstrap technique randomly selects “bootstrap samples” with replacement to estimate the unknown parameters of a population, for instance, by averaging the bootstrap samples. A bootstrap-based estimator can be employed for the stratification of incoming sub-streams. Alternatively, a semi-supervised algorithm (Masud et al. 2012) could be used to stratify a data stream. The advantage of this algorithm is that it can work with both labeled and unlabeled streams to train a classification model.

Related Work

Over the last two decades, the databases community has proposed various approximation techniques based on sampling (Al-Kateb and Lee 2010; Garofalakis and Gibbon 2001), online aggregation (Hellerstein et al. 1997), and sketches (Cormode et al. 2012). These techniques make different trade-offs w.r.t. the output quality, supported queries, and workload. However, the early work in approximate computing was mainly geared towards the centralized database architecture.

Recently, sampling-based approaches have been successfully adopted for distributed data analytics (Agarwal et al. 2013; Srikanth et al. 2016; Krishnan et al. 2016; Quoc et al. 2017b,a). In particular, BlinkDB (Agarwal et al. 2013) proposes an approximate distributed query processing engine that uses stratified sampling (Al-Kateb and Lee 2010) to support ad-hoc queries with error and response time constraints. Like BlinkDB, Quickr (Srikanth et al. 2016) also supports complex ad-hoc queries in big-data clusters. Quickr deploys distributed sampling operators to reduce execution costs of

parallelized queries. In particular, Quickr first injects sampling operators into the query plan; thereafter, it searches for an optimal query plan among sampled query plans to execute input queries. However, these “big data” systems target batch processing and cannot provide required low-latency guarantees for stream analytics.

IncApprox (Krishnan et al. 2016) is a data analytics system that combines two computing paradigms together, namely, approximate and incremental computations (Bhatotia et al. 2011a,b, 2012b) for stream analytics. The system is based on an online “biased sampling” algorithm that uses self-adjusting computation (Bhatotia 2015; Bhatotia et al. 2015) to produce incrementally updated approximate output. Lastly, PrivApprox (Quoc et al. 2017a,b) supports privacy-preserving data analytics using a combination of randomized response and approximate computation. By contrast, STREAMAPPROX supports low-latency in stream processing by employing the proposed “online” sampling algorithm solely for approximate computing, while avoiding the limitations of existing sampling algorithms.

Conclusion

This paper presents STREAMAPPROX, a stream analytics system for approximate computing. STREAMAPPROX allows users to make a systematic trade-off between the output accuracy and the computation efficiency. To achieve this goal, STREAMAPPROX employs an online stratified reservoir sampling algorithm which ensures the statistical quality of the sample selected from the input data stream. The proposed sampling algorithm is generalizable to two prominent types of stream processing models: batched and pipelined stream processing models.

Definitions

Spatial big data is a spatio-temporal data that is too large or requires data-intensive computation that is too demanding for traditional computing architectures. *Stream processing* in this context is the processing of spatio-temporal data in motion. The data is observational; it is produced by sensors – moving or otherwise. Computations on the data are made as the data is produced or received. A *distributed processing cluster* is a networked collection of computers that communicate and process data in a coordinated manner. Computers in the cluster are coordinated to solve a common problem. A *lambda architecture* is a scalable, fault-tolerant data-processing architecture that is designed to handle large quantities of data by exploiting both stream and batch processing methods. *Data partitioning* involves physically dividing a dataset into separate data stores on a distributed processing cluster. This is done to achieve improved scalability, performance, availability, and fault-tolerance. *Distributed file systems*, in the context of big data architectures, are similar to traditional distributed file systems but are intended to persist large datasets on com-

modity hardware in a fault-tolerant manner with simple coherency models. The *MapReduce programming model* is intended for large-scale distributed data processing and is based upon simple concepts involving iterating over data, performing a computation on key/value pairs, grouping the intermediary values by key, iterating over the resulting groups, and reducing each group to provide a result. A *GPU-accelerated distributed processing framework* is an extension to a traditional distributed processing framework that supports offloading tasks to GPUs for further acceleration.

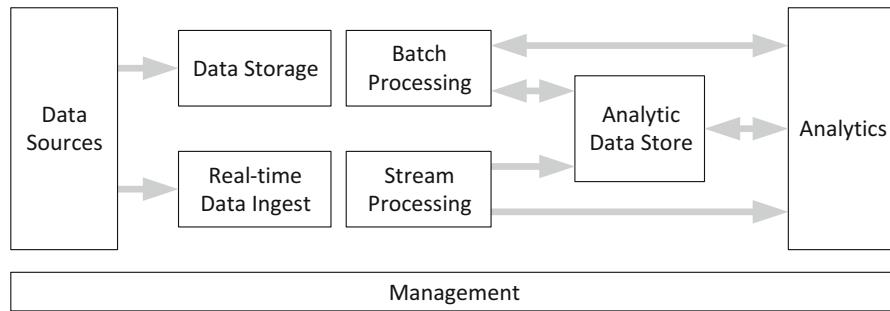

Overview

Spatial big data architectures are intended to address requirements for spatio-temporal data that is too large or computationally demanding for traditional computing architectures (Shekhar et al. 2012). This includes operations such as real-time data ingest, stream processing, batch processing, storage, and spatio-temporal analytical processing.

Spatial big data offers additional challenges beyond what is commonly faced in the big data space. This includes advanced indexing, querying, analytical processing, visualization, and machine learning. Examples of spatial big data include moving vehicles (peer-to-peer ridesharing, delivery vehicles, ships, airplanes, etc.), stationary sensor data (e.g., SCADA, AMI), cell phones (call detail records), IoT devices, as well as spatially enabled content from social media (Fig. 1).

Spatial big data architectures are used in a variety of workflows:

- Real-time processing of observational data (data in motion). This commonly involves monitoring and tracking dynamic assets in real-time; this can include vehicles, aircraft, and vessels, as well as stationary assets such as weather and environmental monitoring sensors.
- Batch processing of persisted spatio-temporal data (data at rest). Workflows with data at rest incorporate tabular and spatial processing

Architectures, Fig. 1 Generic big data architecture

(e.g., summarizing data, analyzing patterns, and proximity analysis), geoenrichment and geoenablement (adding spatial capabilities to non-spatial data, adding information from contextual spatial data collections), and machine learning and predictive analytics (clustering, classification, and prediction).

Architectural Requirements

When designing and developing scalable software systems that can address the high-level workflows encountered in spatial big data systems, a number of basic requirements must be identified. It is important to note that most of these also generally apply to traditional non-spatial big data systems (Mysore et al. 2013; Klein et al. 2016; Sena et al. 2017):

Scalable

Spatial big data systems must be scalable. Scalability encompasses being able to increase and support different amounts of data, processing them, and allocating computational resources without impacting costs or efficiency. To meet this requirement, it is required to distribute data sets and their processing across multiple computing and storage nodes.

High Performant

Spatial big data systems must be able to process large streams of data in a short period of time, thus returning the results to users as efficiently as possible. In addition, the system should support computation intensive spatio-temporal analytics.

Real-time

Big data systems must be able to manage the continuous flow of data and its processing in real time, facilitating decision-making.

Consistent

Big data systems must support data consistency, heterogeneity, and exploitation. Different data formats must be also managed to represent useful information for the system.

Secure

Big data systems must ensure security in the data and its manipulation in the architecture, supporting integrity of information, exchanging data, multilevel policy-driven, access control, and prevent unauthorized access.

Available

Big data systems must ensure high data availability, through data replication horizontal scaling (i.e., distribute a data set over clusters of computers and storage nodes). The system must allow replication and handle hardware failures.

Interoperable

Big data systems must be transparently intercommunicated to allow exchanging information between machines and processes, interfaces, and people.

Key Research Findings

Spatial big data architectures have existed since the early 2000s with some of the original implementations at Google and Microsoft. Some of the key research issues related to spatial big

data architectures include data storage (repositories, distributes storage, NoSQL databases), distributed spatio-temporal analytic processing, stream processing, scalable cloud computing, and GPU-enabled distributed processing frameworks.

Data Storage

Parallel Database Systems

Big data repositories have existed in many forms, frequently built by corporations and governmental agencies with special requirements. Beginning in the 1990s, commercial vendors began offering parallel database management systems to address the needs of big data (DeWitt and Gray 1992). Parallel database systems are classified as being shared memory (processing elements sharing memory), shared disk (processing elements do not share memory, but do share disk storage), or shared nothing (neither memory nor disk storage is shared between processing elements). Significant efforts included those by Teradata, IBM, Digital, Microsoft, Oracle, Google, and Amazon. Additionally, beginning in the 1980s, there were numerous research systems that contributed to these efforts (e.g., GAMMA and Bubba; DeWitt et al. 1986, Alexander and Copeland 1988).

Distributed File Stores

Hadoop Distributed File System (HDFS) is a distributed file-system that stores data on commodity machines, providing very high aggregate bandwidth across the cluster (Shvachko et al. 2010). It was inspired by the Google File System (GFS; Ghemawat et al. 2003). HDFS stores large files (typically in the range of gigabytes to terabytes) across multiple machines. It achieves reliability by replicating the data across multiple hosts, and hence theoretically does not require redundant array of independent disks (RAID) storage on hosts (but to increase input-output (I/O) performance, RAID configurations may be employed). With the default replication value of three, data is stored on three nodes: two on the same rack and one on a different rack. Data nodes can talk to each other to rebalance data, to move copies around, and to keep the replication of data high.

NoSQL Databases

A NoSQL (originally referencing “non-SQL” or “non-relational”) database is a mechanism for the storage and retrieval of data that is modeled differently from standard relational databases (NoSQL 2009; Pavlo and Aslett 2016). NoSQL databases are often considered next generation databases; they are intended to address weaknesses of traditional relational databases such as being readily distributable, simpler in design, open-source, and horizontally scalable (often problematic for relational databases). Many databases supporting these characteristics originated in the late 1960s; the “NoSQL” description was employed beginning in the late 1990s with the requirements imposed by companies such as Facebook, Google, and Amazon. NoSQL databases are commonly used with big data applications. NoSQL systems are also sometimes called “Not only SQL” to emphasize that they may support SQL-like query languages.

In order to achieve increased performance and scalability, NoSQL databases commonly used data structures (e.g., key-value, columnar, document, or graph) that are different from those used in relational databases. NoSQL databases vary in terms of applicability to particular problem domains. NoSQL databases are often classified by their primal data structures; examples include:

- Key-value: Apache Ignite, Couchbase, Dynamo, Oracle NoSQL Database, Redis, Riak
- Columnar: Accumulo, Cassandra, Druid, HBase, Vertica
- Document: Apache CouchDB, Cosmos DB, IBM Domino, MarkLogic, MongoDB
- Graph: AllegroGraph, Apache Giraph, MarkLogic, Neo4J
- Multi-model: Apache Ignite, Couchbase, MarkLogic

Spatial Batch Processing

Spatio-temporal analysis in a batch context involves a very wide scope of functionality. In academia, much of the research has focused on the spatial join (or spatio-temporal join) func-

tion. In commercial systems, spatial analysis also includes summarizing data, incident and similar location detection, proximity analysis, pattern analysis, and data management (import, export, cleansing, etc.).

Spatial Joins

Spatial joins have been widely studied in both the standard sequential environment (Jacox and Samet 2007), as well as in the parallel (Brinkhoff et al. 1996) and distributed environments (Abel et al. 1995). For over 20 years, algorithms have been developed to take advantage of parallel and distributed processing architectures and software frameworks. The recent resurgence in interest in spatial join processing is the results of new-found interest in distributed, fault-tolerant, computing frameworks such as Apache Hadoop, as well as the explosion in observational and IoT data.

With distributed processing architectures, there are two principal approaches that are employed when performing spatial joins. The first, termed a broadcast (or mapside) spatial join, is designed for joining a large dataset with another small dataset (e.g., political boundaries). The large dataset is partitioned across the processing nodes and the complete small dataset is broadcast to each of the nodes. This allows significant optimization opportunities. The second approach, termed a partitioned (or reduce side) spatial join, is a more general technique that is used when joining two large datasets. Partitioned joins use a divide-and-conquer approach (Aji et al. 2013). The two large datasets are divided into small pieces via a spatial decomposition, and each small piece is processed independently.

SJMR (Spatial Join with MapReduce) introduced the first distributed spatial join on Hadoop using the MapReduce programming model (Dean and Ghemawat 2008; Zhang et al. 2009). Spatial-Hadoop (Eldawy and Mokbel 2015) optimized SJMR with a persistent spatial index (it supports grid files, R – trees, and R + trees) that is precomputed. Hadoop-GIS (Aji et al. 2013), which is utilized in medical pathology imaging, features both 2D and 3D spatial join. GIS Tools

for Hadoop (Whitman et al. 2014) is an open source library that implements range and distance queries and k-NN. It also supports a distributed PMR quadtree-based spatial index. GeoSpark (Yu et al. 2015) is a framework for performing spatial joins, range, and k-NN queries. The framework supports quadtree and R-tree indexing of the source data. Magellan (Sriharsha 2015) is an open source library for geospatial analytics that uses Spark (Zaharia et al. 2010). It supports a broadcast join and a reduce-side optimized join and is integrated with Spark SQL for a traditional, SQL user experience. SpatialSpark (You et al. 2015) supports both a broadcast spatial join and a partitioned spatial join on Spark. The partitioning is supported using either fixed-grid, binary space partition or a sort-tile approach. STARK (Hagedorn et al. 2017) is a Spark-based framework that supports spatial joins, k-NN, and range queries on both spatial and spatio-temporal data. STARK supports three temporal operators: contains, containedBy, and intersects) and also supports the DBSCAN density-based spatial clusterer (Ester et al. 1996). MSJS (multi-way spatial join algorithm with Spark (Du et al. 2017)) addresses the problem of performing multi-way spatial joins using the common technique of cascading sequences of pairwise spatial joins. Simba (Xie et al. 2016) offers range, distance (circle range), and k-NN queries as well as distance and k-NN joins. Two-level indexing, global and local, is employed, similar to the various indexing work on Hadoop MapReduce. Location-Spark (Tang et al. 2016) supports range query, k-NN, spatial join, and k-NN join. Location-Spark uses global and local indices – Grid, R-tree, Quadtree, and IR-tree. GeoMesa is an open-source, distributed, spatio-temporal index built on top of Bigtable-style databases (Chang et al. 2008) using an implementation of the Geohash algorithm implemented in Scala (Hughes et al. 2015). The Esri GeoAnalytics Server (Whitman et al. 2017) supports many types of spatial analysis in a distributed environment (leveraging the Spark framework). It provides functionality for summarizing data (e.g., aggregation, spatio-temporal join, polygon overlay), incident and similar location detection, proximity

analysis, and pattern analysis (hot spot analysis, NetCDF generation).

MapReduce Programming Model

MapReduce is a programming model and an associated implementation for processing big data sets with a parallel, distributed algorithm (Sakr et al. 2013). A MapReduce program is composed of a map procedure (or method), which performs filtering and sorting (such as sorting students by first name into queues, one queue for each name), and a reduce method, which performs a summary operation (such as counting the number of students in each queue, yielding name frequencies). A MapReduce framework manages the processing by marshalling the distributed cluster nodes, running the various tasks and algorithms in parallel, managing communications and data transfers between cluster nodes, while supporting fault tolerance and redundancy.

The MapReduce model is inspired by the map and reduces functions commonly used in functional programming (note that their purpose in the MapReduce framework is not the same as in their original forms). The key contributions of the MapReduce model are not the actual map and reduce functions that resemble the Message Passing Interface (MPI) standard's reduce and scatter operations. The major contributions of the MapReduce model are the scalability and fault-tolerance that is supported through optimization of the execution engine. A single-threaded implementation of MapReduce is commonly slower than a traditional (non-MapReduce) implementation; gains are typically realized with multi-node or multi-threaded implementations.

MapReduce libraries have been written in many programming languages, with different levels of optimization. The most popular open-source implementation is found in Apache Hadoop.

Stream Processing

Stream processing is a computer programming paradigm, equivalent to dataflow programming, event stream processing, and reactive programming that allows some applications to more easily exploit a limited form of parallel processing

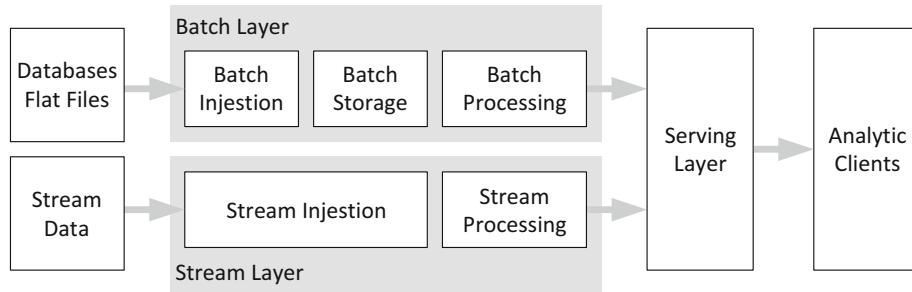

(Gedik et al. 2008). Such applications can use multiple computational units, such as the floating point unit on a graphics processing unit or field-programmable gate arrays (FPGAs), without explicitly managing allocation, synchronization, or communication among those units.

The stream processing paradigm simplifies parallel software and hardware by restricting the parallel computation that can be performed. Given a sequence of data (a stream), a series of operations (kernel functions) is applied to each element in the stream. Kernel functions are usually pipelined, and optimal local on-chip memory reuse is attempted, in order to minimize the loss in bandwidth, accredited to external memory interaction. Uniform streaming, where one kernel function is applied to all elements in the stream, is typical. Since the kernel and stream abstractions expose data dependencies, compiler tools can fully automate and optimize on-chip management tasks.

Lambda Architecture

A Lambda Architecture is an architecture that is intended to process large volumes of data by incorporating both batch and real-time processing techniques (Marz and Warren 2015). This approach to architecture attempts to balance latency, throughput, and fault-tolerance by using batch processing to provide comprehensive and accurate views of batch data, while simultaneously using real-time stream processing to provide views of online data. The two view outputs may be joined before presentation. In addition, historic analysis is used to tune the real-time analytical processing as well as building models for prediction (machine learning). The rise of lambda architecture is correlated with the growth of big data, real-time analytics, and the drive to mitigate the latencies of map-reduce (Fig. 2).

The Lambda architecture depends on a data model with an append-only, immutable data source that serves as a system of record. It is intended for ingesting and processing timestamped events that are appended to existing events rather than overwriting them. State is determined from the natural time-based ordering of the data.

Architectures, Fig. 2 Generic lambda architecture

GPU-Accelerated Distributed Frameworks

Distributed processing frameworks such as Spark (which support in-memory processing) have been extended and enhanced with the incorporation of GPUs for key computationally intensive operations (e.g., machine learning and graph theoretic algorithms, Prasad et al. 2015). Researchers have observed that a few Spark nodes with GPUs can outperform a much larger cluster of non-GPU nodes (Grossman and Sarkar 2016; Hasaan and Elghandour 2016; Yuan et al. 2016; Hong et al. 2017). The main bottlenecks when incorporating GPUs in hybrid architectures often involve data communication, memory and resource management, and differences in programming models. Different approaches to solving these problems have employed GPU-wrapper APIs (e.g., PyCUDA), hybrid RDDs (resilient distributed datasets) where the RDD is stored in the CPU, generating native GPU code from high-level source code written for the distributed framework (e.g., Scala, Java, or Python code with Spark) or native GPU RDDs where data is processed and stored in the GPU device memory (Fig. 3).

Examples of Application

The application of technologies related to spatial big data architectures is broad given the rapidly growing interest in spatial data that has emerged during the twenty-first century. Notable among this family of technologies in terms of significance and application include distributed processing frameworks, geo-spatial stream pro-

cessing, and the numerous implementations of platform as a service (PaaS).

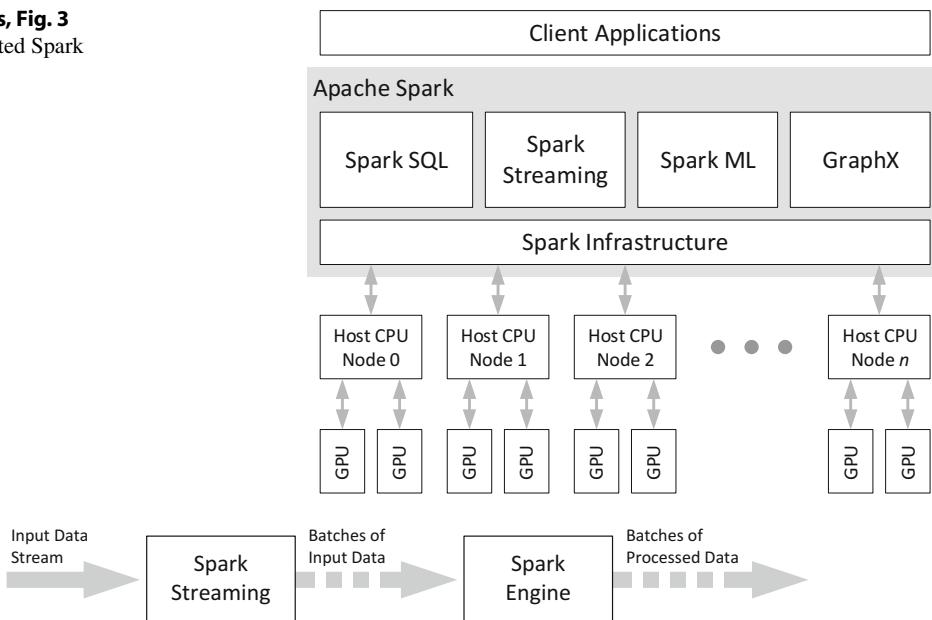

Apache Hadoop

Apache Hadoop (Apache 2006) is an open-source software framework and associated utilities that facilitate using a network of commodity computers to solve problems involving large amounts of data and computation. Inspired by the seminal work at Google on MapReduce and the Google File System (GFS), Hadoop provides a software framework for both the distributed storage and processing of big data using the MapReduce programming model.

Similar to the efforts at Google, Hadoop was designed for computer clusters built from commodity hardware (still the common usage pattern). Hadoop has also been employed on large clusters of higher-end hardware. All the modules in Hadoop are designed with a fundamental assumption that hardware failures are common occurrences and should be automatically handled by the framework.

The core of Apache Hadoop consists of a storage part, known as Hadoop Distributed File System (HDFS), a resource manager, a collection of utilities, and a processing framework that is an implementation of the MapReduce programming model that runs against large clusters of machines. HDFS splits very large files (including those of size gigabytes and larger) into blocks that are distributed across multiple nodes in a cluster. Reliability is achieved by replicating the blocks across multiple nodes (with a default replication factor of 3). Hadoop distributes packaged code into nodes to process the data in parallel.

Architectures, Fig. 3
GPU-accelerated Spark framework

Architectures, Fig. 4 Spark streaming micro-batch architecture

This approach takes advantage of data locality, where nodes manipulate the data they have access to. This allows the dataset to be processed faster and more efficiently than it would be in a more conventional supercomputer architecture that relies on a parallel file system where computation and data are distributed via high-speed networking.

Hadoop has been deployed in traditional data-centers as well as in the cloud. The cloud allows organizations to deploy Hadoop without the need to acquire hardware or specific setup expertise. Vendors who currently have an offering for the cloud that incorporate Hadoop include Microsoft, Amazon, IBM, Google, and Oracle. Most of the Fortune 50 companies currently deploy Hadoop clusters.

Spark Streaming

Spark Streaming is an extension to Spark API that supports scalable, high-throughput, fault-tolerant, stream processing of real-time data streams (Garillot and Maas 2018). Data can be ingested from many sources (e.g., Kafka, Flume, or TCP sockets) and can be processed using

temporally aware algorithms expressed with high-level functions like map, reduce, join, and window. Finally, processed data can be pushed out to filesystems, databases, and live dashboards. Spark's machine learning (Spark ML) and graph processing (GraphX) algorithms can be applied to these data streams.

Internally, Streaming receives live input data streams and divides the data into batches, which are then processed by the Spark engine to generate the final stream of results in batches (Fig. 4).

Spark Streaming provides a high-level abstraction called *discretized stream* or *DStream*, which represents a continuous stream of data. DStreams can be created either from input data streams from sources such as Kafka, Flume, and Kinesis, or by applying high-level operations on other DStreams. Internally, a DStream is represented as a sequence of RDDs.

Big Data as a Service

Platform as a Service (PaaS) is a category of cloud computing services that provides a platform allowing customers to run and

manage applications without the complexity of building and maintaining the infrastructure usually associated with developing and launching an application (Chang et al. 2010). PaaS is commonly delivered in one of three ways:

- As a public cloud service from a provider
- As a private service (software or appliance) inside the firewall
- As software deployed on a public infrastructure as a service

Big Data as a Service (BDaaS) is a new concept that combines Software as a Service (SaaS), Platform as a Service (PaaS), and Data as a Service (DaaS) in order to address the requirements of working with massively large data sets. BDaaS offerings commonly incorporate the Hadoop stack (e.g., HDFS, Hive, MapReduce, Pig, Storm, and Spark), NoSQL data stores, and stream processing capabilities.

Microsoft Azure is a cloud computing service utilizing Microsoft-managed data centers that supports both software as a service (SaaS) and platform as a service (PaaS). It provides data storage capabilities including Cosmos DB (a NoSQL database), the Azure Data Lake, and SQL Server-based databases. Azure supports a scalable event processing engine and a machine learning service that supports predictive analytics and data science applications.

The Google Cloud is a Paas offering that supports big data with data warehousing, batch and stream processing, data exploration, and support for the Hadoop/Spark framework. Key components include BigQuery, a managed data warehouse supporting analytics at scale, Cloud Dataflow, which supports both stream and batch processing, and Cloud Dataproc, a framework for running Apache MapReduce and Spark processes.

Amazon AWS, though commonly considered an Infrastructure as a Service (IaaS) where the user is responsible for configuration, AWS also provides PaaS functionality. Amazon supports Elastic MapReduce (EMR) that works in conjunction with EC2 (Elastic Compute Cloud) and

S3 (Simple Storage Service). Data storage is provided through DynamoDB (NoSQL), Redshift (columnar), and RDS (relational data store). Machine learning and real-time data processing infrastructures are also supported.

Other significant examples of BDaaS providers include the IBM Cloud and the Oracle Data Cloud. Big data Infrastructure as a Service (IaaS) offerings (that work with other clouds such as AWS, Azure, and Oracle) are available from Hortonworks, Cloudera, Esri, and Databricks.

Future Directions for Research

Despite the significant advancements that have been made over the past decade on key topics related to spatial big data architectures, much further research is necessary in order to further democratize the capabilities and application to broader problem domains. Some of the more significant areas needing attention include:

- Spatio-temporally enabling distributed and NoSQL databases such as Accumulo, Cassandra, HBase, Dynamo, and Elasticsearch. This involves not only supporting spatial types but also incorporating rich collections of topological, spatial, and temporal operators.
- Spatio-temporal analytics is another area requiring attention. Much research to date has focused on supporting spatial (or spatio-temporal) joins on distributed frameworks such as MapReduce or Spark. While beneficial, spatio-temporal analytics is a far richer domain that also includes geostatistics (e.g., kriging), spatial statistics, proximity analysis, and pattern analysis.
- Spatially enabling machine learning algorithms that run in a distributed cluster (e.g., extending Spark ML or Scikit-learn (Pedregosa et al. 2011)) is another significant research area given the growing interest and importance of machine learning, predictive analytics, and deep learning. To date, research

- has primarily focused on density-based clustering algorithms such as DBSCAN, HDBSCAN (McInnes and Healy 2017), and OPTICS.
- Recently, much attention has been paid to incorporating GPU processing capabilities into distributed processing frameworks such as Spark. While some basic spatial capabilities can currently be supported (e.g., aggregation and visualization of point data), much work needs to be done to further streamline and optimize the integration of GPU processors and extend the native spatio-temporal capabilities.

Artifact-Centric Process Mining

Dirk Fahland
Eindhoven University of Technology,
Eindhoven, The Netherlands

Synonyms

Multi-instance process mining; Object-centric process mining

Definitions

Artifact-centric process mining is an extension of classical process mining (van der Aalst 2016) that allows to analyze event data with more than one case identifier in its entirety. It allows to analyze the dynamic behavior of (business) processes that create, read, update, and delete multiple data objects that are related to each other in relationships with one-to-one, one-to-many, and many-to-many cardinalities. Such event data is typically stored in relational databases of, for example, Enterprise Resource Planning (ERP) systems (Lu et al. 2015). Artifact-centric process mining comprises artifact-centric process discovery, conformance checking, and enhancement. The outcomes of artifact-centric process mining can be used for documenting the actual data flow in an organization and for analyzing deviations in the data flow for performance and conformance analysis.

The input to *artifact-centric process discovery* is either an event log where events carry information about the data objects and their changes, or a relational database also containing records about data creation, change, and deletion events. The output of artifact-centric process discovery is a data model of the objects (each defining its own case identifier) and relations between objects and an artifact-centric process model, as illustrated in Fig. 1. An artifact-centric process model describes the dynamics of each data object on its own in an *object life-cycle model*, and the

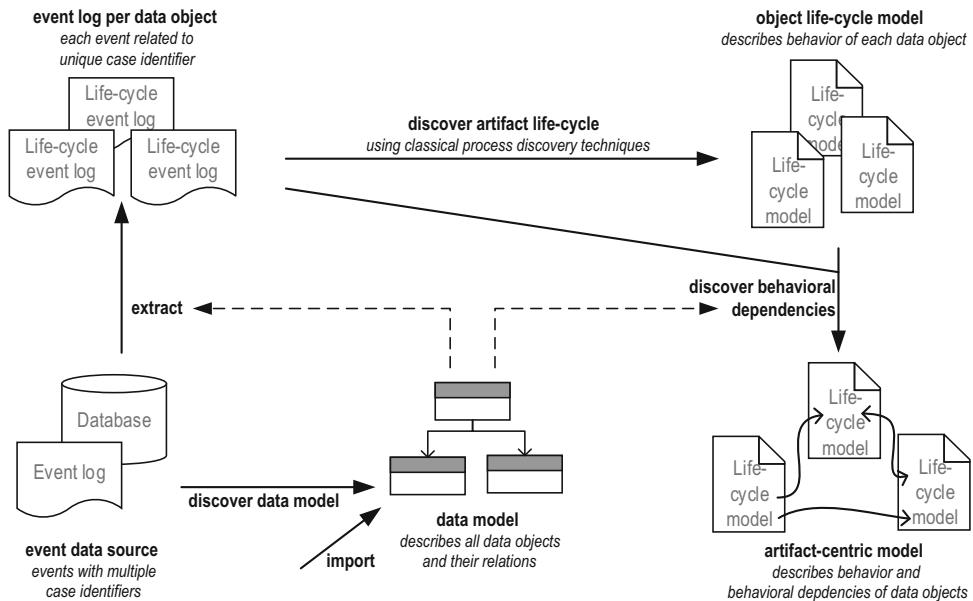

behavioral dependencies between the different data objects. To this end, artifact-centric process discovery integrates the control-flow analysis of event data of classical process mining with an analysis of the data structures and data records related to the events.

During artifact-centric process discovery, each event is associated with one data object in the data source. From the behavioral relations between all events associated with one data object, a *life-cycle model* of the data object is learned using automated process discovery techniques. Each life-cycle model describes the possible changes to the object and their ordering as they have been observed in reality. From behavioral relationships between events in different related data objects, information about *behavioral dependencies between changes in different data objects* is discovered preserving the one-to-one, one-to-many, and many-to-many cardinalities.

Several modeling languages have been proposed to describe a complete artifact-centric model of all object life cycles and their behavioral interdependencies. Existing behavioral modeling languages can be extended to express interdependencies of one-to-many and many-to-many cardinalities including Petri nets (van der Aalst et al. 2001) and UML (Estañol et al. 2012). Specifically designed languages including the Guard-Stage-Milestone (GSM) model (Hull et al. 2011) or data-centric dynamic systems (Hariri et al. 2013) employ both data and behavioral constructs as primary modeling concepts. The Case Management Model and Notation (CMMN) standard v1.1 incorporates several modeling concepts of GSM (OMG 2016).

Artifact-centric conformance checking compares event data to an artifact-centric model with the aim to identify where recorded events *deviate* from the behavior described in the artifact-centric model. Deviations may exist between observed and specified data models, between observed events and the life-cycle model of an artifact, and between observed events and the interactions of two or more artifacts.

Artifact-centric model enhancement uses event data to enrich an artifact-centric model, for example, with information about the frequency of

Artifact-Centric Process Mining, Fig. 1 Overview on artifact-centric process discovery

paths through a life-cycle model or interactions, or to identify infrequent behavior as outliers.

Overview

Historically, artifact-centric process mining addressed the unsolved problem of process mining on event data with multiple case identifiers and one-to-many and many-to-many relationships by adopting the concept of a (business) *artifact* as an alternative approach to describing business processes.

Event Data with Multiple Case Identifiers

Processes in organizations are typically supported by information systems to structure the information handled in these processes in well-defined data objects which are often stored in relational databases. During process execution, various data objects are created, read, updated, and deleted, and various data objects are related to each other in one-to-one, one-to-many, and many-to-many relations. Figure 2 illustrates in a simplified form the data structures typically found in ERP systems. *Sales*, *Delivery*, and

Billing documents are recorded in tables; relation *F1* links *Sales* to *Delivery* documents in a one-to-many relation: *S1* relates to *D1* and *D2*; correspondingly *F2* links *Billing* to *Delivery* documents in a one-to-many relation. Events on process steps and data access are recorded in time stamp attributes such as *Date created* or in a separate *Document Changes* table linked to all other tables.

Convergence and Divergence

Process mining requires to associate events to a *case identifier* in order to analyze behavioral relations between events in the same case (van der Aalst 2016). The data in Fig. 2 provides three case identifiers: *SD id*, *DD id*, and *BD id*. Classical process mining forces to associate all events to a single case identifier. However, this is equivalent to flattening and de-normalizing the relational structure along its one-to-many relationships.

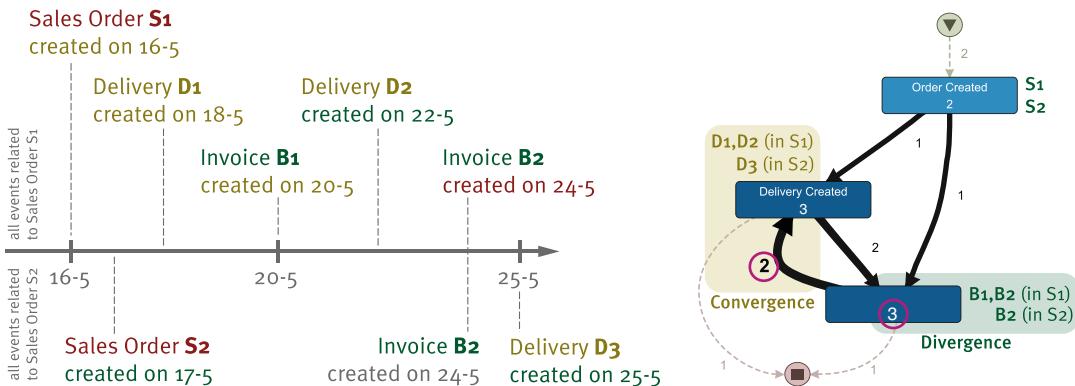

For example, associating all *Create* events of Fig. 2 to *SD id* flattens the tables into the *event log* of Fig. 3(left) having two cases for *S1* and *S2*. Due to flattening, event *Create* of *B2* has been duplicated as it was extracted once for *S1* and once for *S2*, also called *divergence*. Further,

Sales Documents				Billing Documents		
SD id	Date created	Value	Last Change	BD id	Date created	Clearing Date
S1	16-5-2020	100	10-6-2020	B1	20-5-2020	31-5-2020
S2	17-5-2020	200	5-6-2020	B2	24-5-2020	5-6-2020

Delivery Documents				
DD id	Date created	Reference SD id	Reference BD id	Picking Date
D1	18-5-2020	S1	B1	31-5-2020
D2	22-5-2020	S1	B2	5-6-2020
D3	25-5-2020	S2	B2	5-6-2020

Document Changes						
Change id	Date	Ref. id	Table	Change type	Old Value	New Value
1	17-5-2020	S1	SD	Price updated	100	80
2	19-5-2020	S1	SD	Delivery block released	X	-
3	19-5-2020	S1	SD	Billing block released	X	-
4	10-6-2020	B1	BD	Invoice date updated	20-6-2020	21-6-2020

Artifact-Centric Process Mining, Fig. 2 Event data stored in a relational database

Artifact-Centric Process Mining, Fig. 3 An event log (left) serializing the “create” events of the database of Fig. 2 based on the case identifier “SD id.” The resulting directly-follows relation (right) suffers convergence and divergence

Create for *B1* is followed by Create for *D2* although *B1* and *D2* are unrelated in Fig. 2, also called *convergence* (Lu et al. 2015). The behavioral relations which underly automated process discovery become erroneous through convergence and divergence. For example, the directly-follows relation of the log (Fig. 3 right) states erroneously that three *Invoice* documents have been created – whereas the original data source contains only two – and that in two cases *Invoice* creation was followed by *Delivery* creation (between related data objects), whereas in the original data source this only happened once for *B2* and *D3*.

Convergence and divergence may cause up to 50% of erroneous behavioral relations (Lu et al. 2015) in event logs. Convergence and divergence can be avoided partially by scoping extraction of event data into event logs with a single case identifier in a manual process (Jans 2017).

Artifact-Centric Process Models

Artifact-centric process mining adopts modeling concept of a (business) artifact to analyze event data with multiple case identifiers in their entirety (Lu et al. 2015; Nooijen et al. 2012; van Eck et al. 2017). The notion of a (business) *artifact*

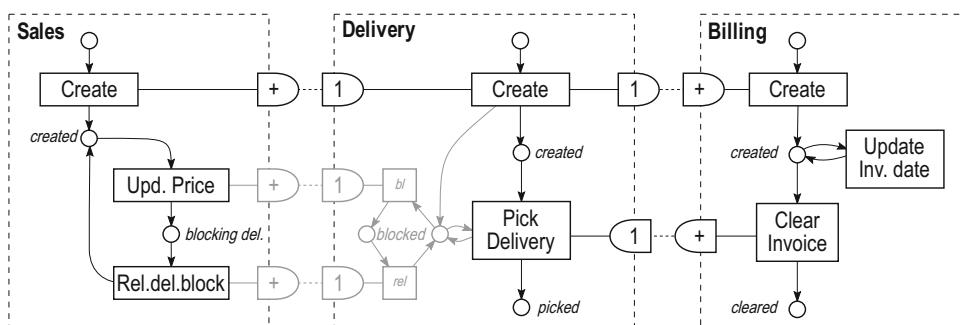

was proposed by Nigam and Caswell (2003) as an alternative approach to describing business processes. This approach assumes that any process materializes itself in the (data) objects that are involved in the process, for instance, sales documents and delivery documents; these objects have properties such as the values of the fields of a paper form, the processing state of an order, or the location of a package. Typically, a *data model* describes the (1) classes of objects that are relevant in the process, (2) the relevant properties of these objects in terms of class attributes, and (3) the relations between the classes. A process execution instantiates new objects and changes their properties according to the process logic. Thereby, the relations between classes describe how many objects of one class are related to how many objects of another class.

An *artifact-centric process model* enriches the classes of the data model themselves with process logic restricting how objects may evolve during execution. More precisely, one *artifact* (1) encapsulates several classes of the data model (e.g., *Sales Documents* and *Sales Document Lines*), (2) provides *actions* that can update the classes attributes and move the artifact to a particular state, and (3) defines a *life cycle*. The artifact life cycle describes when an instance of the artifact (i.e., a concrete object) is created, in which state of the instance which actions may occur to advance the instance to another state (e.g., from *created* to *cleared*), and which goal state the instance has to reach to complete a case. A complete artifact-centric process model provides a life-cycle model for each artifact in the process and

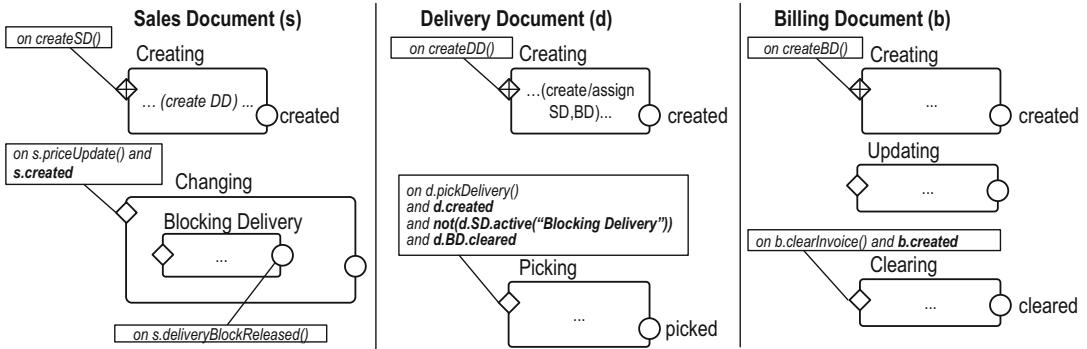

describes which *behavioral dependencies* exist between actions and states of different artifacts (e.g., *pick delivery* may occur for a *Delivery* object only if all its *Billing* objects are in state *cleared*). Where business process models created in languages such as BPMN, EPC, or Petri nets describe a process in terms of activities and their ordering in a single case, an artifact-centric model describes process behavior in terms of creation and evolution of instances of multiple related data objects. In an artifact-centric process model, the unit of modularization is the *artifact*, consisting of data and behavior, whereas in an activity-centric process modeling notation, the unit of modularization is the *activity*, which can be an elementary task or a sub-process. A separate entry in this encyclopedia discusses the problem of automated discovery of activity-centric process models with sub-processes.

Figure 4 shows an artifact-centric process model in the notation of *Proclcts* (van der Aalst et al. 2001) for the database of Fig. 2. The life cycle of each document (*Sales*, *Delivery*, *Billing*) is described as a Petri net. Behavioral dependencies between actions in different objects are described through *interface ports* and *asynchronous channels* that also express cardinalities in the interaction. For example, the port annotation “+” specifies that *Clear Invoice* in *Billing* enables *Pick Delivery* in *multiple related Delivery* objects. Port annotation “1” specifies that *Pick Delivery* can occur after *Clear Invoice* occurred in the *one Billing* object related to the *Delivery*.

The gray part of Fig. 4 shows a more involved behavioral dependency. Whenever *Update Price*

Artifact-Centric Process Mining, Fig. 4 Example of an artifact-centric process model in the proclct notation

Artifact-Centric Process Mining, Fig. 5 Example of an artifact-centric process model in the Guard-Stage-Milestone notation

occurs in a *Sales* document, all related *Delivery* documents get *blocked*. Only after *Release delivery block* occurred in *Sales*, the *Delivery* document may be updated again, and *Pick Delivery* may occur. For the sake of simplicity, the model does not show further behavioral dependencies such as “*Update price* also blocks related *Billing* documents.”

Figure 5 shows the same model in the *Guard-Stage-Milestone* notation (Hull et al. 2011) (omitting some details). Each round rectangle denotes a *stage* that can be entered when its *guard* condition (diamond) holds and is left when its *milestone* condition (circle) holds. The guard and milestone conditions specify declarative constraints over data attributes, stages, and milestones of *all* artifacts in the model. For example, *Picking* can start when the *pickDelivery* event is triggered in the process, the delivery document has reached its *created* milestone, the billing document related to the delivery document has reached its *cleared* milestone (*d.BD.cleared*), and the stage *Blocking Delivery* is not active in the related sales document.

Artifact-Centric Process Mining

The behavior recorded in the database of Fig. 2 does not *conform* to the models in Figs. 4 and 5:

1. *Structural conformance* states how well the data model describes the data records observed in reality. The proclet model of Fig. 4 structurally conforms to the data in Fig. 2

regarding objects and relations but not regarding actions: the recorded event data shows two additional event types for the life cycle of the *Sales* document – *Release billing block* and *Last Change*.

2. *Life-cycle conformance* states how well the life-cycle model of each artifact describes the order of events observed in reality. This corresponds to conformance in classical process mining. For example, in Fig. 2, *Update invoice date* occurs in *Billing* after *Clear Invoice* which does not conform to the life-cycle model in Fig. 4.
3. *Interaction conformance* states how well the entire artifact centric model describes the behavioral dependencies between artifacts. In Fig. 2, instance *D3* of *Delivery* is *created* after its related instance *B2* of *Billing*. This does not conform to the channels and ports specified in Fig. 4.

The objective of artifact-centric process mining is to relate recorded behavior to modeled behavior, through (1) *discovering* an artifact-centric process model that conforms to the recorded behavior, (2) *checking* how well recorded behavior and an artifact-centric model *conform* to each other and detecting *deviations*, and (3) extending a given artifact-centric model with further information based on recorded event data.

Artifact-centric process discovery is a technique to automatically or semiautomatically learn artifact-centric process models from event data.

The problem is typically solved by a decomposition into the following four steps:

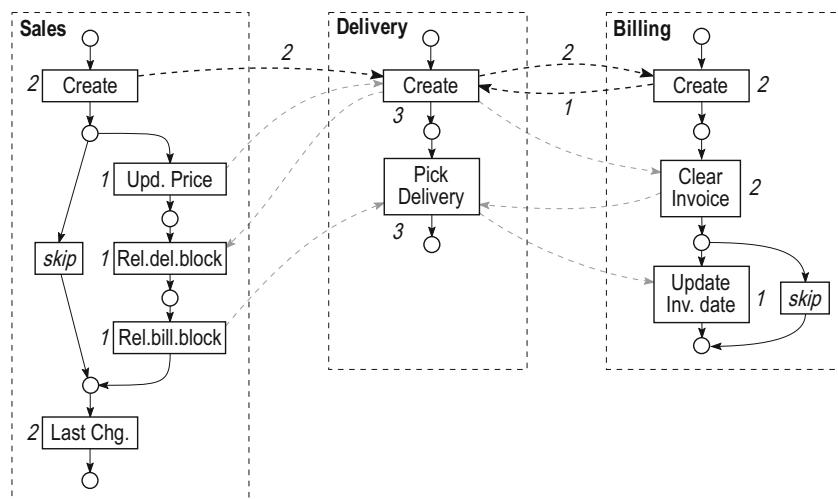

1. Discovering the data model of entities or tables, their attributes, and relations from the data records in the source data. This step corresponds to *data schema recovery*. It can be omitted if the data schema is available and correct; however, in practice foreign key relations may not be documented at the data level and need to be discovered.
2. Discovering artifact types and relations from the data model and the event data. This step corresponds to transforming the data schema discovered in step 1 into a domain model often involving undoing horizontal and vertical (anti-) partitioning in the technical data schema and grouping entities into domain-level data objects. User input or detailed information about the domain model are usually required.
3. Discovering artifact life-cycle models for each artifact type discovered in step 2. This step corresponds to automated process discovery for event data with a single case identifier and can be done fully automatically up to parameters of the discovery algorithm.
4. Discovering behavioral dependencies between the artifact life cycles discovered in step 3

based on the relations between artifact types discovered in step 2. This step is specific to artifact-centric process mining; several alternative, automated techniques have been proposed. User input may be required to select domain-relevant behavioral dependencies among the discovered ones.

In case the original data source is a relational database, steps 3 and 4 require to *automatically extract event logs* from the data source for discovering life-cycle models and behavioral dependencies. As in classical process discovery, it depends on the use case to which degree the discovered data model, life-cycle model, and behavioral dependencies shall conform to the original data.

Artifact-centric conformance checking and *Artifact-centric model enhancement* follow the same problem decomposition into data schema, artifact types, life cycles, and interactions as artifact-centric discovery. Depending on which models are available, the techniques may also be combined by first discovering data schema and artifact types, then extracting event logs, and then checking life-cycle and behavioral conformance for an existing model or enhancing an existing artifact model with performance information.

Figure 6 shows a possible result of artifact-centric process discovery on the event data in

Artifact-Centric Process Mining, Fig. 6 Possible result of artifact-centric process discovery from the event data in Fig. 2

Fig. 2 using the technique of Lu et al. (2015) where the model has been enhanced with information about the *frequencies* of occurrences of events and behavioral dependencies.

Key Research Findings

Artifact-type discovery. Nooijen et al. (2012) provide a technique for automatically discovering artifact types from a relational database, leveraging schema summarization techniques to cluster tables into artifact types based on information entropy in a table and the strength of foreign key relations. The semiautomatic approach of Lu et al. (2015) can then be used to refine artifact types and undo horizontal and vertical (anti-) partitioning and to discover relations between artifacts. Popova et al. (2015) show how to discover artifact types from a rich event stream by grouping events based on common identifiers into entities and then deriving structural relations between them.

Event log extraction. In addition to discovering artifact types, Nooijen et al. (2012) also automatically create a mapping from the relational database to the artifact-type specification. The technique of Verbeek et al. (2010) can use this mapping to generate queries for event log extraction for life-cycle discovery automatically. Jans (2017) provides guidelines for extracting specific event logs from databases through user-defined queries. The event log may also be extracted from database redo logs using the technique of de Murillas et al. (2015) and from databases through a meta-model-based approach as proposed by de Murillas et al. (2016).

Life-cycle discovery. Given the event log of an artifact, artifact life-cycle discovery is a classical automated process discovery problem for which various process discovery algorithms are available, most returning models based on or similar to Petri nets. Weerdt et al. (2012) compared various discovery algorithms using real-life event logs. Lu et al. (2015) advocates the use of the

Heuristics Miner of Weijters and Ribeiro (2011) and vanden Broucke and Weerdt (2017) with the aim of visual analytics. Popova et al. (2015) advocate to discover models with precise semantics and free of behavioral anomalies that (largely) fit the event log (Leemans et al. 2013; Buijs et al. 2012) allowing for translating the result to the Guard-Stage-Milestone notation.

Behavioral dependencies. Lu et al. (2015) discover behavioral dependencies between two artifacts by extracting an *interaction event log* that combines the events of any two related artifact instances into one trace. Applying process discovery on this interaction event log then allows to extract “flow edges” between activities of the different artifacts, also across one-to-many relations, leading to a model as shown in Fig. 6. This approach has been validated to return only those dependencies actually recorded in the event data but suffers when interactions can occur in many different variants, leading to many different “flow edges.”

van Eck et al. (2017) generalize the interaction event log further and create an integrated event log of all artifact types to be considered (two or more) where for each combination of related artifact instances, all events are merged into a single trace. From this log, a composite state machine model is discovered which describes the synchronization of all artifact types. By projecting the composite state machine onto the steps of each artifact type, the life-cycle model for each artifact is obtained, and the interaction between multiple artifacts can be explored interactively in a graphical user interface through their relation in the composite state machine. This approach assumes one-to-one relations between artifacts.

Popova and Dumas (2013) discover behavioral dependencies in the form of data conditions over data attributes and states of other artifacts, similar to the notation in Fig. 5 but is limited to one-to-one relations between artifacts.

Conformance checking. Artifact life-cycle conformance can be checked through extracting artifact life-cycle event logs and then applying classical conformance checking techniques (Fahland

et al. 2011a). The technique in Fahland et al. (2011b) checks interaction conformance in an artifact life-cycle model if detailed information about which artifact instances interact is recorded in the event data.

Models for artifacts. Artifact-centric process mining techniques originated and are to a large extent determined by the modeling concepts available to describe process behavior and data flow with multiple case identifiers. Several proposals have been made in this area. The Procler notation (van der Aalst et al. 2001) extended Petri nets with ports that specify one-to-many and many-to-many cardinality constraints on messages exchanged over channels in an asynchronous fashion. Fahland et al. (2011c) discuss a normal form for procler-based models akin to the second normal form in relational schemas. The Guard-Stage-Milestone (GSM) notation (Hull et al. 2011) allows to specify artifacts and interactions using event-condition-actions rules over the data models of the different artifacts. Several modeling concepts of GSM were adopted by the CMMN 1.1 standard of OMG (2016). Hariri et al. (2013) propose data-centric dynamic systems (DCDS) to specify artifact-centric behavior in terms of updates of database records using logical constraints. Existing industrial standards can also be extended to describe artifacts as shown by Lohmann and Nyolt (2011) for BPMN and by Estañol et al. (2012) for UML. Freedom of behavioral anomalies can be verified for UML-based models (Calvanese et al. 2014) and for DCDS (Montali and Calvanese 2016). Meyer and Weske (2013) show how to translate between artifact-centric and activity-centric process models, and Lohmann (2011) shows how to derive an activity-centric process model describing the interactions between different artifacts based on behavioral constraints.

Examples of Application

Artifact-centric process mining is designed for analyzing event data where events can be related

to more than one case identifier or object and where more than one case identifier has to be considered in the analysis.

The primary use case is in analyzing processes in information systems storing multiple, related data objects, such as Enterprise Resource Planning (ERP) systems. These systems store documents about business transactions that are related to each other in one-to-many and many-to-many relations. Lu et al. (2015) correctly distinguish normal and outlier flows between 18 different business objects over 2 months of data of the Order-to-Cash process in an SAP ERP system using artifact-centric process mining. The same technique was also used for identifying outlier behavior in processes of a project management system together with end users. van Eck et al. (2017) analyzed the personal loan and overdraft process of a Dutch financial institution. Artifact-centric process mining has also been applied successfully on software project management systems such as Jira and customer relationship management systems such as Salesforce (Calvo 2017).

Artifact-centric process mining can also be applied on event data outside information systems. One general application area is analyzing the behavior of physical objects as sensed by multiple related sensors. For instance, van Eck et al. (2016) analyzed the usage of physical objects equipped with multiple sensors. Another general application area is analyzing the behavior of software components from software execution event logs. For instance, Liu et al. (2016) follow the artifact-centric paradigm to structure events of software execution logs into different components and discover behavioral models for each software component individually.

Future Directions for Research

At the current stage, artifact-centric process mining is still under development allowing for several directions for future research.

Automatically discovering artifact types from data sources is currently limited to summarizing the structures in the available data. Mapping these

structures to domain concepts still requires user input. Also the automated extraction of event logs from the data source relies on the mapping from the data source to the artifact-type definition. How to aid the user in discovering and mapping the data to domain-relevant structures and reducing the time and effort to extract event logs, possibly through the use of ontologies, is an open problem. Also little research has been done for improving the queries generated for automated event log extraction to handle large amount of event data.

For discovering behavioral dependencies between artifacts, only few and limited techniques are available. The flow-based discovery of Lu et al. (2015) that can handle one-to-many relations is limited to interactions between two artifacts and suffers in the presence of many different behavioral variants of the artifacts or the interactions. The alternative approaches (Popova and Dumas 2013; van Eck et al. 2017) are currently limited to one-to-one relations between artifacts. Solving the discovery of behavioral dependencies between artifacts thereby faces two fundamental challenges:

1. Although many different modeling languages and concepts for describing artifact-centric processes have been proposed, the proposed concepts do not adequately capture these complex dynamics in an easy-to-understand form (Reijers et al. 2015). Further research is needed to identify appropriate modeling concepts for artifact interactions.
2. Systems with multiple case identifiers are in their nature complex systems, where complex behaviors and multiple variants in the different artifacts multiply when considering artifact interactions. Further research is needed on how to handle this complexity, for example, through generating specific, interactive views as proposed by van Eck et al. (2017).

Although several, comprehensive conformance criteria in artifact-centric process mining have been identified, only behavioral conformance of artifact life cycles can currently be measured. Further research for measuring

structural conformance and interaction conformance is required, not only for detecting deviations but also to objectively evaluate the quality of artifact-centric process discovery algorithms.

Definitions

An examination of the implementation, execution, and results of a test or benchmark, generally

performed by an independent third-party, and resulting in a report of findings

Historical Background

The use of a third-party audit to attest to the veracity of a claim has historically been commonplace in the financial sector. The goal of such audit activities is to bolster the credibility of an organization's claims regarding its financial standing. Similar auditing activities are found in other fields where there is value in validating the level at which a set of requirements have been followed.

As formal definitions of computer systems performance benchmarks started to emerge, so did the call for independent certification of published results. The Transaction Processing Performance Council (TPC – www.tpc.org) was the first industry standard benchmark consortium to formalize the requirement for independent auditing of benchmark results.

Foundations

The purpose of auditing in the context of a performance test or benchmark is to validate that the test results were produced in compliance with the set of requirements defining the test. These requirements are used to define multiple aspects of the test, including what is being tested, how it is being tested, how the test results are measured, and how accurately are they documented. Auditing a test or benchmark result consists in validating some or all of these requirements.

Benchmark requirements can be viewed as belonging to one of the following categories: implementation rules, execution rules, results collection, pricing rules, and documentation. The motivation behind auditing a set of requirements, and the process involved in such validation, is largely based on which of these categories the requirements belong to.

Auditing the Implementation

Some benchmarks are provided in the form of a complete software kit that can simply be installed

and executed to measure the underlying system. Other benchmarks are provided in the form of a set of functional requirements to be implemented using any fitting technology. In this later case, the level at which the implementation meets the stated requirements can directly affect the results of the test. Consider a benchmark requiring the execution of two tasks acting on the same data set. An implementation that correctly implements the tasks but fails to have them act on the same data set would avoid potential data access conflicts.

The process of auditing a benchmark implementation includes all aspects of that implementation. This may include reviewing custom code, examining data generation tools and their output, executing functional testing to verify the proper behavior of required features, and validating the integration of the various benchmark components.

Auditing the Execution

Most benchmarks involve the execution of multiple steps, for a prescribed duration and in some specified sequence. The level at which these execution rules are followed can greatly impact the outcome of the test. Consider a benchmark requiring that two tasks be executed concurrently for a specified duration. An execution that runs the tasks for the specified duration but schedules them in a serial manner would avoid potential contention for system resources.

The process of auditing a benchmark execution involves verifying that controls are in place to drive the execution based on the stated rules and that sufficient traces of the execution steps are captured. This may be accomplished by reviewing execution scripts, witnessing the execution in real time, and examining logs that were produced during the execution.

Auditing the Results

The end goal of implementing and executing a benchmark is to produce a result for use in performance engineering, marketing, or other venue. While a benchmark may be implemented correctly and executed according to all stated rules, it may produce a flawed outcome if the results

are not collected properly. Consider a benchmark that involves a workload that gradually ramps up until the system under test reaches saturation, with the goal of measuring the system's behavior at that saturation point. A test that measures the system's behavior too early during ramp-up would avoid the potential disruptions caused by saturation.

The process of auditing the collection of results during a benchmark execution involves verifying that all necessary conditions are met for the measurement to be taken. In cases where metrics are computed from combining multiple measurements, it also involves verifying that all the components of the metric are properly sourced and carry sufficient precision.

Auditing the Pricing

When benchmarks are executed for the purpose of competitive analysis, the cost of the tested configuration may also be part of the benchmark's metrics. Including a cost component in the metrics provides a measure of value, in addition to the measure of performance. This value metric may help differentiate between systems under test with comparable performance metrics. But the price of a SUT can be greatly influenced by the rules regulating the pricing methodology. For instance, the price of a leasing contract may not be comparable to that of an outright purchase, discount levels may vary widely across markets, and maintenance costs vary based on service level agreements.

The process of auditing the pricing of a SUT involved in a benchmark execution consists in verifying that all of the pricing rules defined by the benchmark have been adhered to. It may also involve a verification of the stated prices by attempting to obtain an independent pricing quotation from the vendors or distributors of the components in the SUT.

Auditing the Documentation

Benchmark results are best understood within their proper context. The purpose of documenting a benchmark result is to provide sufficient context to allow a full understanding of the significance of the result. Without proper context, a

benchmark result can be misunderstood and lead to incorrect conclusions. Consider a benchmark with a body of existing results that have been produced on single-socket systems. A new, record-breaking result may be received more favorably if the documentation omits to disclose that it was produced on a dual-socket system, leaving the reader to assume that a single socket was used.

The process of auditing the documentation of a benchmark result consists in verifying that all relevant information has been provided with accuracy and candor. A criterion to determine if the documentation of a test result is sufficient is when the information provided allows another party to independently reproduce the result.

Key Applications

First Formal Use

According to Serlin (1993), one of the first formal audit of a benchmark result took place "in March, 1987, when Tandem hired Codd & Date Consulting to certify the 208 tps result obtained under a version of DebitCredit." Tom Sawyer, the auditor on this tandem test, later collaborated with Ormi Serlin to author a proposal for a formal performance test framework that became the impetus for the creation of the TPC.

Around the time of the release of its third standard benchmark specification, TPC Benchmark™ C (Raab 1993), in August 1992, the TPC added to its policies (TPC. TPC Policies) the call for a mandatory audit of all its benchmark results. This addition to its policies also established a process by which the TPC certifies individuals who are qualified to conduct such audits.

Auditing Adoption

The practice of independently auditing benchmark results has been adopted by multiple organizations involved in performance testing. A formal benchmark result auditing requirement was adopted by the Storage Performance Council (SPC – www.storageperformance.org), shortly after its inception in 1998. It is a common practice for system vendors to

publish nonstandard test results in support of performance claims or to document a proof of concept. A number of these publications include an independent certification to bolster the credibility of the results. The practice of independently auditing test results has also been adopted by private and governmental organizations conducting comparative performance testing as part of their technology selection process.

Internal Peer Review

Some standard benchmark organizations, such as the Standard Performance Evaluation Corporation (SPEC – www.spec.org), have opted for a peer review process to validate the benchmark results they publish. This review is conducted internally by members of the organization. The TPC also gives test sponsors the option of a peer review process for results against its benchmarks in a category called “express.” In both of these cases of internal peer review, test results from one vendor are reviewed by competing vendors. The strength of this review process is in the assumption that the reviewers are intimately familiar with the testing requirements and the tested technology by having conducted similar tests themselves. The downside is in the potential for a loss of independence in the validation process.

Independent Third-Party Auditor

To maintain its integrity, auditing is best when conducted by an independent third party that has no conflict of interest with the object of the audit. These conflicts can take many forms in the context of a benchmark audit. Following are a few examples of conflicts of interest that may compromise the independence of validation process: having a vested interest in how the benchmark result may affect the image of a tested product; having a financial stake attached to the outcome of the test; or being directly involved in conducting the test or improving the test results.

Automated Discovery of Hierarchical Process Models

► Hierarchical Process Discovery

Automated Process Discovery

Sander J. J. Leemans

Queensland University of Technology, Brisbane,
Australia

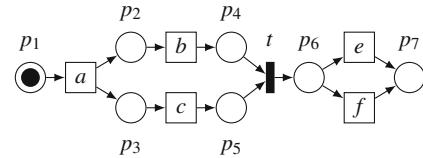

Definitions

An *event log* contains a historical record of the steps taken in a business process. An event log consists of *traces*, one for each case, customer, order, etc. in the process. A trace contains *events*, which represent the steps (*activities*) that were taken for a particular case, customer, order, etc.

An example of an event log derived from an insurance claim handling process is [*{receive claim, check difficulty, decide claim, notify customer}*¹⁰, *{receive claim, check difficulty, check fraud, decide claim, notify customer}*⁵]. This event log consists of 15 traces, corresponding to 15 claims made in the process. In 10 of these traces, the claim was received, its difficulty assessed, the claim was decided and the customer was notified.

A *process model* describes the behaviour that can happen in a process. Typically, it is represented as a Petri net (Reisig 1992) or a BPMN model (OMG 2011).

A Petri net consists of places, which denote the states the system can be in, and transitions, which denote the state changes of the system. For instance, Fig. 1 shows an example of a Petri net. This net starts with a *token* in place p_1 . Firing transition a removes the token from p_1 and puts tokens in p_2 and p_3 . This denotes the execution of the activity a in the process. Then, transitions b and c can fire independently, each consuming the token of p_2 or p_3 and producing a token in p_4 or p_5 . Next, the silent transition t fires and

Automated Process Discovery, Fig. 1 Example of a Petri net

puts a token in p_6 . As t is a silent transition, no corresponding activity is executed in the process. Finally, either e or f can be fired, putting a token in p_7 and ending the process.

A *workflow net* is a Petri net with an initial place (without incoming arcs), a final place (without outgoing arcs) and every place and transition lying on a path between these places. The behaviour of a workflow net is clear: a token is put in the initial place, and every sequence of transitions firings that leads to a token in the final place and nowhere else, is a trace of the behaviour of the net.

A workflow net is *sound* if the net is free of deadlocks, unexecutable transitions and other anomalies (van der Aalst 2016). A workflow net is *relaxed sound* if there is a sequence of transition firings that lead to a token in the final place and nowhere else.

Overview

Automated process discovery aims to extract information from recorded historical information about business processes by means of automatic methods. In this chapter, we discuss challenges and algorithms for process discovery.

Automated Process Discovery

Organisations nowadays store considerable amounts of data: in many business processes such as for booking a flight, lodging an insurance claim or hiring a new employee, every step is supported and recorded by an information system. From these information systems, event logs can be extracted, which contain the steps that were taken for a particular customer, booking,

claim, etc. Process mining aims to derive information and insights from these event logs.

Many process mining techniques depend on the availability of a process model. Process models can be elicited by hand, however this can be a tedious and error-prone task. Instead, if event logs are available, these can be used to discover a process model automatically.

In this chapter, the research field of algorithms that automatically discover process models from event logs is described. First, quality criteria for models are discussed, and how algorithms might have to tradeoff between them. Second, process discovery algorithms are discussed briefly.

Quality Criteria & Tradeoffs

The quality of a discovered model can be assessed using several concepts: whether it possesses clear semantics, whether it is simple, how well it represents the event log and how well it represents the process.

Semantics & Soundness

As a first quality criterion, the behaviour described by the model should be clear. That is, it should be clear which traces the model can produce. If the returned model is a Petri net or a BPMN model, this model should be free of deadlocks, unexecutable transitions and other anomalies (it should be *sound* (van der Aalst 2016)). While unsound nets can be useful for manual analysis, they should be used with care in automated analyses as, for instance, conformance checking techniques might give unreliable answers or simply not work on unsound nets. At a bare minimum, conformance checking techniques such as alignments (Adriansyah 2014) require relaxed sound models.

Simplicity

Second, given two models, all other things equal, the simplest model is usually the best of the two (a principle known as Occam's razor). That is, a model should be as understandable as possible, for instance sma.

Log Quality

Third, one can consider the quality of a discovered model with respect to the event log from which it was discovered, to assess whether the model represents the available information correctly. Typically, besides simplicity, three quality dimensions are considered: fitness, precision and generalisation. Fitness expresses the part of the event log that is captured in the behaviour of the process model. Precision expresses the part of the behaviour of the model that is seen in the event log. Generalisation expresses what part of future behaviour will be likely present in the model.

To illustrate these quality measures, consider the following event log L :

$$\begin{aligned} & [\langle a, d, b \rangle^{50}, & \langle a, b, c, d, b \rangle^{20}, \\ & \langle a, b, d, c, b, c, b \rangle^2, & \langle a, b, c, d, b, c, b \rangle^2, \\ & \langle a, b, c, b, d, c, b \rangle, & \langle a, b, c, b, c, b, d \rangle, \\ & \langle a, b, c, b, d, c, b, c, b \rangle, & \langle a, b, c \rangle] \end{aligned}$$

Figure 2 contains a possible process model for L , which supports only a single trace. This model has a poor fitness, as many traces of L are not part of its behaviour. However, it has a high precision, as the single trace it represents was seen in L . Compared to the event log, this model is not very informative.

An extreme model is shown in Fig. 3. This model is a so-called *flower model*, as it allows for all behaviour consisting of a, b, c and d , giving it a low fitness and high precision. Even though this model is simple and certainly generalises, it is completely useless as it does not provide any information besides the presence of $a-d$ in the process.

On the other end of the spectrum is the *trace model*, shown in Fig. 4. This model simply

Automated Process Discovery, Fig. 2 A process model with low fitness, high precision, low generalisation and high simplicity w.r.t. L

lists all traces of L , thereby achieving perfect fitness and precision. However, this model does not generalise the behaviour in the event log, that is, it only shows the traces that were seen in L , and does not provide any extra information.

As a final model, we consider the model shown in Fig. 5. This model has a high fitness, precision, generalisation and simplicity. However, the model still does not score *perfect* as the last trace of L , $\langle a, b, c \rangle$, is not captured by this model, which lowers fitness a bit. Furthermore, precision is not perfect as the trace $\langle a, b, c, b, c, d, b \rangle$ is possible in the model but did not appear in L , which lowers precision.

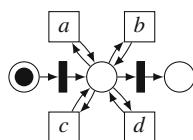

The models shown for L illustrate that process discovery algorithms might have to tradeoff and strike a balance between quality criteria. For some event logs, a model scoring high on all log-quality measures and simplicity might not exist (Buijs et al. 2012b). The necessary balance might depend on the use case at hand. For instance, manual analysis where the “main flow” of a process is sought might require the omission of the last trace of L from the model, yielding a simple and precise model. However, for auditing purposes, one might opt for a perfectly fitting model by including this last trace of L in the behaviour of the model.

Process Quality

A downside of measuring the quality of a model with respect to the event log is that an event log contains only *examples* of behaviour of an (unknown) business process rather than the full behaviour, and that the log might contain traces that do not correspond to the business process (*noisy* traces). Therefore, one can also consider how it compares to the process from which the event log was recorded. In the ideal case, the behaviour of the process is rediscovered by a discovery algorithm. That is, the behaviour (language) of the model is the same as the behaviour of the process.

As the business process is assumed to be unknown, whether an algorithm can find a model that is behaviourally equivalent to the process (*rediscoverability*) is a formal property of the algorithm. Without rediscoverability, an algorithm is *unable* to find a model equivalent to the process, which makes the algorithm rather unsuitable to study this process.

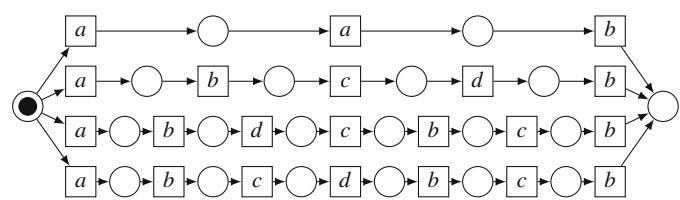

Rediscoverability is typically proven using assumptions on the process and the event log, for instance that it is representable as a model in the formalism of the algorithm (Petri nets, BPMN), and for instance that the event log contains enough information and does not contain too much noise, as well as assumptions on the process.

For benchmarks and a more exhaustive overview, please refer to Augusto et al. (2017b) (algorithms after 2012) and Weerdt et al. (2012) (algorithms before 2012). Not all algorithms can be benchmarked reliably; the selection here contains all benchmarked algorithms of Augusto et al. (2017b).

Several of these algorithms are available in the ProM framework (van Dongen et al. 2005), which is available for download from <http://www.promtools.org>, or in the Apromore suite (Rosa et al. 2011), which can be accessed via <http://apromore.org>.

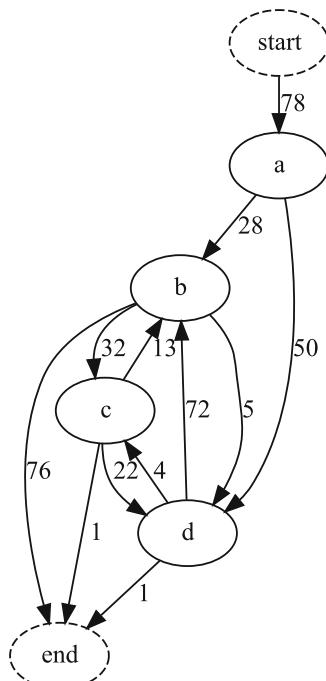

The algorithms are discussed in three stages: firstly, algorithms that do not support concurrency, secondly algorithms that guarantee soundness and thirdly the remaining algorithms.

Directly Follows-Based Techniques

As a first set, techniques based on the directly follows relations are discussed. The section starts with an explanation of directly follows graphs, after which some tools that use this concept are listed and the limitations of such techniques are discussed.

In a directly follows graph, the nodes represent the activities of the event log, and the edges represent that an activity is directly followed by another activity in the event log. Numbers on the edges indicate how often this happened. Additionally, a start and an end node denote the events with which traces in the event log start or end. For instance, Fig. 6 shows the directly follows graph for our event log L .

For more complicated processes, a directly follows graph might get incomprehensibly complicated. Therefore, discovery techniques typically filter the directly follows graph, for instance by removing little-occurring edges. Com-

Automated Process Discovery, Fig. 6 Directly follows graph of event log L

mercial techniques that filter and show directly follows graphs include Fluxicon Disco (Fluxicon 2017), Celonis Process Mining (Celonis 2017) and ProcessGold Enterprise Platform (ProcessGold 2017). Another strategy to reduce complexity, applied by the Fuzzy Miner (Günther and van der Aalst 2007), is to cluster similar activities into groups, thereby providing capabilities to zoom in on details of the process (by clustering less), or to abstract to the main flow of the process by clustering more.

While these graphs are intuitive, it can be challenging to distinguish repetitive and concurrent behaviour, as both manifest as edges forth- and back between activities. For instance, in Fig. 6, it seems that b , c and d can be executed repeatedly, while in the log L this never happened for d . In contrast, it also seems that b , c and d are concurrent, while in L , b and c are always executed repeatedly. Due to this, directly follows graphs tend to have a low precision and high generalisation: in our example, almost any sequence of b , c and d is included.

Nevertheless, directly follows-based techniques are often used to get a first idea of the process behind an event log.

Soundness-Guaranteeing Algorithms

Soundness is a prerequisite for further automated or machine-assisted analysis of business process models. In this section, soundness or relaxed soundness guaranteeing algorithms are discussed.

Evolutionary Tree Miner

To address the issue of soundness, the Evolutionary Tree Miner (ETM) (Buijs et al. 2012a) discovers process trees. A process tree is an abstract hierarchical view of a workflow net and is inherently sound.

ETM first constructs an initial population of models; randomly or from other sources. Second, some models are selected based on fitness, precision, generalisation and simplicity with respect to the event log. Third, the selected models are smart-randomly mutated. This process of selection and mutation is repeated until a satisfactory model is found, or until time runs out.

ETM is flexible as both the selection and the stopping criteria can be adjusted to the use case at hand; one can prioritise (combinations of) quality criteria. However, due to the repeated evaluation of models, on large event logs of complex processes, stopping criteria might force a user to make the decision between speed and quality.

Inductive Miner Family

The Inductive Miner (IM) family of process discovery algorithms, like the Evolutionary Tree Miner, discovers process trees to guarantee that all models that are discovered are sound. The IM algorithms apply a recursive strategy: first, the “most important” behaviour of the event log is identified (such as sequence, exclusive choice, concurrency, loop, etc.). Second, the event log is split in several parts, and these steps are repeated until a base case is encountered (such as a log consisting of a single activity). If no “most important” behaviour can be identified, then the algorithms try to continue the recursion

by generalising the behaviour in the log, in the worst case ultimately ending in a flower model.

Besides a basic IM (Leemans et al. 2013a), algorithms exist that focus on filtering noise (Leemans et al. 2013b), handling incomplete behaviour (when the event log misses crucial information of the process) (Leemans et al. 2014a), handling lifecycle information of events (if the log contains information of e.g. when activities started and ended) (Leemans et al. 2015), discovering challenging constructs such as inclusive choice and silent steps (Leemans 2017), and handling very large logs and complex processes (Leemans et al. 2016), all available in the ProM framework.

Several IM-algorithms guarantee to return a model that perfectly fits the event log, and all algorithms are capable of rediscovering the process, assuming that the process can be described as a process tree (with some other restrictions, such as no duplicated activities) and assuming that the event log contains “enough” information. However, due to the focus on fitness, precision tends to be lower on event logs of highly unstructured processes.

All Inductive Miner algorithms are available as plug-ins of the ProM framework, and some as plug-ins of the Apromore framework. Furthermore, the plug-in Inductive visual Miner (Leemans et al. 2014b) provides an interactive way to apply these algorithms and perform conformance checking.

An algorithm that uses a similar recursive strategy, but lets constructs compete with one another is the Constructs Competition Miner (Redlich et al. 2014), however its implementation has not been published.

Structured Miner

The Structured Miner (STM) (Augusto et al. 2016) applies a different strategy to obtain highly block-structured models and to tradeoff the log quality criteria. Instead of discovering block-structured models directly, SM first discovers BPMN models and, second, structures these models. The models can be obtained from any other discovery technique, for instance Heuristics Miner or Fodina, as these models need not be

sound. These models are translated to BPMN, after which they are made block-structured by shifting BPMN-gateways in or out, thereby duplicating activities.

STM benefits from the flexibility of the used other discovery technique to strike a flexible balance between log-quality criteria and can guarantee to return sound models. However, this guarantee comes at the price of equivalence (the model is changed, not just restructured), simplicity (activities are duplicated) and speed (the restructuring is $O(n^n)$).

STM is available as both a ProM and an Apromore plugin.

(Hybrid) Integer Linear Programming Miner

The Integer Linear Programming Miner (ILP) van der Werf et al. (2009) constructs a Petri net, starting with all activities as transitions and no places, such that every activity can be arbitrarily executed. Second, it adds places using an optimisation technique: a place is only added if it does not remove any trace of the event log from the behaviour of the model. Under this condition, the behaviour is restricted as much as possible.

ILP focusses on fitness and precision: it guarantees to return a model that fits the event log, and the most precise model within its representational bias (Petri nets, no duplicated activities). However, the ILP miner does not guarantee soundness, does not handle noise and tends to return complex models (Leemans 2017).

The first of these two have been addressed in the HybridILPMiner (van Zelst et al. 2017), which performs internal noise filtering. Furthermore, it adjusts the optimisation step to guarantee that the final marking is always reachable, and, in some cases, returns workflow nets, thereby achieving *relaxed soundness*.

Declarative Techniques

Petri nets and BPMN models express what *can* happen when executing the model. In contrast, declarative models, such as Declare models, express what *cannot* happen when executing the model, thereby providing greater flexibility in modelling. Declare miners such as Maggi et al.

(2011), Di Ciccio et al. (2016), and Ferilli et al. (2016) discover the constraints of which Declare models consist using several acceptance criteria, in order to be able to balance precision and fitness. However, using such models in practice tends to be challenging (Augusto et al. 2017b).

Other Algorithms

Unsound models are unsuitable for further automated processing, however might be useful for manual analysis. In the remainder of this section, several algorithms are discussed that do not guarantee soundness.

α -Algorithms

The first process discovery algorithm described was the α -algorithm (van der Aalst et al. 2004). The α algorithm considers the directly follows graph and identifies three types of relations between sets of activities from the graph: sequence, concurrency and mutual exclusivity. From these relations, a Petri net is constructed by searching for certain maximal patterns.

The α algorithm is provably (Badouel 2012) able to rediscover some processes, assuming that the log contains enough information and with restrictions on the process. In later versions, several restrictions have been addressed, such as: (a) no short loops (activities can follow one another directly; addressed in α^+ (de Medeiros et al. 2004)), (b) no long-distance dependencies (choices later in the process depend on choices made earlier; addressed in Wen et al. (2006)), (c) no non-free-choice constructs (transitions that share input places have the same input places; addressed in α^{++} (Wen et al. 2007a)), and (d) no silent transitions (addressed in $\alpha^\#$ (Wen et al. 2007b, 2010) and in $\alpha^\$$ (Guo et al. 2015)). Furthermore, a variant has been proposed, called the Tsinghua- α (Wen et al. 2009), that deals with non-atomic event logs. That is, event logs in which executions of activities take time.

However, these algorithms guarantee neither soundness nor perfect fitness nor perfect precision, the algorithms cannot handle noise and cannot handle incompleteness. Furthermore, the α algorithms might be less fast on complex event logs, as typically they are exponential. Therefore,

the α -algorithms are not very suitable to be applied to real-life logs.

Little Thumb (Weijters and van der Aalst 2003) extends the α algorithms with noise-handling capabilities: instead of considering binary activity relations, these relations are derived probabilistically and then filtered according to a user-set threshold.

Causal-Net Miners

The Flexible Heuristics Miner (FHM) (Weijters and Ribeiro 2011) uses the probabilistic activity relations of Little Thumb and focuses on soundness. To solve the issue of soundness, FHM returns causal nets, a model formalism in which it is defined that non-sound parts of the model are not part of the behaviour of the net.

The Fodina algorithm (vanden Broucke and Weerdt 2017) extends FHM with long-distance dependency support and, in some cases, duplicate activities. The Proximity miner (Yahya et al. 2016) extends FHM by incorporating domain knowledge. For more algorithms using causal nets, please refer to Weerdt et al. (2012) and Augusto et al. (2017b).

Even though causal nets are sound by definition, they place the burden of soundness checking on the interpreter/user of the net, and this still does not guarantee, for instance, that every activity in the model can be executed. Therefore, translating a causal net to a Petri net or BPMN model for further processing does not guarantee soundness of the translated model.

FHM, Fodina (<http://www.processmining.be/fodina>) and Proximity Miner (<https://sourceforge.net/projects/proxi-miner/>) are all available as ProM plug-ins and/or Apromore plug-ins.

Split Miner

To strike a different balance in log-quality criteria compared to IM that favours fitness, while improving in speed over ETM, Split Miner (SPM) (Augusto et al. 2017a) preprocesses the directly follows graph before constructing a BPMN model. In the preprocessing of directly follows graphs, first, loops and concurrency are identified and filtered out. Second, the graph is filtered in an optimisation step: each node must

be on a path from start to end, the total number of edges is minimised, while the sum of edge frequencies is maximised. Then, splits and joins (BPMN gateways) are inserted to construct a BPMN model.

SPM aims to improve over the precision of IM and the speed of ETM for real-life event logs. The balance between precision and fitness can be adjusted in the directly follows-optimisation step, which allows users to adjust the amount of noise filtering. However, the returned models are not guaranteed to be sound (proper completion is not guaranteed), and several OR-joins might be inserted, which increases complexity.

SPM is available as a plug-in of Apromore and as a stand-alone tool via <https://doi.org/10.6084/m9.figshare.5379190.v1>.

Conclusion

Many process mining techniques require a process model as a prerequisite. From an event log, process discovery algorithms aim to discover a process model, this model preferably having clear semantics, being sound, striking a user-adjustable balance between fitness, precision, generalisation and simplicity, and having confidence that the model represents the business process from which the event log was recorded. Three types of process discovery algorithms were discussed: directly follows-based techniques, soundness-guaranteeing algorithms and other algorithms, all targeting a subset of these quality criteria.

In explorative process mining projects, choosing a discovery algorithm and its parameters is a matter of repeatedly trying *soundness-guaranteeing* algorithms, evaluating their results using conformance checking and adjusting algorithm, parameters and event log as new questions pop up (van Eck et al. 2015).

Guangdong, China

Synonyms

Approximate reasoning; Inference; Logical reasoning; Semantic computing

Definitions

Reasoning is the process of deriving conclusions in a logical way. Automatic reasoning is concerned with the construction of computing systems that automate this process over some knowledge bases.

Automated Reasoning is often considered as a subfield of artificial intelligence. It is also studied in the fields of theoretical computer science and even philosophy.

Overview

The development of formal logic (Frege 1884) played a big role in the field of automated reasoning, which itself led to the development of artificial intelligence.

Historically, automated reasoning is largely related to theorem proving, general problem solvers, and expert systems (cf. the section

of “A Bit of History”). In the context of big data processing, automated reasoning is more relevant to modern knowledge representation languages, such as the W3C standard Web Ontology Language (OWL) (<https://www.w3.org/TR/owl2-overview/>), in which a knowledge base consists of a schema component (TBox) and a data component (ABox).

From the application perspective, perhaps the most well-known modern knowledge representation mechanism is Knowledge Graph (Pan et al. 2016b, 2017). In 2012, Google popularized the term “Knowledge Graph” by using it for improving its search engine. Knowledge Graphs are then adopted by most leading search engines (such as Bing and Baidu) and many leading IT companies (such as IBM and Facebook). The basic idea of Knowledge Graph is based on the knowledge representation formalism called semantic networks. There is a modern W3C standard for semantic networks called RDF (Resource Description Framework, <https://www.w3.org/TR/rdf11-concepts/>). Thus RDF/OWL graphs can be seen as exchangeable knowledge graphs, in the big data era.

While this entry will be mainly about automated reasoning techniques in the big data era, their classifications, key contributions, typical systems, as well as their applications, it starts with a brief introduction of the history.

A Bit of History

Many consider the Cornell Summer Meeting of 1957, which brought together many logicians and computer scientists, as the origin of automated reasoning.

The first automated reasoning systems were theorem provers, systems that represent axioms and statements in first-order logic and then use rules of logic, such as modus ponens, to infer new statements. The first system of this kind is the implementation of Presburger's decision procedure (which proved that the sum of two even numbers is even) by Davis (1957).

Another early type of automated reasoning system were general problem solvers, which at-

tempt to provide a generic planning engine that could represent and solve structured problems, by decomposing problems into smaller more manageable subproblems, solving each subproblem and assembling the partial answers into one final answer. The first system of this kind is Logic Theorist from Newell et al. (1957).

The first practical applications of automated reasoning were expert systems, which focused on much more well-defined domains than general problem solving, such as medical diagnosis or analyzing faults in an aircraft, and on more limited implementations of first-order logic, such as modus ponens implemented via IF-THEN rules. One of the forerunners of these systems is MYCIN by Shortliffe (1974).

Since 1980s, there have been prosperous studies of practical subsets of first-order logics as ontology languages, such as description logics (Baader et al. 2003) and answer set programming (Lifschitz 2002), as well as the standardization of ontology language OWL (version 1 in 2004 and version 2 in 2009). The wide adoption of ontology and Knowledge Graph (Pan et al. 2016b, 2017), including by Google and many other leading IT companies, confirms the status of ontology language in big data era.

In the rest of the entry, we will focus on automated reasoning with Ontology languages.

Classification

There can be different ways of classifying research problems related to automated ontology reasoning.

From the *purpose* point of view, automatic ontology reasoning can be classified into (1) deductive ontology reasoning (Levesque and Brachman 1987), which draws conclusions from given premises; (2) abductive ontology reasoning (Colucci et al. 2003), which finds explanations for observations that are not consequences of given premises; as well as (3) inductive ontology reasoning (Lisi and Malerba 2003), which concludes that all instances of a class have a certain property if some instances of the class have the property.

From the *direction* point of view, automatic ontology reasoning can be classified into (1) forward reasoning Baader et al. (2005), in which the inference starts with the premises, moves forward, and ends with the conclusions; (2) backward reasoning (Grosof et al. 2003), in which the inference starts with the conclusions, moves backward, and ends with the premises; as well as (3) bi-directional reasoning (MacGregor 1991) in which the inference starts with both the premises and the conclusions and moves forward and backward simultaneously or interactively, until the intermediate conclusions obtained by forward steps include all intermediate premises required by backward steps.

From the *monotonicity* point of view, automatic ontology reasoning can be classified into (1) monotonic ontology reasoning in which no existing conclusions will be dropped when new premises are added, as well as (2) nonmonotonic ontology reasoning (Quantz and Suska 1994) in which some existing conclusions can be dropped when new premises are added.

From the *scalability* point of view, automatic ontology reasoning can be classified into (1) parallel ontology reasoning (Bergmann and Quantz 1995), in which reasoning algorithms can exploit multiple computation cores in a computation nodes, and (2) distributed ontology reasoning (Borgida and Serafini 2003) and (Serafini 2005), in which reasoning algorithms can exploit a cluster of computation nodes. Scalable ontology reasoning is also often related to strategies of modularization (Suntisrivaraporn et al. 2008) and approximation (Pan and Thomas 2007).

From the *mobility* point of view, automated ontology reasoning can be classified into (1) reasoning with temporal ontologies (Artale and Franconi 1994), in which the target ontologies contain temporal constructors for class and property descriptions, and (2) stream ontology reasoning (Stuckenschmidt et al. 2010; Ren and Pan 2011), which, given some continuous updates of the ontology, requires updating reasoning results without naively recomputing all results.

From the *certainty* point of view, automatic reasoning can be classified into (1) ontology reasoning with certainty in which both premises and

conclusions are certain and either true or false, as well as (2) uncertainty ontology reasoning (Koller et al. 1997) in which either premises or conclusions are uncertain and often have truth values between 0/ – 1 and 1. There are different kinds of uncertainties within ontologies, such as probabilistic ontologies (Koller et al. 1997), fuzzy ontologies (Straccia 2001), and possibilistic ontologies (Qi et al. 2011).

Key Contributions

The highlight on contributions of automated ontology reasoning is the standardization of the Web Ontology Language (OWL).

The first version of OWL (or OWL 1) was standardized in 2004. It is based on the *SHOIQ* DL (Horrocks and Sattler 2005). However, there are some limitations of OWL 1:

1. The datatype support is limited (Pan and Horrocks 2006);
2. The only sub-language, OWL-Lite, of OWL 1 is not tractable;
3. The semantics of OWL 1 and RDF are not fully compatible (Pan and Horrocks 2003).

The second version of OWL (or OWL 2) was standardized in 2009. It is based on the *SROIQ* DL (Horrocks et al. 2006). On the one hand, OWL 2 has more expressive power, such as the stronger support of datatypes (Pan and Horrocks 2006; Motik and Horrocks 2008) and rules (Krötzsch et al. 2008). On the other hand, OWL 2 has three tractable sub-languages, including OWL 2 EL (Baader et al. 2005), OWL 2 QL (Calvanese et al. 2007), and OWL 2 RL (Grosof et al. 2003).

This two-layer architecture of OWL 2 allows approximating OWL 2 ontologies to those in its tractable sub-languages, such as approximations toward OWL 2 QL (Pan and Thomas 2007), toward OWL 2 EL (Ren et al. 2010), and toward OWL 2 RL (Zhou et al. 2013), so as to exploit efficient and scalable reasoners of the sub-languages. The motivation is based on the fact

that real-world knowledge and data are hardly perfect or completely digitalized.

Typical Reasoning Systems

Below are descriptions of some well-known OWL reasoners (in alphabetical order).

CEL

CEL (Baader et al. 2006) is a LISP-based reasoner for \mathcal{EL} (Baader et al. 2008), which covers the core part of OWL 2 EL. CEL is the first reasoner for the description logic \mathcal{EL} , supporting as its main reasoning task the computation of the subsumption hierarchy induced by \mathcal{EL} ontologies.

ELK

ELK (Kazakov et al. 2012) is an OWL 2 EL reasoner. At its core, ELK uses a highly optimized parallel algorithm (Kazakov et al. 2011). It supports stream reasoning in OWL 2 EL (Kazakov and Klinov 2013).

FaCT

FaCT Horrocks (1998) is a reasoner for the description logic *SHIF* (OWL-Lite). It is the first modern reasoner that demonstrates the feasibility of using optimized algorithms for subsumption checking in realistic applications.

FaCT++

FaCT++ (Tsarkov and Horrocks 2006) is a reasoner for (partially) OWL 2. It is the new generation of the well-known FaCT reasoner which is implemented using C++, with a different internal architecture and some new optimizations.

HermiT

HermiT (Glimm et al. 2014) is a reasoner for OWL 2. It is the first publicly available OWL 2 reasoner based on a hypertableau calculus (Motik et al. 2009), with a highly optimized algorithm for ontology classification (Glimm et al. 2010). HermiT can handle DL-Safe rules (Motik et al. 2005) on top of OWL 2.

Konclude

Konclude (Steigmiller et al. 2014b) is a reasoner for OWL 2. It supports almost all datatypes in OWL 2. Konclude implements a highly optimized version of tableau calculus enhanced with tableau saturation (Steigmiller and Glimm 2015). It supports parallel reasoning and nominal schemas (Steigmiller et al. 2014a) and DL-safe rules.

Mastro

Mastro (Calvanese et al. 2011) is an ontology-based data access (OBDA) management system for OWL 2 QL. It allows data to be managed by external relational data management or data federation systems. It uses the Presto algorithm Rosati and Almatelli (2010) for query rewriting.

Ontop

Ontop (Calvanese et al. 2016) is an ontology-based data access (OBDA) management system for RDF and OWL 2 QL, as well as SWRL with limited forms of recursions. It also supports efficient SPARQL-to-SQL mappings via R2RML (Rodriguez-Muro and Rezk 2015). Ontop has some optimizations on query rewriting based on database dependencies (Rodriguez-Muro et al. 2013).

Pellet

Pellet (Sirin et al. 2007) is a reasoner for OWL 2. It also has dedicated support for OWL 2 EL. It incorporates optimizations for nominals, conjunctive query answering, and incremental reasoning.

Racer

Racer (Haarslev and Möller 2001) is a reasoner for OWL 1. It has a highly optimized version of tableau calculus for the description logic $S\mathcal{H}\mathcal{T}\mathcal{Q}(D)$ (Horrocks and Patel-Schneider 2003).

RDFox

RDFox (Motik et al. 2014) is a highly scalable in-memory RDF triple store that supports shared memory parallel datalog (Ceri et al. 1989) reasoning. It supports stream reasoning (Motik et al.

2015b) and has optimizations for owl:sameAs (Motik et al. 2015a).

TrOWL

TrOWL (Thomas et al. 2010) is a highly optimized approximate reasoner (Pan et al. 2016a) for OWL 2. TrOWL outperforms some sound and complete reasoners in the time-constrained ORE (Ontology Reasoner Evaluation) competitions designed for sound and complete ontology reasoners. TrOWL has stream reasoning capabilities for both OWL 2 and OWL 2 EL (Ren and Pan 2011; Ren et al. 2016). It supports local closed world reasoning in NBox or closed predicates (Lutz et al. 2013).

Applications

Automated ontology reasoning has been widely used in web applications, such as for content management (BBC), travel planning and booking (Skyscanner), and web search (Google, Bing, Baidu).

It is also being applied in a growing number of vertical domains. One typical example is life science. For instance, OBO Foundry includes more than 100 biological and biomedical ontologies. The SNOMED CT (Clinical Terminology) ontology is widely used in healthcare systems of over 15 countries, including the USA, the UK, Australia, Canada, Denmark, and Spain. It is also used by major US providers, such as Kaiser Permanente. Other vertical domains include, but not limited to, agriculture, astronomy, oceanography, defense, education, energy management, geography, and geoscience.

While ontologies are widely used as structured vocabularies, providing integrated and user-centric view of heterogeneous data sources in the big data era, benefits of using automated ontology reasoning include:

1. Reasoning support is critical for development and maintenance of ontologies, in particular on derivation of taxonomy from class definitions and descriptions.

2. Easy location of relevant terms within large structured vocabulary;
3. Query answers enhanced by exploiting schema and class hierarchy.

An example in the big data context is the use of ontology and automated ontology reasoning for data access in Statoil, where about 900 geologists and geophysicists use data from previous operations in nearby locations to develop stratigraphic models of unexplored areas, involving diverse schemata and TBs of relational data spread over 1000s of tables and multiple databases. Data analysis is the most important factor for drilling success. 30–70% of these geologists and geophysicists' time is spent on data gathering. The use of ontologies and automated ontology reasoning enables better use of experts' time, reducing turnaround for new queries significantly.

Outlook

Despite the current success of automated ontology reasoning, there are still some pressing challenges in the big data era, such as the following:

1. Declarative data analytics (Kaminski et al. 2017) based on automated ontology reasoning;
2. Effective approaches of producing high-quality (Ren et al. 2014; Konev et al. 2014) ontologies and Knowledge Graphs;
3. Integration of automated ontology reasoning with data mining (Lecue and Pan. 2015) and machine learning (Chen et al. 2017) approaches.

Benchmark Harness

Nicolas Michael
Oracle, San Francisco, CA, USA

Synonyms

Test harness

Definitions

A benchmark harness is a software that provides the infrastructure to conduct benchmarks of a software and/or hardware system, typically with the goal to quantitatively assess the system's characteristics and capabilities or to compare the characteristics and capabilities of multiple systems relative to each other. It facilitates the development and execution of benchmarks and the analysis of benchmark results. Typical components of a big data benchmark harness include a tool to generate data, an execution environment to run benchmarks, a data collection component to monitor the benchmark run, and a reporting component to calculate and summarize benchmark results.

Overview

In computing, benchmarking is the process of assessing a system's quantitative characteristics

and capabilities by running a benchmark workload (or set of workloads) against it. The assessed system, also referred to as the *system under test (SUT)*, may be a software and/or hardware system. The SUT's characteristics and capabilities of interest are often its performance but may also include its availability, reliability, quality-of-service, cost, or other nonfunctional aspects. A benchmark workload exercises functionality of the SUT by submitting requests or jobs to the system, invoking its operations, or through other triggers, typically in a way representative for a common use of the system.

The primary objective of the benchmark workload is to measure the SUT's operations in a quantitative way using metrics such as throughput, capacity, execution time, or resource usage. The validation for correctness of SUT's responses or outputs, however, is often of lower priority, and correct operation is assumed as a prerequisite. Benchmark results are typically expressed as a set of metrics, which can be used to compare the performance or other nonfunctional aspects of different systems, or to optimize or tune a system. A *benchmark harness* facilitates this process by providing the necessary infrastructure to conduct benchmarks.

While the terms *benchmarking* and *testing* and consequently *benchmark harness* and *test harness* are often used interchangeably, the term *benchmarking* always refers to a quantitative evaluation of a system's nonfunctional operation such as its performance, while the term *testing*

often refers to a functional validation of a system's specific behavior.

A benchmark harness often provides reusable functionality that can be shared across a set of benchmarks or workloads and provides well-defined interfaces to implement or integrate multiple benchmarks or workloads into the same harness and to execute them. Such common functionality may include:

- Preparing and configuring the test environment
- Generating and loading of data
- Starting, supervising, and stopping of a benchmark workload
- Scheduling and accounting of benchmark operations
- Monitoring of the system under test
- Collecting runtime statistics from the benchmark workload and system under test
- Generating benchmark reports (including benchmark metrics and result validation)

Benchmark harnesses typically implement a subset, if not all, of the above features, which are discussed in more detail below.

In the context of big data, the generation of test data is a crucial part of many big data benchmarks. Real-world data sets are often difficult to obtain and not necessarily of the desired scale. Many big data benchmarks therefore rely on either synthetic data sets or synthetically scaled-up real-world data sets. The ability to generate meaningful test data at any scale, suitable for reproducible benchmark runs, is therefore important for most big data benchmark harnesses.

Key Research Findings

While there is no single architecture for benchmark harnesses, many benchmark harnesses are structured in a similar way and provide some or all of the above-noted features. Research around benchmark harnesses is sparse, and only little detailed description of benchmark harness features

exist in literature. This article summarizes some of them and provides an overview of features and functionality a benchmark harness should provide.

Han (Han et al. 2014) formulates requirements on how to design big data benchmarks (or big data benchmark harnesses). He proposes a design consisting of a user interface layer, a function layer, and an execution layer. The user interface layer shall provide users the ability to select benchmark workloads, data sets, and scale and to initiate benchmark runs. The function layer shall consist of data generators, test generators, and metrics, while the execution layer shall provide system configuration tools, data format conversion tools, a result analyzer, and a result reporter. All these components shall be shared across benchmarks and data sets and provide mechanisms to implement various benchmark workloads on a common harness, which can be adapted to a variety of environments.

Test Environment Preparation

Before a benchmark can be run, the test environment needs to be prepared and configured. Depending on the complexity of the test environment, its degree of automation or integration with deployment tools, the preparation of a test environment can be a lengthy, tedious, and error-prone task. Han therefore proposes that benchmark harnesses should have “configuration tools” to enable a benchmark to run on a specific software stack (Han et al. 2014). Such tools should help a user to set up a properly and compliantly configured test environment.

Since most benchmarks are designed to be executed against arbitrary systems of different vendors, which might evolve over time or even are released only after the benchmark has been created, it is generally difficult for a benchmark harness to integrate with the software and hardware stack of every single relevant product. In some cases, benchmark harnesses may provide configuration tools for selective products. Ideally, benchmark harnesses should be extensible by providing interfaces that allow users to integrate them with various products.

The product-agnostic benchmark harness CloudPerf (Michael et al. 2017) provides APIs for additional “service modules” to implement “precondition checks” that validate a system configuration before a test run and potentially take corrective action. Each service may also implement a preparation method to set up or prepare a test environment, which is invoked through a callback before the workload starts running.

Test Data Generation

Test data is a central aspect of every big data benchmark. Most big data benchmarks rely on synthetically generated or synthetically scaled-up real-world data sets. Baru argues that the pure use of real data sets is often impractical as those can be hard to obtain, download, and store but most importantly are difficult to scale (Baru et al. 2012). As Han states “synthetic data generation preserving the 4V properties of big data is the foundation of producing meaningful and credible evaluation results”(Han et al. 2014). Rabl discusses requirements for parallel data generation and introduces the parallel data generation framework PDGF (Rabl and Poess 2011). Wang describes approaches and trade-offs of synthetic data generation (Wang et al. 2014), and many other researchers have written about this subject (Baru et al. 2012; Ghazal et al. 2013).

Han describes an architecture for test data generators in benchmark harnesses, including format conversion tools as a post-processing step to convert the generated data into a format usable by a specific workload and environment. BigDataBench uses BDGS as a data generator (Ming et al. 2013). Capotă et al. describe data set generation as one module of the Graphalytics architecture (Capotă et al. 2015).

Benchmark Workload Execution

The central function of every benchmark harness is the execution of the benchmark workload itself. As a minimum, the benchmark harness must support features to start and stop the benchmark workload or to detect its completion. Typically the harness would also monitor and supervise the benchmark workload while it is running.

Some benchmark harnesses provide additional features for workload execution through abstractions or APIs. Graphalytics has a platform-specific algorithm implementation to adapt benchmark functions to particular big data platforms (Capotă et al. 2015). CloudPerf *drivers*, which are started and supervised by the CloudPerf framework, can each execute an individual workload and either wrap existing workloads or run native workloads implemented using CloudPerf’s workload modeling APIs (Michael et al. 2017).

Scheduling and Accounting of Benchmark Operations

A big data benchmark typically consists of multiple operations which are executed either randomly or in a particular order at a configurable concurrency, rate, or timing. The elapsed time of benchmark operations as well as the total number of successfully completed operations, number of failures, or rate and concurrency of operations must be captured during workload execution to calculate benchmark metrics and evaluate the benchmark run after completion.

Most benchmark harnesses rely on the benchmark workload itself to schedule and monitor its benchmark operations and only gather the collected workload statistics through some defined interface such as a log file. In this model, each benchmark workload might use different methodology to schedule operations and account for them. Alternatively, a benchmark harness could have the ability to schedule and account for benchmark operations directly built into the harness. Benchmark workloads would then only implement the benchmark operations itself, while the infrastructure to run and measure operations is provided by a common harness. The benchmark harness must then specify interfaces for benchmark workloads to implement benchmark operations, which are then invoked by the harness during a benchmark run. CloudPerf follows this models for natively implemented workloads (Michael et al. 2017), while BigDataBench relies on each individual benchmark to capture schedule and account for its operations (Wang et al. 2014).

System Monitoring and Statistics Collection

The previous section discussed the need to monitor the benchmark workload itself. The objective of running a benchmark can be technical or competitive (Baru et al. 2012). In the technical use of benchmarks, the objective is to optimize a system, while in the competitive use of a benchmark, the objective is to compare the relative performance of different systems. Both cases require the collection of additional system statistics to fully evaluate a benchmark run, analyze its resource usage, and eventually optimize the system.

A benchmark harness should therefore also be capable of collecting system statistics across all relevant layers of the stack during a benchmark run. In the Graphalytics benchmark harness, a “system monitor” component is “responsible for gathering resource utilization statistics from the SUT” (Capotă et al. 2015). CloudPerf’s statistics framework enables application- and environment-specific statistics providers to capture and push statistics into the harness for live monitoring and post-run analysis (Michael et al. 2017).

Benchmark Report Generation

The outcome of a benchmark run is typically documented in a report. The benchmark report should include information about the benchmark itself, its configuration and scale, and the system environment on which it was conducted and contain benchmark metrics as well as relevant system statistics. Its intention is to summarize the outcome of a benchmark and potentially validate its result to classify it as “passed” or “failed”. The report should allow to compare two different systems against each other and allow to judge them with respect to their relative performance. Additional desirable metrics include each system’s cost (in terms of necessary system components or power consumption), quality-of-service, and maximum capacity with respect to data volume, supported users, or concurrency. For technical benchmarking (Ghazal et al. 2013), the report should further include relevant system

statistics that help engineers to analyze and troubleshoot performance bottlenecks and tune or optimize a system.

Han describes components for their layered harness architecture that allow the definition of metrics and the analysis and reporting of results (Han et al. 2014). Metrics can be classified as user-perceived metrics such as request rates and response times and architectural metrics such as resource utilization and other system statistics from the SUT (Wang et al. 2014).

Graphalytics (Capotă et al. 2015) contains an output validator module, which receives data from the benchmark workload itself as well as the big data platform. Benchmark configuration data from the benchmark, evaluation of the benchmark’s correctness from the output validator, as well as system statistics from the system monitor component are then processed by the report generator to compile a benchmark report, which is then stored in a result database. CloudPerf (Michael et al. 2017) supports the definition of metrics, result checks, and key performance indicators (KPIs), which are evaluated by a reporter component at the end of a run based on both workload and system statistics. The report includes system configuration information, benchmark and system metrics, KPIs, a validation whether the benchmark run was successful or failed based on the configured result checks, as well as detailed workload and system runtime statistics.

Examples of Application

BigDataBench (Wang et al. 2014) is a benchmark suite of a rather loosely coupled collection of benchmarks, data sets, and data generators (Ming et al. 2013), with little common harness functionality across the various benchmarks, but contains a large number of benchmark workloads (originally 19, which have since then been enhanced to 37 benchmark workloads (Zhan et al. 2016)). Graphalytics on the other hand implements a modular and extensible benchmark harness “which facilitates the addition of new

datasets, algorithms, and platforms, as well as the actual performance evaluation process, including result collection and reporting” (Capotă et al. 2015). CloudPerf (Michael et al. 2017), a benchmark harness primarily designed for distributed multi-tenant systems, consists of an extensible framework with well-defined APIs to implement workloads, data loading, statistics collection, fault injection, and cloud deployment while providing common functionality in the harness itself.

Definitions

Intrinsic characteristics of IoT big data are identified and classified. Potential IoT applications bringing significant changes in many domains are described. Many new challenges and open issues to be addressed in IoT are discussed.

Overview

This entry firstly discusses the intrinsic characteristics of IoT big data and classifies them into three categories: data generation, data quality, and data interoperability. Specific characteristics of each category are identified. Then it introduces ongoing and/or potential IoT applications, which show that IoT can bring significant changes in many domains, i.e., cities and homes, environment monitoring, health, energy, business, etc. Since many new challenges and issues around IoT big data have not been addressed, which require substantial efforts from both academia and industry, this entry also identifies several key directions for future research and development from a data-centric perspective.

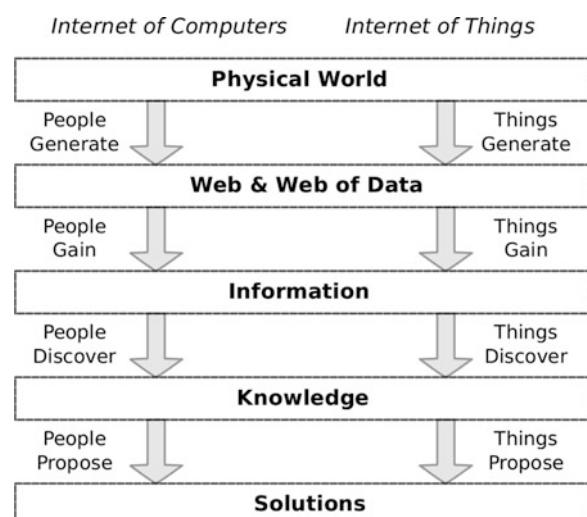

Introduction

The Internet is a global system of networks that interconnect computers using the standard Internet protocol suite. It has significant impact on the world as it can serve billions of users worldwide. Millions of private, public, academic, business, and government networks, of local to global scope, all contribute to the formation of the Internet. The traditional Internet has a focus on computers and can be called the Internet of Computers. In contrast, evolving from the Internet of Computers, the Internet of Things (IoT) emphasizes things rather than computers (Ashton 2009). It aims to connect everyday objects, such as coats, shoes, watches, ovens, washing machines, bikes, cars, and even humans, plants, animals, and changing environments, to the Internet to enable communication/interactions between these objects. The ultimate goal of IoT is to enable computers to see, hear, and sense the real world. It is predicted by Ericsson that the number of Internet-connected things will reach 50 billion by 2020. Electronic devices and systems exist around us providing different services to the people in different situations: at home, at work, in their office, or driving a car on the street. IoT also enables the close relationship between human and opportunistic connection of smart things (Guo et al. 2013).

Big Data Analysis and IoT, Fig. 1 Internet of Computers v.s. Internet of Things

There are several definitions or visions of IoT from different perspectives. From the viewpoint of services provided by things, IoT means “a world where things can automatically communicate to computers and each other providing services to the benefit of the human kind” (CASAGRAS 2000). From the viewpoint of connectivity, IoT means “from anytime, anyplace connectivity for anyone, we will now have connectivity for anything” (ITU 2005). From the viewpoint of communication, IoT refers to “a world-wide network of interconnected objects uniquely addressable, based on standard communication protocols” (INFSO 2008). Finally, from the viewpoint of networking, IoT is the Internet evolved “from a network of interconnected computers to a network of interconnected objects” (European Commission 2009).

We focus on our study of IoT from a *data perspective*. As shown in Fig. 1, data is processed differently in the Internet of Things and traditional Internet environments (i.e., Internet of Computers). In the Internet of Computers, both main data producers and consumers are human beings. However, in the Internet of Things, the main actors become *things*, which means things are the majority of data producers and consumers. Therefore, we give our definition of IoT as follows:

In the context of the Internet, addressable and interconnected things, instead of humans, act as the main data producers, as well as the main data consumers. Computers will be able to learn and gain information and knowledge to solve real world problems directly with the data fed from things. As an ultimate goal, computers enabled by the Internet of Things technologies will be able to sense and react to the real world for humans.

As of 2012, 2.5 quintillion (2.5×10^{18}) bytes of data are created daily (<http://www-01.ibm.com/software/data/bigdata/>). In IoT, connecting all of the things that people care about in the world becomes possible. All these things would be able to produce much more data than nowadays. The volumes of data are vast, the generation speed of data is fast, and the data/information space is global (James et al. 2009). Indeed, IoT is one of the major driving forces for *big data analytics*. Given the scale of IoT, topics such as storage, distributed processing, real-time data stream analytics, and event processing are all critical, and we may need to revisit these areas to improve upon existing technologies for applications of this scale.

In this entry, we systematically investigate the key technologies related to the development of IoT applications, particularly from a data-centric perspective. Our aim is to provide a better understanding of IoT data characteristics, applications, and issues. Although some reviews about IoT have been conducted recently (e.g., Atzori et al. 2010; Zeng et al. 2011; An et al. 2013; Perera et al. 2013; Li et al. 2014; Yan et al. 2014), they focus on high-level general issues and are mostly fragmented. Sheng et al. (2017) covers a number of areas in Web of Things. These efforts do not specifically cover topics on IoT data characteristics and potential applications from a data-centric perspective, which is fundamentally critical to fully embrace IoT.

The remainder of the chapter is organized as follows. Section “**IoT Data Taxonomy**” identifies an IoT data taxonomy. In section “**Potential IoT Applications**”, some typical ongoing and/or potential IoT applications where data techniques for IoT can bring significant changes are described. Finally, section “**Open Issues**” highlights

some research open issues on IoT from the data perspective, and section “**Summary**” offers some concluding remarks.

B

IoT Data Taxonomy

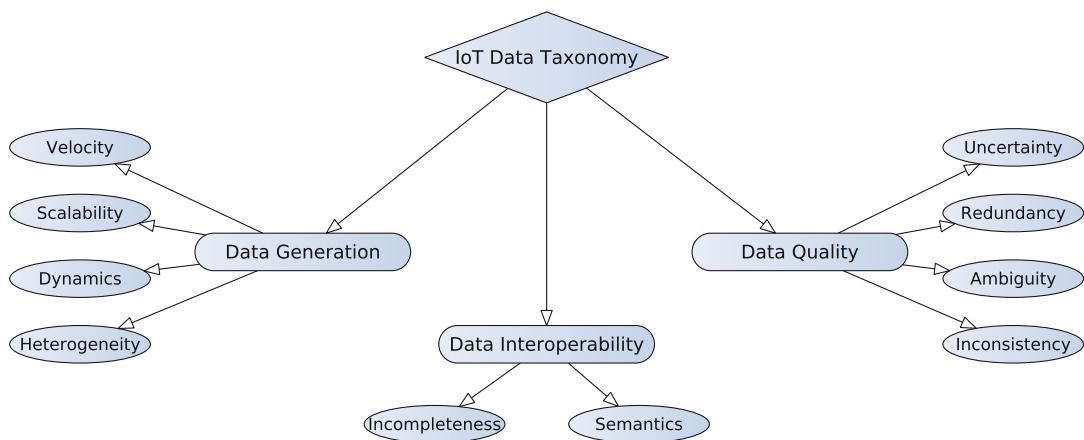

In this section, we identify the intrinsic characteristics of IoT data and classify them into three categories: *data generation*, *data quality*, and *data interoperability*. We also identify specific characteristics of each category, and the overall IoT data taxonomy is shown in Fig. 2.

Data Generation

- **Velocity.** In IoT, data can be generated at different rates. For example, for GPS-enabled moving vehicles in road networks, the GPS signal sampling frequency could be every few seconds, every few minutes, or even every half an hour. But some sensors can scan at a rate up to 1,000,000 sensing elements per second (<https://www.tekscan.com/support/faqs/what-are-sensors-sampling-rates>). On one hand, it is challenging to handle very high sampling rates, which require efficient processing of the fast generated data. On the other hand, it is also challenging to deal with low sampling rates, due to the fact that some important information may be lost for data processing and decision making.

- **Scalability.** Since things are able to continuously generate data together with the foreseeable excessively large number of things, the IoT data is expected to be at an extremely large scale. It is easy to image that, in IoT data processing systems, scalability will be a long-standing issue, aligning with the current big data trend.

- **Dynamics.** There are many dynamic elements within IoT data. Firstly, many things are mobile, which will lead to different locations at different times. Since they will move to different environments, the sensing results of things will also be changing to reflect the real world. Secondly, many things are fragile. This means the generated data will change over time due to the failure of things. Thirdly, the

Big Data Analysis and IoT, Fig. 2 IoT data taxonomy

connections between things could be intermittent. This also creates dynamics in any IoT data processing system.

- **Heterogeneity.** There will be many kinds of things potentially connecting to the Internet in the future, ranging from cars, robots, fridges, and mobile phones to shoes, plants, watches, and so on. These kinds of things will generate data in different formats using different vocabularies. In addition, there will be assorted IoT data processing systems, which will also provide data in customized formats to tailor different data needs.

Data Quality

- **Uncertainty.** In IoT, uncertainty may come from different sources. In RFID data, the uncertainty can refer to missing readings, readings of nonexisting IDs, etc. In wireless sensor networks, uncertainty can refer to sensing precision (the degree of reproducibility of a measurement), accuracy (the maximum difference that will exist between the actual value and the indicated value), etc.
- **Redundancy.** Redundancy can also be easily observable in IoT. For example, in RFID data, the same tags can be read multiple times at the same location (because multiple RFID readers exist at the spot or tags are read multiple times at the same spot) or at different locations. In wireless sensor networks, a group

of sensors of the same type may also be deployed in a nearby area, which can produce similar sensing results of that area. For the same sensor, due to the possible high sampling rates, redundant sensing data can be produced.

- **Ambiguity.** Dealing with large amount of ambiguity in IoT data is inevitable. The data produced by assorted things can be interpreted in different ways due to different data needs from different things or other data consumers. Such data can also be useful and important to any other things, which brings about the challenges of proper interpretation of the produced data to different data consumers.

- **Inconsistency.** Inconsistency is also prevalent in IoT data. For example, in RFID data, inconsistency can occur due to missing readings of tags at some locations along the supply chain. It is also easy to observe inconsistency in sensing data as when multiple sensors are monitoring the same environment and reporting sensing results. Due to the precision and accuracy of the sensing process and other problems including packet loss during transmission, data inconsistency is also an intrinsic characteristic in sensing data.

Data Interoperability

- **Incompleteness.** In order to process IoT data, being able to detect and react to events in real

time, it is important to combine data from different types of data sources to build a big and complete picture of relevant backgrounds of the real world. However, as this process relies on the cooperation of mobile and distributed things that are generating relevant background data, incompleteness is easily observable in IoT data. Suppose there are a large number of available data sources. It is of great importance to determine which data sources can best address the incompleteness of data for a given data processing task.

- **Semantics.** To address the challenges posed by the deluge of IoT data, things, or machines acting as the major data consumers should be a promising trend for data processing in the IoT era. Inspired by Semantic Web technologies, in order to enable machines to understand data for human beings, injecting semantics into data could be an initial step. Therefore, semantics within IoT data will play an important role in the process of enabling things/machines to understand and process IoT data by themselves.

Potential IoT Applications

As pointed out by Ashton (2009) that IoT “has the potential to change the world, just as the Internet did.” The ongoing and/or potential IoT applications show that IoT can bring significant changes in many domains, i.e., cities and homes, environment monitoring, health, energy, business, etc. IoT can bring the ability to react to events in the physical world in an automatic, rapid, and informed manner. This also opens up new opportunities for dealing with complex or critical situations and enables a wide variety of business processes to be optimized. In this section, we overview several representative domains where IoT can make some profound changes.

Smart Cities and Homes

IoT can connect billions of smart things and can help capture information in cities. Based on IoT, cities would become smarter and more efficient. Below are some examples of promising IoT

applications in future smart cities. In a modern city, lots of digital data traces are generated there every second via cameras and sensors of all kinds (Guinard 2010). All this data represents a gold mine for everyone, if people in the city would be able to take advantage of it in an efficient and effective way. For example, IoT can facilitate resource management issues for modern cities. Specifically, static resources (e.g., fire stations, parking spots) and mobile resources (e.g., police cars, fire trucks) in a city can be managed effectively using IoT technologies. Whenever events (fires, crime reports, cars looking for parking) arise, IoT technologies would be able to quickly match resources with events in an optimal way based on the information captured by smart things, thereby reducing cost and saving time. Taxi drivers in the city would also be able to better serve prospective passengers by learning passenger’s mobility patterns and other taxi drivers’ serving behaviors through the help of IoT technologies (Yuan et al. 2011). One study estimated a loss of \$78 billion in 2007 in the form of 4.2 billion lost hours and 2.9 billion gallons of wasted gasoline in the United States alone (Mathur et al. 2010). IoT could bring fundamental changes in urban street parking management, which would greatly benefit the whole society by reducing traffic congestion and fuel consumption.

Security in a city is of great concerns, which can benefit a lot from the development of IoT technologies. Losses resulted from property crimes were estimated to be \$17.2 billion in the United States in 2008 (Guha et al. 2010). Current security cameras, motion detectors, and alarm systems are not able to help track or recover stolen property. IoT technologies can help to deter, detect, and track personal property theft since things are interconnected and can interact with each other. IoT technologies can also help improve stolen property recovery rates and disrupt stolen property distribution networks. Similarly, a network of static and mobile sensors can be used to detect threats on city streets and in open areas such as parks.

With IoT technologies, people can browse and manage their homes via the Web. For example,

they would be able to check whether the light in their bedrooms is on and could turn it off by simply clicking a button on a Web page. Similar operations and management could be done in office environments. Plumbing is ranked as one of the ten most frequently found problems in homes (Lai et al. 2010). It is important to determine the spatial topology of hidden water pipelines behind walls and underground. In IoT, smart things in homes would be able to report plumbing problems automatically and report to owners and/or plumbers for efficient maintenance and repair.

Environment Monitoring

IoT technologies can also help to monitor and protect environments thereby improving human's knowledge about environments. Take water as an example. Understanding the dynamics of bodies of water and their impact on the global environment requires sensing information over the full volume of water. In such context, IoT technologies would be able to provide effective approaches to study water. Also IoT could improve water management in a city. Drinking water is becoming a scarce resource around the world. In big cities, efficiently distributing water is one of the major issues (Guinard 2010). Various reports show that on average 30% of drinkable water is lost during transmission due to the aging infrastructure and pipe failures. Further, water can be contaminated biologically or chemically due to inefficient operation and management. In order to effectively manage and efficiently transport water, IoT technologies would be of great importance.

Soil contains vast ecosystems that play a key role in the Earth's water and nutrient cycles, but scientists cannot currently collect the high-resolution data required to fully understand them. Many soil sensors are inherently fragile and often produce invalid or uncalibrated data (Ramanathan et al. 2009). IoT technologies would help to validate, calibrate, repair, or replace sensors, allowing to use available sensors without sacrificing data integrity and meanwhile minimizing the human resources required.

Sound is another example where IoT technologies can help. Sound is multidimensional,

varying in intensity and spectra. So it is difficult to quantify, e.g., it is difficult to determine what kind of sound is noise. Further, the definitions and feelings of noise are quite subjective. For example, some noises could be pleasant, like flowing water, while others can be annoying, such as car alarms, screeching breaks, and people arguing. A device has been designed and built to monitor residential noise pollution to address the above problems (Zimmerman and Robson 2011). Firstly, noise samples from three representative houses are used, which span the spectrum of quiet to noisy neighborhoods. Secondly, a noise model is developed to characterize residential noise. Thirdly, noise events of an entire day (24 h) are compressed into a 1-minute auditory summary. Data collection, transmission, and storage requirements can be minimized in order to utilize low-cost and low-power components, while sufficient measurement accuracy is still maintained.

Intel has developed smart sensors that can warn people about running outside when the air is polluted (<http://www.fastcoexist.com/1680111/intels-sensors-will-warn-you-about-running-outsides-when-the-air-is-polluted>). For example, if someone is preparing to take a jog along his/her regular route, an application on his/her smartphone pushes out a message: air pollution levels are high in the park where he/she usually runs. Then he/she could try a recommended route that is cleaner. Currently, many cities already have pollution and weather sensors. They are usually located on top of buildings, far from daily human activities.

Health

Covering a number of markets including manufacturing, transportation, systems, software, services, and so on, IoT in healthcare is expected to grow to a market size of \$300 billion by 2022 (Firouzi et al. 2018). In future IoT environments, an RFID-enabled information infrastructure would be likely to revolutionize areas such as healthcare and pharmaceutical. For example, a healthcare environment such as a large hospital or aged care could tag all pieces of medical equipment (e.g., scalpels, thermometers) and drug products for inventory management. Each

storage area or patient room would be equipped with RFID readers that could scan medical devices, drug products, and their associated cases. Such an RFID-based infrastructure could offer a hospital unprecedented near real-time ability to track and monitor objects and detect anomalies (e.g., misplaced objects) as they occur.

As personal health sensors become ubiquitous, they are expected to become interoperable. This means standardized sensors can wirelessly communicate their data to a device many people already carry today (e.g., mobile phones). It is argued by Lester et al. (2009) that one challenge in weight control is the difficulty of tracking food calories consumed and calories expended by activity. Then they present a system for automatic monitoring of calories consumed using a single body-worn accelerometer. To be fully benefited from such data for a large body of people, applying IoT technologies in such area would be a promising direction.

Mobile technology and sensors are creating ways to inexpensively and continuously monitor people's health. Doctors may call their clients to schedule an appointment, rather than vice versa, because the doctors could know their clients' health conditions in real time. Some projects for such purpose have been initiated. For example, EveryHeartBeat (<http://join.everyheartbeat.org/>) is a project for Body Computing to "connect the more than 5 billion mobile phones in the world to the health ecosystem." In the initial stage, heart rate monitoring is investigated. Consumers would be able to self-track their pulse, and studies show heart rate monitoring could be useful in detecting heart conditions and enabling early diagnosis. The future goal is to include data on blood sugar levels and other biometrics collected via mobile devices.

Energy

Home heating is a major factor in worldwide energy use. In IoT, home energy management applications could be built upon embedded Web servers (Priyantha et al. 2008). Through such online Web services, people can track and manage their home energy consumption. A system is designed by Gupta et al. (2009) for augmenting

these thermostats using just-in-time heating and cooling based on travel-to-home distance obtained from location-aware mobile phones. The system makes use of a GPS-enabled thermostat which could lead to savings of as much as 7%. In IoT, as things in homes would become smart and connected to the Internet, similar energy savings could be more effective. For example, by automatically sensing occupancy and sleep patterns in a home, it would be possible to save energy by automatically turning off the home's HVAC (heating, ventilation, and air conditioning) system.

Besides home heating, fuel consumption is also an important issue. GreenGPS, a navigation service that uses participatory sensing data to map fuel consumption on city streets, has been designed by Ganti et al. (2010). GreenGPS would allow drivers to find the most fuel-efficient routes for their vehicles between arbitrary end points. In IoT, fuel consumption would be further reduced by enabling cars and passengers to communicate with each other for ride sharing (Yuan et al. 2011).

Business

IoT technologies would be able to help to improve efficiency in business and bring other impacts on business (Mattern and Floerkemeier 2010):

- From a commercial point of view, IoT can help increase the efficiency of business processes and reduce costs in warehouse logistics and in service industries. This is because more complete and necessary information can be collected by interconnected things. Owing to its huge and profound impact on the society, IoT research and applications can also trigger new business models involving smart things and associated services.
- From a social and political point of view, IoT technologies can provide a general increase in the quality of life for the following reasons. Firstly, consumers and citizens will be able to obtain more comprehensive information. Secondly, care for aged and/or disabled people can be improved with smarter assistance

systems. Thirdly, safety can be increased. For example, road safety can be improved by receiving more complete and real-time traffic and road condition information.

- From a personal point of view, new services enabled by IoT technologies can make life more pleasant, entertaining, independent, and also safer. For example, business taking advantages of technologies of search of things in IoT can help locate lost things quickly, such as personal belongings, pets, or even other people (Tran et al. 2017).

Take improving information handover efficiency in a global supply chain as an example. The concept of *digital object memories* (DOM) is proposed in Stephan et al. (2010), which stores order-related data via smart labels on the item. Based on DOM, relevant life cycle information could be attached to the product. Considering the potential different stakeholders including manufacturer, distributor, retailer, and end customer along the supply/value chain, this approach facilitates information handover.

Further, there are many important bits of information in an IoT-based supply chain, such as the 5W (what, when, where, who, which). It is also necessary to integrate them efficiently and in real time in other operations. The EPCIS (Electronic Product Code Information System) network is a set of tools and standards for tracking and sharing RFID-tagged products in IoT. However, much of this data remains in closed networks and is hard to integrate (Wu et al. 2013). IoT technologies could be used to make it easier to use all this data, to integrate it into various applications, and to build more flexible, scalable, global application for better (even real-time) logistics.

Open Issues

The development of IoT technologies and applications is merely beginning. Many new challenges and issues have not been addressed, which require substantial efforts from both academia and industry. In this section, we identify some key

directions for future research and development from a data-centric perspective.

- *Data Quality and Uncertainty:* In IoT, as data volume increases, inconsistency and redundancy within data would become paramount issues. One of the central problems for data quality is *inconsistency detection*, and when data is distributed, the detection would be far more challenging (Fan et al. 2010). This is because inconsistency detection often requires shipping data from one site to another. Meanwhile, inherited from RFID data and sensor data, IoT data would be of great uncertainty, which also presents significant challenges.
- *Co-space Data:* In an IoT environment, the physical space and the virtual (data) space co-exist and interact simultaneously. Novel technologies must be developed to allow data to be processed and manipulated seamlessly between the real and digital spaces (Ooi et al. 2009). To synchronize data in both real and virtual worlds, large amount of data and information will flow between co-spaces, which pose new challenges. For example, it would be challenging to process heterogeneous data streams in order to model and simulate real world events in the virtual world. Besides, more intelligent processing is needed to identify and send interesting events in the co-space to objects in the physical world.
- *Transaction Handling:* When the data being updated is spread across hundreds or thousands of networked computers/smart things with differing update policies, it would be difficult to define what the transaction is. In addition, most of things are resource-constrained, which are typically connected to the Internet using lightweight, *stateless* protocols such as CoAP (Constrained Application Protocol) (<http://tools.ietf.org/html/draft-ietf-core-coap-18>) and 6LoWPAN (IPv6 over Low-Power Wireless Personal Area Networks) (<http://tools.ietf.org/wg/6lowpan>) and accessed using RESTful Web services. This makes transaction handling in IoT a great challenge. As pointed out by James et al. (2009) that the problem is that the world is

- changing fast, the data representing the world is on multiple networked computers/smart things, and existing database technologies cannot manage. Techniques developed for streamed and real-time data may provide some hints.
- *Frequently Updated Time-Stamped Structured (FUTS) Data:* The Internet, and hence IoT, contains potentially billions of Frequently Updated Time-Stamped Structured (FUTS) data sources, such as real-time traffic reports, air pollution detection, temperature monitoring, crops monitoring, etc. FUTS data sources contain states and updates of physical world things. Current technologies are not capable in dealing with FUTS data sources (James et al. 2009) because (i) no data management system can easily display FUTS past data, (ii) no efficient crawler or storage engine is able to collect and store FUTS data, and (iii) querying and delivering FUTS data is hardly supported. All these pose great challenges for the design of novel data management systems for FUTS data.
 - *Distributed and Mobile Data:* In IoT, data will be increasingly distributed and mobile. Different from traditional mobile data, distributed and mobile data in IoT would be much more highly distributed and data intensive. In the context of interconnecting huge numbers of mobile and smart objects, centralized data stores would not be a suitable tool to manage all the dynamics of mobile data produced in IoT. Thus there is a need for novel ways to manage distributed and mobile data efficiently and effectively in IoT.
 - *Semantic Enrichment and Semantic Event Processing:* The full potentials of IoT would heavily rely on the progress of Semantic Web. This is because things and machines should play a much more important role than humans in IoT to process and understand data. This calls for new research in semantic technologies. For example, there are increasing efforts in building public knowledge bases (such as DBpedia, FreeBase, Linked Open Data Cloud, etc.). But how these knowledge bases can be effectively used to

add to the understanding of raw data coming from sensor data streams and other types of data streams? To resolve this challenge, semantic enrichment of sensing data is a promising research direction. Further, consider the potential excessively large amount of subscriptions to IoT data. To produce proper semantic enrichment to meet different enrichment needs from different subscribers poses great challenges. Finally, how to effectively incorporate semantic enrichment techniques with semantic event processing to provide much better expressiveness in event processing is still at its initial stage. This will also demand a large amount of research efforts.

- *Mining:* Data mining aims to facilitate the exploration and analysis of large amounts of data, which can help to extract useful information for huge volume of IoT data. Data mining challenges may include extraction of temporal characteristics from sensor data streams, event detection from multiple data streams, data stream classification, activity discovery, and recognition from sensor data streams. Besides, clustering and table summarization in large data sets, mining large (data, information or social) networks, sampling, and information extraction from the Web are also great challenges in IoT.
- *Knowledge Discovery:* Knowledge discovery is the process of extracting useful knowledge from data. This is essential especially when connected things populate their data to the Web. The following issues related to knowledge discovery in IoT have been identified by (Weikum 2011; Tran et al. 2017): (i) automatic extraction of relational facts from natural language text and multimodal contexts; (ii) large-scale gathering of factual knowledge candidates and their reconciliation into comprehensive knowledge bases; (iii) reasoning on uncertain hypotheses, for knowledge discovery and semantic search; and (iv) deep and real-time question answering, e.g., to enable computers to win quiz game shows.
- *Security:* Due to the proliferation of embedded devices in IoT, effective device security

mechanisms are essential to the development of IoT technologies and applications (Huang et al. 2017). The National Intelligence Council (Anonymous 2008) argues that, to the extent that everyday objects become information security risks, the IoT could distribute those risks far more widely than the Internet has to date. For example, RFID security presents many challenges. Potential solutions should consider aspects from hardware and wireless protocol security to the management, regulation, and sharing of collected RFID data (Welbourne et al. 2009). Besides, it is argued by Lagesse et al. (2009) that there is still no generic framework for deploying and extending traditional security mechanisms over a variety of pervasive systems. Regarding security concerns of the network layer, it is suggested by Kounavis et al. (2010) that the Internet can be gradually encrypted and authenticated based on the observations that the recent advances in implementation of cryptographic algorithms have made general purpose processors capable of encrypting packets at high rates. But how to generalize such algorithms to IoT would be challenging as things in IoT normally only maintain low transmission rates and connections are usually intermittent.

- *Privacy:* Privacy protection is a serious challenge in IoT. One of the fundamental problems is the lack of a mechanism to help people expose appropriate amounts of their identity information. Embedded sensing is becoming more and more prevalent on personal devices such as mobile phones and multimedia cite layers. Since people are typically wearing and carrying devices capable of sensing, details such as activity, location, and environment could become available to other people. Hence, personal sensing can be used to detect their physical activities and bring about privacy concerns (Klasnja et al. 2009). Patient's electronic health record (EHR) is becoming medical big data with high volume Yang et al. (2018). The e-health IoT network is growing very fast, leading to big medical private data on the

Internet. There are many challenges, such as the information privacy, search, updating, and sharing, to be addressed.

- *Social Concerns:* Since IoT connects everyday objects to the Internet, social concerns would become a hot topic in the development of IoT. Further, online social networks with personal things information may incur social concerns as well, such as disclosures of personal activities and hobbies, etc. Appropriate economic and legal conditions and a social consensus on how the new technical opportunities in IoT should be used also represent a substantial task for the future (Mattern and Floerkemeier 2010). Trust management could play an important role in addressing social concerns (Lin and Dong 2018). With the help of trust models for social IoT, malicious behaviors can be detected effectively.

Summary

It is predicted that the next generation of the Internet will be comprised of trillions of connected computing nodes at a global scale. Through these nodes, everyday objects in the world can be identified, connected to the Internet, and take decisions independently. In this context, the Internet of Things (IoT) is considered as a new revolution of the Internet. In IoT, the possibility of seamlessly merging the real and the virtual worlds, through the massive deployment of embedded devices, opens up many new and exciting directions for both research and development. In this entry, we have provided an overview of some key research areas of IoT, specifically from a data-centric perspective. It also presents a number of fundamental issues to be resolved before we can fully realize the promise of IoT applications. Over the last few years, the Internet of Things has gained momentum and is becoming a rapidly expanding area of research and business. Many efforts from researchers, vendors, and governments have been devoted to creating and developing novel IoT applications. Along with the current research efforts, we encourage more insights into the problems of this promising

technology and more efforts in addressing the open research issues identified in this entry.

Big Data Analysis for Smart City Applications

Eugenio Cesario

Institute of High Performance Computing and Networks of the National Research Council of Italy (ICAR-CNR), Rende, Italy

Introduction

The twenty-first Century is frequently referenced as the “Century of the City”, reflecting the unprecedented global migration into urban areas that is happening nowadays (Butler 2010; Zheng et al. 2014). As a matter of fact, the world is rapidly urbanizing and undergoing the largest wave of urban growth in history. In fact, according to a United Nations report, urban population is expected to grow from 2.86 billion in 2000 to 4.98 billion in 2030 (UNR 2014): this translates to roughly 60% of the global population living in cities by 2030.

Such a steadily increasing urbanization has been leading to many big cities and bringing significant social, economic and environmental transformations. On the one hand it is modernizing people’s lives and giving increased opportunities offered in urban areas, on the other hand it is engendering big challenges in city management issues, such as large-scale resource planning, increased energy consumption, traffic congestion, air pollution, water quality, crime rising, etc. (Zheng et al. 2014).

Tackling these challenges seemed nearly impossible years ago given the complex and dynamic settings of cities. However, the widespread diffusion of sensing technologies and large-scale computing infrastructures has been enabling the collection of big and heterogeneous data (i.e., mobility, air quality, water/electricity consumption, etc.) that are daily produced in urban spaces (Al Nuaimi et al. 2015). Such big data imply rich knowledge about a city and are a valuable opportunity to achieve improvements in urban policies and management issues.

Motivated by the challenging idea of building more intelligent cities, several research projects are devoted to the development of Smart City applications. A Smart City is a city seeking to address public issues via ICT-based solutions on the basis of a multi-stakeholder, municipality based partnership (EUP 2017). The goal of building a smart city is to improve the quality of citizens' lives by using computer systems and technology to provide smart and efficient services and facilities. In this scenario, data analytics offers useful algorithms and tools for searching, summarizing, classifying and associating data turning it into useful knowledge for citizens and decision makers. Moreover, managing data coming from large and distributed sensing nodes poses significant technical challenges that can be solved through innovative solutions in parallel and distributed architectures, Cloud platforms, scalable databases, and advanced data mining algorithms and tools. Such issues pose several challenges and opportunities of innovations in urban environments, as described in the following sections of this article.

Research, Technological and Social Challenges in Smart Cities

A Smart City is a complex ecosystem that poses several research and technological challenges, which are complementary and connected among them. In fact, successful smart city deployments require a combination of methodological and technological solutions, ranging from the low-level sensors/actuators, effective data communi-

cations, data gathering, and analysis, finalized to effectively deliver smart applicative innovations to cities and citizens (Lea 2017). The most important data-related issues are briefly discussed in the following.

Networking and communications. The communication infrastructure of a smart city must support the connection among devices, buildings, facilities, people, and gather data and deliver services to myriad endpoints. Moreover, the heterogeneity of services in a smart city ecosystems requires a holistic approach to networking and communications, i.e. from low bandwidth wireless technologies to dedicated fiber optics as connection backbones. Such issues represent a technological challenge to deal with.

Cyber-physical systems and the IoT. Cyber-physical systems and the Internet of Things (IoT) are critical to the growth of smart cities, providing an urban connectivity architecture in which the objects of everyday life are equipped with micro-controllers, transceivers for digital communication, and suitable protocol stacks that will allow effective connectivity among devices and with users (Zanella et al. 2014). This enables the interaction among a wide variety of devices (i.e., home appliances, surveillance cameras, monitoring sensors) that collect enormous volume of data, making the smart city a digital data-rich ecosystem (Cicirelli et al. 2017).

Cloud computing. Cloud computing has a significant influence on the development of smart cities for two main reasons. First, it affects the way cities manage and deliver services, and enables a broader set of players to enter the smart city market. Second, the analysis of high-volume data (often to be processed in near real-time) takes crucial advantage from the scalable and elastic execution environments offered by Cloud architectures.

Open Data. Another significant challenge in smart cities is the adoption and exploitation of open data. Open data in the context of smart cities refer to public policy that requires or encourages public agencies to release data sets (e.g., citywide crime statistics, city service levels, infrastructure data) and make them freely accessible. The most important challenges associated with open data

include data security and in particular privacy issues. The evolution of open data represents a broadening of available information related to city operations, representing de-facto another source of city data.

Big data analytics. As above described, cities are collecting massive and heterogeneous amounts of data (text, video, audio), some of it is static but increasingly large parts are real-time. These data exhibit the classic characteristics of big data: volume, velocity (real-time generation), variety (extremely heterogeneous), veracity and value (very useful for business and research applications). For such a reason, a big effort is required to develop suitable data analytics methodologies to deal with such massive volumes of data, extremely heterogeneous in its sources, formats, and characteristics.

Citizen engagement. Citizen engagement represents a complementary aspect of smart cities and although not strictly a technical consideration, it concerns to make citizens feel into the “collective intelligence” of cities. A matter of fact, their willingness to exploit web applications (or other dialogue channels) for meaningful dialogue between cities and their citizens (i.e., reporting city issues, accidents, quality of services, etc.), is a crucial issue for the success of smart city initiatives.

Urban Big Data Collected in Smart Cities

Due to the complex and dynamic settings of cities, urban data are generated from many different sources in many different formats. A list of the most representative types of data and their brief description is reported in the following (Yuan et al. 2013; Zheng et al. 2014).

Traffic Data. Such a kind of data concerns the mobility of people and vehicles in urban and extra-urban areas. Traffic data can be collected in different ways, i.e. using loop sensors, surveillance cameras, and floating cars. Loop sensors are usually used to compute several mobility measures (i.e., speed of vehicles, traffic volume

on a road, etc.). Surveillance cameras are widely installed in urban areas, generating a huge volume of images and videos reflecting traffic patterns, thus providing a visual ground truth of traffic conditions to people. Floating car data are generated by vehicles traveling around a city with a GPS sensor, whose trajectories can be matched to a road network for deriving speeds on road segments. As many cities have already installed GPS sensors in taxicabs, buses, and logistics trucks for different purposes, floating car data have already been widely available and they have had higher flexibility and a lower deployment cost with respect to loop sensors and surveillance camera-based approaches.

Mobile Phone Data. Mobile telephone calls produce a huge amount of data every day. In fact, a call detail record contains attributes that are specific to a single instance of a phone call, such as the user’s location, start time, duration of the call, etc. The analysis of such kind of data allows users’ community detection, citywide human mobility discovery, etc.

Geographical Data. Geographical data describe the road network of the urban area under analysis. It is usually represented by a graph that is composed of a set of edges (denoting road segments) and a collection of geo-referenced nodes (standing for road intersections). Each edge can be enriched by several properties, such as the length, speed constraint, type of road, and number of lanes. Each node can also include information about point of interest (POI), i.e., restaurants, shopping malls, usually described by a name, address, category, and a set of geo-spatial coordinates; however, the information of POIs could vary in time (e.g., a restaurant may change its name, be moved to a new location, or even be shut down), so they need to be updated frequently. *Commuting Data.* Commuting data include data generated by people that leave an electronic footprint of their activities in urban environments. For example, people traveling in cities continuously generate digital traces of their passage, i.e., card swiping data in a subway/bus system, ticketing data in parking lots, records left by users when they borrow/return a bike in a bike sharing system, etc., thus producing huge

volume of commuting data that support decisions of urban planners and policy makers.

Environmental Data. Environmental data includes meteorological information (humidity, temperature, barometer pressure, wind speed, and weather conditions), air quality data (concentration of CO, CO₂, NO₂, PM_{2.5}, SO₂), environmental noise, etc. that can be collected by sensors placed in the city, portable sensors mounted on public vehicles, or air quality monitoring stations. There are also data collected by satellites that scan the surface of the earth with rays of different lengths to generate images representing the ecology and meteorology of a wide region.

Social Network Data. The huge volume of user-generated data in social media platforms, such as Facebook, Twitter and Instagram, are valuable information sources concerning human dynamics and behaviors in urban areas. In particular, social network data can be considered in two different forms. One is a social structure, represented by a graph, denoting the relationship, interdependency, or interaction among users. The other one is the user-generated social media data, such as texts, photos, and videos, which contain rich information about a user's behaviors/interests. Moreover, posts are often tagged with geo-graphical coordinates or other information (e.g., tags, photos) that allow identifying users' positions and build trajectories from geo-tagged social data. Therefore, social media users moving through a set of locations produce a huge amount of geo-referenced data that embed extensive knowledge about human mobility, crowded zones, interests and social dynamics in urban areas.

Economy Data. There is a variety of data representing a city's economic dynamics. For example, transaction records of credit cards, stock prices, housing prices, and people's incomes are valuable information to capture the economic rhythm of a city, therefore predicting which urban assets and features can positively (or negatively) influence future economy.

Energy Data. Energy data includes electricity consumption of buildings, energy costs, gas consumption of vehicles, etc. and provides funda-

mental information about city's resource usage. Such data can be obtained directly from sensors mounted on vehicles or in gas stations, by electricity and gas smart meters, or inferred from other data sources implicitly. Such data can be used to evaluate a city's energy infrastructures (e.g., the distribution of gas stations), find the most gas-efficient driving route, calculate the pollution emission from vehicles on road surfaces, optimize the energy electricity usage in residential areas, etc.

Health Care Data. A large volume of health care and disease data is generated by hospitals and clinics. In addition, the advances of wearable computing devices enable people to monitor their own health conditions, such as heart rate, pulse, and sleep time. Such data can be exploited for diagnosing a disease and doing a remote medical examination. In urban environments, this data can be aggregated to study the impact of environmental change on people's health, i.e. how urban noise impact people's mental health, how air pollution influences asthma-related diseases, etc.

Smart City Applications

A large number of smart city applications, exploiting urban data, have been implemented world-wide. A brief survey of the most important applications, grouped in seven categories, is reported below.

Smart Transportation. The joint analysis of traffic and commuting data provides useful knowledge to improve public and private mobility systems in a city. For example, intensive studies have been done to learn historical traffic patterns aimed at suggesting fast driving routes (Bejan et al. 2010; Herrera et al. 2010), at predicting real-time traffic flows (Herrera et al. 2010) and forecasting future traffic conditions on individual road segments (Castro-Neto et al. 2009). Mobility can also benefit in scenarios where traffic information collected through sensors, smart traffic lights and on-vehicle devices can be used to take action for specific critic events or to alleviate/resolve a traffic problem. Moreover, several applications are devoted to improve taxi services: some systems

provide taxi drivers with some locations (and routes) which they are more likely to pick up passengers quickly, while others schedule taxis to pick-up passengers via ride-sharing (subject to time, capacity and monetary constraints) maximizing the profit of the trip (Yuan et al. 2013; Ma et al. 2013). Finally, big data are also profitably used to build more reliable and efficient public transportation systems: for example, (i) real-time arrival time predictions of buses are more accurate by predicting traffic traces; (ii) bike sharing system operators may benefit from accurate models of bicycle flows in order to appropriately load-balance the stations throughout the day (Al Nuaimi et al. 2015; Zheng et al. 2014).

Smart Healthcare. Big data analysis is profitably exploited to provide smart healthcare solutions, which can improve the quality of patient care through enhanced patient handling. New systems can support a real-time monitoring and analysis of clinic data, or enable clinic parameters checking on demand or on a given frequency (i.e., hourly, daily or weekly). In particular, for certain patients' health issues, several benefits can be obtained from real-time data (blood pressure, cholesterol, sleeping patterns) monitoring through smart devices, which are connected to home or hospital for accurate and timely responses to health issues and for a comprehensive patient history records (Al Nuaimi et al. 2015; Zheng et al. 2014).

Smart Energy. The rapid progress of urbanization is consuming more and more energy, calling for technologies that can sense city-scale energy cost, improve energy infrastructures, and finally reduce energy consumption (Zheng et al. 2014). To this purpose, innovative systems are developed (i) to allow near-real forecasting of energetic demand through efficient analysis of big data collected, or (ii) to facilitate decision-making related to the supply levels of electricity in line with actual demand of the citizens and over all affecting conditions. Moreover, intelligent demand response mechanisms can also be profitably used to shift energy usage to periods of low demand or to periods of high availability of renewable energy. For example, intelligent algorithms (running at either device level or at community/trans-

former level) may enable a more efficient energy management to stay within community-assigned energy usage limits.

Smart Environment. The analysis of environmental data (i.e., urban air quality, noise, pollution) provides new knowledge about how environmental phenomena are influenced by multiple complex factors, such as meteorology, traffic volume, and land uses, or the impact that noise pollution has on people's mental and physical health, etc. (Zheng et al. 2014). Moreover, accurate weather forecasts can support country's agriculture effectiveness, it can inform people of possible hazardous conditions by supporting a more efficient management of energy utilization (Al Nuaimi et al. 2015). For example, a recent research study at MIT developed a real-time control system based on transport data and weather data to predict taxi demand with different weather conditions (Liv 2017).

Smart Safety and Security. Environmental disasters, pandemics, severe accidents, crime and terrorism attacks pose additional threats to public security and order. The wide availability of different kinds of urban data provides the opportunity to build predictive models with the ability, on one hand, to learn from history how to handle the aforementioned threats correctly and, on the other hand, to detect them in a timely manner or even predict them in advance (Zheng et al. 2014). For example, new technologies are enabling police departments to access growing volumes of crime-related data that can be analyzed to understand patterns and trends (Cesario et al. 2016), to anticipate criminal activity and thus to optimize public safety resource allocation (officers, patrol routes, etc.). Other studies are devoted to predict future environmental changes or natural disasters: some projects (Cesario and Talia 2010) are specifically aimed at developing new frameworks for earthquakes forecasting and to predict how the ground will shake as a result, which will give an opportunity to save lives and resources.

Smart Education. From assessment of graduates to online attitudes, each student generates a unique data track. By analyzing these data, education institutes (from elementary schools to universities) can realize whether they are using

their resources correctly and producing profitable didactic results. For example, data concerning student attendance, misconducts resulting in suspensions, college eligibility, dropout rate, on-track rate, etc., can be collected and analyzed to understand how different teaching strategies can address specific learning results. In addition, behavioural patterns can be extracted and exploited for student profiling, which will have positive effect on the knowledge levels and will suggest teaching/learning tools aimed at improving student's performance on the basis of his/her attitudes.

Smart Governance. Smart governance, whose term has been coined few years ago, is about using technological innovation to improve the performance of public administration, to enhance accountability and transparency, and to support politics in better planning and decision making. Specifically, political decisions can benefit from big data analytics models, which can support governments' focus on citizens' concerns related to health and social care, housing, education, policing, and other issues. In this way, more appropriate and effective decisions related to employment, production, and location strategies can be made. On the other hand, citizens can use governance data to make suggestions and enhance the quality of government services. Finally, information technology enables the integration and collaboration of different government agencies and combine or streamline their processes. This will result in more efficient operations, better handling of shared data, and stronger regulation management and enforcement (Al Nuaimi et al. 2015).

Future Directions for Research

Urban environments will continue generating larger and larger volumes of data, which will steadily represent a valuable opportunity for the development of Smart City applications and to achieve improvements in urban policies and management issues. This will lead towards several research directions aimed at making the storage, management and analysis of smart city

data more and more effective and efficient. From a methodological side, it is expected that more advanced algorithms for urban Big Data analysis will be studied through a higher integration with conventional city-related disciplines' theories; this will converge towards a multidisciplinary research field, where computer sciences meet traditional urban sciences (i.e, civil engineering, transportation, economics, energy engineering, environmental sciences, ecology, and sociology) to inspire data-driven smart city services. Furthermore, video and audio analytics methodologies, real-time data mining algorithms, advanced data-driven mobility applications, etc. will provide smart solutions to deal with the different conditions that dynamically change during the day in a city. From a technological side, advanced solutions for gathering, storing and analyzing data will be investigated: for example, further research in Cloud Computing, IoT, communication infrastructures will undoubtedly provide an essential support for innovative and scalable solutions able to capture, transmit, storage, search, and analyze data in so ever increasing data-rich cities.

Big Data Analysis for Social Good

Robert M. Goerge
Chapin Hall at the University of Chicago,
Chicago, IL, USA

Overview

Big data is not just the 3, 4, or 5 Vs (Volume, Velocity, Variety, Veracity and Value) that characterize it but has become a catchall term for innovative uses of large datasets to gain additional benefit and build knowledge (Japec et al. 2015). How it is used can range from straightfor-

ward repackaging of it to make it user-friendly to using it to drive artificial intelligence applications. Much of what has been done with big data for social good revolves around making daily activities more information driven, such as mapping applications for daily commutes and providing better weather forecasts. These types of uses can benefit everyone in some way. This chapter focused on the analysis of big data to build knowledge that can benefit individuals and families at risk of harm, illness, disability, educational failure, or other special needs. This type of social good is focused on solutions to major ongoing social problems as opposed to the incremental improvement of daily living for the majority of the population (Coulton et al. 2015; Liebman 2018).

The Data

The primary source of big data to address social problems is the data from administrative information systems of government and nongovernmental agencies. Criminal justice, health care, income assistance, child and adult protective services, disability programs, employment, economic development, early childhood programs, K-12 schools, and postsecondary education are all example of programs that produce large datasets that can be used to produce evidence around who participates in these programs and how effective they might be. The data can range from data on who is enrolled in these programs to expenditures to detailed notes from the service provider on the characteristics of the individuals and the need they have. Many of the information systems for these programs have been in place since the 1980s, and they have become ubiquitous since the turn of the century. Therefore, data on hundreds of millions of individuals with billions of transactions is now available.

However, unlike increasingly more examples of data that is open and accessible on government websites, the type of data that is needed to conduct rigorous research and analysis is not widely accessible outside of the organizations

that collect them (Goerge 2018). The value to these data is that they are person-specific and provide information about health conditions, negative behaviors, educational attainment, employment and income, welfare program receipt, and violent behavior. Therefore, they are quite sensitive and could be used to harm people. At a minimum, they can be used to stigmatize individuals. Therefore, these data are kept as secure, and access to them is only provided when there is a clear benefit over the potential risks.

These are the data that are a potential boom for building evidence about the effectiveness of public policies and programs (Card et al. 2010). Social scientists are anxious to find ways to access these data so that more evidence can be developed to improve the social good. The Commission on Evidence-Based Policy, a bipartisan effort of the US Congress, signed into being by President Obama, provides one blueprint for increasing evidence and maintaining confidentiality of sensitive data (Commission on Evidence-Based Policymaking 2017).

As the tools that can increase secure access have become more available, access to these data has increased. In addition, best practices have been established to put forth protections against unlawful disclosure when data is shared with an organization or individual external to the data collection agencies.

Combining Data

Each individual dataset provides one piece of an individual's experience in a system of services or in a school. By combining datasets, one can enhance the utility of the data. For example, combining employment and education data can provide insight into one kind of educational trajectories lead to higher incomes. However, in the United States, there is no one identifier that is used by every government agency to identify an individual. While the Social Security Number has become a default national identification number, many states prohibit the use of the SSN for identification purposes.

Computational Power

As computational power has increased, a whole new set of analytic techniques and new algorithms are possible (Wang et al. 2016). This is because computers can now process a greater amount of data through many more iterations allowing for models to be developed that in the past would not be possible. Therefore, larger datasets, built through combining data from multiple sources, can be built that describe more characteristics of more individuals and the contexts in which they live. Analyses of large datasets that could have taken weeks to run just a decade ago can now be ran in minutes. Therefore, the ability to take advantage of these large datasets is no longer limited by technology but only non-technological issues.

An example of this is an analysis and replication completed by the author and his colleagues. Records on 3 million individuals in the Supplemental Nutritional Assistance Program (SNAP) and child protective services (CPS) system in Illinois were combined into families based on relationship information contained in the state information systems. Data on family member interactions with the criminal justice and juvenile justice system, child protective services (foster care), mental health services, and substance abuse treatment were connected to these individuals. We learned that 23 percent of the families accounted for 86 percent of the expenditures across these 5 program areas. This work was originally done for individuals in SNAP and CPS in 2008. It took roughly 1 week to create the analytic file, using SAS. When we replicated this work in 2016, because of programming the algorithm in Python, the dataset creation step took a matter of hours.

Similarly, cloud computing and the ability to ensure security is being embraced by the federal government and increasingly by state governments (Foster 2018). This is potentially a game changer since datasets can be stored in the cloud and data providers can provide permission for either internal or external analysts to access those data with confidence that there are sufficient controls for monitoring access. One such initia-

tive is New York University and University of Chicago's Administrative Research Data Facility, also known as the Coleridge Initiative (Commission on Evidence-Based Policymaking 2017) (<https://coleridgeinitiative.org/>).

Non-technological Barriers

Given the sensitivity of these data, not only to those individuals in the data but to the organizational leaders who could potentially be negatively affected in multiple ways by disclosure of the data, there are rules and regulations specific to each dataset that govern the uses of the data (Petrla 2018). For the most part, the use of the data should promote the administration of the program. For example, the Family Educational Rights and Privacy Act (FERPA) allows disclosure of personally identifiable information if the purpose is to "improve instruction." Determining whether or not the use has the potential to improve instruction is not clearly established and open to interpretation by each educational entity. Therefore, access to these data is predominantly still relied on developing relationships with the data providers (Goerge 2018).

Given the ambiguity of many of the rules and regulations around the use of sensitive administrative data, beyond keeping the data secure, it is necessary to partner with data providing agencies in a way that can both build trust and also ensure that the data providing agency can benefit from any analysis done. Trust involves multiple factors that must be addressed over time, but a process whereby the data providers can review the work of analysts is critical to ensure not only the proper use of the data but also that data providers are simply aware of where analysis of their information is disseminated.

Analysis of These Data

The types of analyses that are done with these data to support the social good are expanding at a significant rate. Predictive analytics are beginning to be used to affect frontline decision-

making. For example, Allegheny County in Pennsylvania is using predictive risk models to determine if a child is going to be re-referred to child protective services. This information can be used to determine if services should be provided at the time of a call to child protective services (Hurley 2018). It is safe to say that there are high stakes around these decisions and the receptivity of frontline workers to use these data, when they are shouldering the risks of these decisions, may be less than enthusiastic. Careful evaluations and the need to ensure that no harm comes as a result of decisions driven by big data are of the utmost importance.

Coulton et al. (2015) provides a number of examples of data analysis that have been conducted in welfare programs, child welfare services, homelessness programs, Medicaid, and participation in multiple programs. Multiple traditional designs, such as randomized controlled trials and quasi-experimental studies, are also being used. While it is clear that these efforts will provide significant additional knowledge, translating these findings to action – to promote social good – is not a trivial task. "Translational data science" is the term that speaks to how the data science can improve services and achieve social good and improvements in social welfare (<https://cdis.uchicago.edu/news/2017/4/21/translational-data-science-workshop>).

With increased use of machine learning techniques, such as decision trees, dimension reduction methods, nearest neighbor algorithms, support vector models, and penalized regression, with administrative data, new possibilities for impact on social good are on the horizon (Hindman 2015). Research organizations and universities are preparing to apply these methods to improve the social good. One caution, which many have expressed, is that it is important to understand the interventions and processes that professionals, from medical professionals to social works to teachers, use to address specific conditions. Simply processing big data can lead to spurious correlations on one hand and recommendations that are completely unfeasible on another. Many professionals are very constrained in what they can do with their data, even if they know that

there are confirmed relationships between particular characteristics of individuals and future outcomes. We live in a country where confidentiality and privacy are predominant social values and where research ethics must be practiced (Commission on Evidence-Based Policymaking 2017).

A lack of understanding of how a particular analysis or algorithm may be applied could lead to unintended consequences (Sandvig et al. 2016). The issue of race is one of the most sensitive. Often, because of how much variance, without rich data, a race variable can explain; too much is attributed to this characteristic. It can lead to profiling and inappropriate targeting and, at a minimum, ineffective practices.

Conclusion

Whether the innovative analyses of big data have caught up to the ethical use of those analyses is an open question. As data scientists attempt to implement innovations based on analytics in high stakes domains, such as health and human services, great caution must be taken to ensure that no harm is done. While this is not new to be concerned about potential harms, the algorithms used may not be sufficiently transparent to make clear what potential actions might cause harm or action based on race, gender, sexuality, ethnicity, disability, or some other characteristics.

and with the person's environment" (Source National Human Genome Research Institute).

Proteomics "Proteomics describes the study of all the proteins (the proteome) in an organism, tissue type, or cell" (Source National Human Genome Research Institute).

Interactomics "Interactomics describes the study the whole set of molecular interactions (the interactome) in an organism, tissue type, or cell."

Pharmacogenetics "Pharmacogenetics is the field of study dealing with the variability of responses to medications due to variation in single genes" (Source National Human Genome Research Institute).

Pharmacogenomics "Pharmacogenomics is similar to pharmacogenetics, except that it typically involves the search for variations in multiple genes that are associated with variability in drug response" (Source National Human Genome Research Institute).

Overview

The chapter discusses big data aspects of bioinformatics data with special focus on omics data and related data analysis pipelines. Main challenges related to omics data storage, preprocessing and analysis are presented. After describing main omics data, such as genomics, proteomics and interactomics data, the chapter describes main biological databases, and presents several data analysis pipelines for analyzing big omics data that attempt to face big data challenges.

Introduction

Omics disciplines such as genomics, proteomics, and interactomics, to cite a few, are at the core of modern biomedical research. Omics studies are enabled by three main factors: (i) the availability of high-throughput experimental platforms, such as microarray, mass spectrometry, and next generation sequencing, that produce an overwhelming amount of experimental data; (ii) the integration of omics data with clinical data (e.g., bioimages, pharmacology data, etc.); (iii) the development of bioinformatics algorithms and comprehensive data analysis pipelines that preprocess, analyze, and extract knowledge from such data. The peculiar characteristics of big data in the context of bioinformatics can be declined as follows.

- **Volume:** the volume of big data in bioinformatics is having an explosion, especially in healthcare and medicine, due to many reasons: high resolution of experimental platforms that may produce terabytes of omics data, increasing number of subjects enrolled in omics studies, increasing digitalization of healthcare data (laboratory tests, visits to the doctor, administrative data about payments) that in the past was stored on paper.
- **Velocity:** in bioinformatics new data is created at increasing speed due to technological advances in experimental platforms and due to increased sampling rate of sensors for health monitoring. This requires that data are ingested and analyzed in near real time. As an example, considering the medical devices used to monitor patients or the personal sensors used by general subjects to collect data, big data analytics platforms need to analyze that data and to transmit results to medical doctors or to the user itself in near real time. Moreover, the use of the IoT (Internet of Things) devices in medicine will increase velocity of big data in bioinformatics.
- **Variety:** there is a great variety and heterogeneity of data in bioinformatics coming from medicine, biology, and healthcare. Other than raw experimental omics data, there are clinical data, administration data, sensors data, and social data that contribute to variety.
- **Variability:** how the data is captured in bioinformatics may vary due to several factors, such as experiment setup, use of standard for-

mats or proprietary formats, and use of local conventions in the collection of data. Thus variability may lead to wrong interpretation of data.

- **Value:** the value of big data produced in bioinformatics is related not only to the cost of infrastructures to produce (experimental platforms) and to analyze (software tools, computing infrastructures) them but also to the biomedical knowledge it is possible to extract from data.

The emerging of this big data trend in bioinformatics poses new challenges for computer science solutions, regarding the efficient storage, preprocessing, integration, and analysis of omics and clinical data that is today the main bottleneck of the analysis pipeline. To face those challenges, main trends are (i) use of high-performance computing in all steps of analysis pipeline, including parallel processing of raw experimental data, parallel analysis of data, and efficient data visualization; (ii) deployment of data analysis pipelines and main biological databases on the Cloud; (iii) use of novel data models that combine structured (e.g., relational data) and unstructured (e.g., text, multimedia, biosignals, bioimages) data, with special focus on graph databases; (iv) development of novel data analytics methods such as sentiment analysis, affective computing, and graph analytics that overcome the limits of traditional statistical and data mining analysis; (v) particular attention to issues regarding privacy of data and users, as well as permitted ways to use and analyze biomedical data (e.g., with extensive development of anonymization techniques and privacy-preserving rules and models). The rest of the chapter first introduces big omics data in bioinformatics, then describes main biological databases, and finally presents several data analysis pipelines for analyzing omics data.

Big Data in Bioinformatics

This section introduces the most relevant big data generated in bioinformatics. Such data are mainly

generated through high-throughput experimental platforms (e.g., microarray, mass spectrometry, next generation sequencing) that produce the so-called *omics data* (e.g., genomics, proteomics, and interactomics data). The volume of these data is increasingly huge because the resolution of such platforms is increasingly high and because the biomedical studies usually involve thousands of biological samples.

Microarray Data

Microarrays allow to detect, among the others, gene expression data, single nucleotide polymorphism (SNP) data, and drug metabolism enzymes and transporters (DMET) SNP data. A main difference among such data is that gene expressions are represented as numerical data, while SNPs are encoded as strings. The analysis of microarray data presents several challenges (Guzzi and Cannataro 2011) that are outlined in the following.

Gene Expression Data

Main biological processes are carried out by genes and proteins. According to the central dogma of molecular biology, genes encode the formation of proteins, and, in particular, genes regulate the formation of proteins through the transcription process which produces RNA (ribonucleic acid). The expression level of RNA (or mRNA – messenger RNA) is an indirect measure about the production of the proteins. Microarrays allow to study the expression level of the RNA associated to several genes (and thus their potential protein transcriptions) in a single experiment. Moreover, microarrays also allow the study of the microRNA (miRNA) that are short noncoding molecules of RNA that contain about 22 nucleotides and have a role in various functions and especially in regulation of gene expression (Di Martino et al. 2015). In a typical microarray experiment, first the RNA is extracted from a biological sample, and then it is put onto the microarray chip that contains a set of probes to bind the RNA. Probes are formed by oligonucleotides or complementary DNA (c-DNA). A light source is used to bleach the fluorescent markers, and then the results are stored in a high-definition image. At this

point, a preprocessing phase is needed to remove the noise, recognize the position of different probes, and identify corresponding genes. The correspondence among probes and genes is usually encoded into a location file that needs to be used to correctly locate the expression level of each gene. Starting from a raw microarray data (named .CEL file in the Affymetrix terminology), the resulting preprocessed file contains the expression level of each gene (among the analyzed genes) in a sample. Joining all the data related to several samples, it is possible to obtain a matrix where each column indicates a sample, each row indicates a gene, and the element (i, j) contains the expression level of gene i in sample j .

SNP Data

DNA is made up of four bases called adenine (A), cytosine (C), guanine (G), and thymine (T). These elements are organized as double helices that form long chains called chromosomes. Each chromosome contains a DNA molecule, and each DNA molecule is made up of many genes that are segments of DNA. Genes are then translated into proteins by the mediation of the ribonucleic acid (RNA) that has a simpler structure with respect to the DNA and is made of a single filament made up of four subunits, called adenine (A), cytosine (C), guanine (G), and uracil (U). Each individual has a unique sequence of DNA that determines his/her characteristics, and differences among sequences are measured in terms of substitutions of bases in the same position. The substitution of a single base that occurs in a small subset of population is named mutation or single nucleotide polymorphism (SNP), e.g., if we consider the sequence (ATGT) and the modified one (ACGT), then the SNP is denoted with the symbol T/C. A SNP dataset is thus constituted by a table where each row indicates a gene or a specific portion of a gene, each column indicates a sample (patient), and a cell (i, j) contains the SNP, if any, on the gene i , detected in sample j . SNPs data are represented by strings over the A, C, G, T alphabet. A SNP marker is just a single base change in a DNA sequence, and several works demonstrated the correlation

between SNPs and diseases or between the presence of SNPs and response to drugs (Wollstein et al. 2007).

DMET Data

Pharmacogenomics is a subfield of genomics that studies how variations in genes (e.g., SNPs) are responsible for variation in the metabolism of drugs, and it also investigates the so-called adverse drug reactions (ADR) that happen when a drug has a narrow therapeutic index (a measure of the amount of drug that may cause lethal effect), i.e., the difference between the lethal and the therapeutic dose of the drug is little. The Affymetrix DMET (drug metabolism enzymes and transporters) platform (Arbitrio et al. 2016b) analyzes simultaneously the polymorphisms of 225 ADME-related genes, i.e., genes known to be related to drug absorption, distribution, metabolism, and excretion (ADME) (Li et al. 2010). In particular, the current Affymetrix DMET microarray chip allows the investigation of 1936 probes, corresponding to 1936 different nucleotides each one representing a portion of the genes having a role in drug metabolism. A DMET SNP dataset is a table where each row indicates a gene or a specific portion of a gene, each column indicates a sample (patient), and a cell (i, j) contains the SNP, if any, on the ADME gene i , detected in sample j .

The importance of the analysis of DMET data is demonstrated by different works that evidenced the correlation between genetic variations in ADME genes and different effects of drug treatments (Di Martino et al. 2011; Arbitrio et al. 2016a).

Mass Spectrometry Data

Proteomics is about the study of the proteins expressed in an organism or a cell. Computational proteomics is about the algorithms, databases, and methods used to manage, store, and analyze proteomics data (Cannataro 2008). Mass spectrometry (MS), the main experimental platform for proteomics, uses the mass spectrometer to investigate the proteins expressed in a sample (Aebersold and Mann 2003). In a very intuitive way, MS measures the mass (in Dalton) of all

molecules contained in a sample. More precisely, the output of a MS experiment, said spectrum, is a long sequence of pairs of numbers (i, m_z), where m_z is the mass-to-charge ratio of a molecule and i is the intensity or abundance of that molecule. The manual inspection of spectra is unfeasible, so several algorithms to manage and analyze them are available. An important role is played by preprocessing algorithms that regard the way how spectra are cleaned, preprocessed, organized, and stored in an efficient way. Computational proteomics includes (i) qualitative proteomics, i.e., the identification of the sequence of the detected proteins; (ii) quantitative proteomics, i.e., the determination of the relative abundance of proteins in a sample; and (iii) biomarker discovery, i.e., finding most discriminant features among spectra coming from two different populations (e.g., healthy versus diseased).

Interaction Data

Interactomics is a recent omics discipline that refers to the study of the *interactome*, i.e., the list of all the interactions in an organism (Cannataro et al. 2010b). Interactomics focuses on the modeling, storage, and retrieval of protein-to-protein interactions (PPI) and protein interaction networks (PINs). Interactomics is important to explain and interpret protein functions because many of them are performed when proteins interact with each other. If interactions are stable along the time, they form the so-called *protein complexes*, and computational methods of interactomics may be used to discover and predict protein complexes. Wet lab experiments allow to find binary interactions that involve only two proteins, or multiple interactions, such as protein complexes. Computational (in silico) methods of interactomics may predict novel interactions without the execution of wet lab experiments. PPIs are often stored in databases as a list of binary interactions in the form (P_i, P_j). Such databases offer efficient storing and retrieval of single PPI data or the entire PIN, using expressive querying mechanisms. A way to represent all PPIs of an organism is through a graph named protein interaction network (PIN) (Cannataro and Guzzi 2012). The nodes of a PIN are the proteins, while the edges

represent the interactions among them. The PINs are represented through undirected graphs, but sophisticated models use directed and labeled edges that carry on additional information on each interaction. The PIN of an organism is built by extracting all the binary interactions (P_i, P_j) from a PPI database and by building the related graph. A key activity of interactomics is the study of the PIN of an organism or the comparison of the PINs of different organisms. In summary, computational methods of interactomics regard the prediction, storage, and querying of PPIs data and the analysis and comparison of PINs graphs.

Biological Databases

This section presents main databases containing information about biological data, with special focus on protein sequences, structures, and interactions.

Sequences Databases

Sequences databases contain the primary structure of proteins (i.e., the amino acids sequence) and related annotations, such as the experiment and scientist that discovered them. They offer a querying interface that can be interrogated using a protein identifier or a sequence fragment, e.g., to retrieve similar proteins. Similar proteins to a target protein are retrieved by using a matching algorithm named *sequence alignment*.

The EMBL Nucleotide Sequence Database

The EMBL (European Molecular Biology Laboratory) Nucleotide Sequence Database (Boeckmann et al. 2003) stores primary nucleotide sequences, and, through an international collaboration, it is synchronized with the DDBJ (DNA Data Bank of Japan) and GenBank databases. The database contains information about the CDS (coding DNA sequence), i.e., the coding region of genes and other information. Currently it contains more than three billions nucleotides and more than 1.3 millions sequences. Data are made available as txt, XML, or FASTA. FASTA is a standard format

to represent nucleotide sequences or peptide sequences, where nucleotides or amino acids are represented with single-letter code. As an example, the FASTA format of TC5b (Trp-Cage Miniprotein Construct, accession number 1L2Y) protein, one of the smallest protein with only 20 amino acids, is the following, where the first row contains metadata and the second one contains the sequence:

```
>1L2Y:A|PDBID|CHAIN|SEQUENCE\\
NLYIQWLKDGGPSSGRPPPS
```

Uniprot Database

Swiss-Prot (Boeckmann et al. 2003) was one of the first database storing protein sequences, and it was characterized by the use of flat files, the manual curation of data to avoid redundancies, and an extensive use of annotations. In 2002 Swiss-Prot was merged with the Tr-EMBL (Boeckmann et al. 2003) and the PSD-PIR (Barker et al. 1999) databases, resulting in the UniProt (Universal Protein Resource) database (Consortium 2010), that contains a large volume of protein sequences and functional information. UniProt contains (i) the UniProt Knowledgebase (UniProtKB) that is the access point for information about protein function, classification, and cross-references; (ii) the UniProt Reference Clusters (UniRef); and (iii) the UniProt Archive (UniParc). In particular, UniProtKB comprises the UniProtKB/Swiss-Prot section that is manually annotated and reviewed and the UniProtKB/Tr-EMBL section that is not reviewed and is automatically annotated. UniProt database is publicly accessible at www.uniprot.org.

dbSNP

The Single Nucleotide Polymorphism database (dbSNP) (Sherry et al. 2001) contains several molecular variations such as single nucleotide polymorphisms (SNPs), short deletion and insertion polymorphisms (indels/DIPs), microsatellite markers or short-tandem repeats (STRs), multi-nucleotide polymorphisms (MNPs), heterozygous sequences, and named variants. Currently it contains several millions distinct variants for many organisms, including *Homo sapiens* and other

species. dbSNP is publicly accessible at www.ncbi.nlm.nih.gov/SNP/.

PharmGKB

The Pharmacogenomics Knowledge Base (PharmGKB) (Hewett et al. 2002) stores data collected from several pharmacogenetic works, including genomic, phenotype, and clinical information. Users can browse, query, and download the knowledge base, and they can extract pathways and clinical information. PharmGKB stores pathways related to drugs that have pharmacogenetic role, including pharmacokinetic pathways (what the body does to the drug) or pharmacodynamic pathways (what the drug does to the body). Cross-links are connected to pharmacogenomic concepts forming the knowledge base for pharmacogenomic researchers. PharmGKB is publicly accessible at www.pharmgkb.org.

Structures Databases

Structures databases contain the secondary and tertiary structure of proteins and several tools for 3D visualization of proteins. The secondary structure of proteins refers to the way in which the amino acids are organized into well-defined structures such as helix, sheets, or random coil. It is represented as a string of characters belonging to the Dictionary of Protein Secondary Structure (DSSP) having the same length of the primary structure (i.e., the amino acids sequence). DSSP codes eight types of secondary structures, e.g., H (4 – *turnhelix* or *α helix*), E (*β sheet*), C (*coil*), and so on. The tertiary structure of proteins refers to the way in which the amino acids (each atom) are organized into the 3D space. It contains the *x*, *y*, *z* coordinates of each atom of all amino acids. Distances are expressed in Angstroms. Relevant annotations regard the methods used to discover the 3D structure, e.g., X-ray crystallography or nuclear magnetic resonance (NMR). Similar proteins to a target protein are retrieved by using a matching algorithm named *structure alignment*.

Protein Data Bank (PDB)

The Protein Data Bank (PDB) (Berman et al. 2000) contains structural data of biological

macromolecules generated by using crystallography and nuclear magnetic resonance (NMR) experiments. Each PDB entry is stored in a single flat file. PDB is publicly accessible at www.rcsb.org. As an example, the sequence and secondary structure for protein 1L2Y (chain A) is reported below (empty, means no structure assigned; *H*, α -helix; *G*, 3/10helix).

NLYIQWLKD GPSSGRPPPS
HHHHHHHTT GGGGT

Proteomics Databases

Proteomics databases considered here are those containing mass spectrometry data.

Global Proteome Machine Database

The Global Proteome Machine Database (Craig et al. 2004) is a system for storing, analyzing, and validating proteomics tandem mass spectrometry (MS/MS) data. The system implements a relational database and uses a model based on the Hypo-PSI Minimum Information About Proteomic Experiment (MIAPE) (Taylor et al. 2006) scheme. The Global Proteome Machine Database is publicly accessible at www.thegpm.org.

Peptide Atlas

PeptideAtlas (Desiere et al. 2006) is a database that stores mass spectrometry experiments and data about peptides and proteins identified by liquid chromatography tandem mass spectrometry (LC-MS/MS). PeptideAtlas uses spectra as primary information to annotate the genome; thus, the operation of this database involves these main phases: (i) identification of peptides through LC-MS/MS, (ii) genome annotation using peptide data, and (iii) storage of such genomics and proteomics data in the PeptideAtlas database. Users can query the system using a web interface or can download the database. The Global Proteome Machine Database is publicly accessible at www.peptideatlas.org.

PRIDE

The PRoteomics IDEntifications database (PRIDE) stores protein and peptide identifica-

tions and all information about the performed mass spectrometry experiment (Jones et al. 2006). Protein identifications are identified by unique accession numbers and accompanied by a list of one or more peptide identifications and related sequence and position of the peptide within the protein. Peptide identifications are encoded using the PSI (Proteomic Standard Initiative) mzData format and its evolutions. PRIDE is publicly accessible at www.ebi.ac.uk/pride.

Protein-Protein Interactions Databases

Databases of experimentally determined interactions obtained through high-throughput experiments, and databases of predicted interactions, obtained through in silico prediction, are presented in the following.

DIP

The Database of Interacting Proteins (DIP) contains interactions experimentally determined in different organisms, including Escherichia coli, Rattus norvegicus, Homo sapiens, Saccharomyces cerevisiae, Mus musculus, Drosophila melanogaster, and Helicobacter pylori. The DIP database is implemented as a relational database, and it stores data about proteins, experiments, and interactions data. The entry of new interactions is manually curated, and interactions need to be described in peer-reviewed journals. Users have different ways to query DIP through a web-based interface: (i) *Node*, by specifying a protein identifier; (ii) *BLAST*, by inserting a protein sequence that is used by DIP to retrieve all the matching proteins; (iii) *Motif*, by specifying a sequence motif described as regular expression, (iv) *Article*, by inserting an article identifier that is used by DIP to search for interactions described in that article; and (v) *pathBLAST*, by inserting a list of proteins composing a pathway that are used by DIP to extract all the interaction pathways that align with the query pathway. DIP also allows to export the whole PIN of an organism using different formats, such as PSI-MI XML and PSI-MI TAB. DIP is publicly accessible at dip.mbi.ucla.edu/dip/.

BIND

The Biomolecular Interaction Network Database (BIND) (Alfarano et al. 2005) contains experimentally determined protein interactions annotated with information about molecular function extracted from literature. Supported organisms include *Homo sapiens*, *Saccharomyces cerevisiae*, *Mus musculus*, and *Helicobacter pylori*. BIND contains three main data types: interaction, molecular complex, and pathway. An interaction record stores the reaction event between two objects, e.g., proteins. A molecular complex record stores the interactions, temporally sorted, producing it. A pathway, defined as a network of interactions that mediate some cellular functions, is described as a series of reactions. The database supports different query methods: by inserting identifiers from other biological databases or by providing search terms about literature, structure, and gene. Results are visualized with the BIND Interaction viewer.

I2D

The Interologous Interaction Database (I2D) (Brown and Jurisica 2007) contains predicted interactions between human proteins. It combines interaction data derived from literature, from a set of curated journals, and from databases such as MINT or BIND, using predictions from other organisms (e.g., *Saccharomyces cerevisiae*, *Caenorhabditis elegans*, *Drosophila melanogaster*, and *Mus musculus*). The prediction algorithm inside I2D is based on the hypothesis that patterns of molecular interactions are conserved through the evolution (Pagel et al. 2004; Brown and Jurisica 2007). Such algorithm allows to map interactions of model organisms into interactions of human. The database is built starting from known interactions: the algorithms first determine orthologs by using BLASTP, and then an interaction in the model organism is mapped into human if both the interactors have a correspondent ortholog into the human. I2D can be queried by using single or multiple protein identifiers. Results can be visualized by using the I2D graph visualization tool, or by using NAViGaTOR (Network Analysis, Visualization, Graphing TORonto)

(Brown et al. 2009), a visualization tool freely available at (ophid.utoronto.ca/navigator/). Data can be exported both in PSI-MI or tab-delimited formats. I2D is publicly accessible at ophid.utoronto.ca.

IntNetDB

The Integrated Network Database (IntNetDB) (Kai et al. 2006) contains human-predicted protein-protein interactions. The prediction algorithm uses a probabilistic model that exploits 27 datasets containing genomic, proteomic, and functional annotations data. IntNetDB can be queried by inserting protein identifiers through a web interface. Results are visualized in a tabular format or as graphs that may be exported in SVG (Scalable Vector Graphics) or visualized using the SVGviewer. IntNetDB provides further functions for network visualization and analysis.

STRING

The Search Tool for the Retrieval of Interacting Genes/Proteins database (STRING) (von Mering et al. 2005) is a database of predicted interactions with special focus on protein-to-protein, protein-to-DNA, and DNA-to-DNA interactions. The database can be queried by specifying a protein identifier or the protein primary sequence. Results are showed in a prediction summary window and edges of the graph are colored to indicate different types of evidence (fusion evidence, neighborhood evidence, or co-occurrence evidence). STRING is publicly accessible at string-db.org.

Biological Databases on the Cloud

Usually bioinformatics data analysis pipelines include access to public available biological databases that provides web services interfaces (e.g., through the RESTful approach). To improve performance and scalability, such pipelines are deployed on the cloud (Calabrese and Cannataro 2016). To further improve performance when accessing biological databases available on the Internet, such databases are ported on the cloud too. By loading both software tools and databases on the cloud and providing them as a service, it is possible to increase

the level of integration between software, experimental data, and biological databases that improves the analysis and the storage of bioinformatics big data. The provision of data using the data as a service (DaaS) paradigm is thus an emerging approach for the deployment of biological databases. Examples of biological databases deployed on the cloud are contained in the DaaS of the Amazon Web Services (AWS), which provides a centralized repository of public data sets, such as GenBank, Ensembl, 1000 Genomes Project, Unigene, and Influenza Virus (aws.amazon.com/publicdatasets) (Fusaro et al. 2011). The work (Calabrese and Cannataro 2015) presents an overview of main cloud-based bioinformatics systems and discusses challenges and problems related to the use of the cloud in bioinformatics.

Data Analysis Pipelines in Bioinformatics

This section presents main software pipelines for preprocessing and analysis of microarray, mass spectrometry, and interactomics big data.

Analysis of Microarray Data: Gene Expression

The preprocessing of gene expression microarray data can be organized as a pipeline of different tools that aims (i) to identify and remove noise and artifacts related to the microarray experiment, (ii) to extract the correct value of expression for each gene, (iii) to match probes with nucleotide sequences, and (iv) to enrich data through annotations. For each step several algorithms have been developed that may be general purpose or may be designed for a specific chip of the various microarray platforms. Main microarray developers are Affymetrix and Illumina that generate respectively Affymetrix CEL Files and Illumina Tagged Images files. In detail, the workflow for preprocessing and analyzing microarray data comprises four phases (i) preprocessing, which includes summarization and normalization; (ii) annotation, which enriches preprocessed data; (iii) statistical and/or data mining analysis;

and (iv) biological interpretation. Summarization recognizes the position of different genes in raw images, associating some set of pixels to the gene that generated them. Normalization corrects the variation of gene expression in the same microarray due to experimental bias. Filtering reduces the number of investigated genes considering biological aspects, e.g., genes of known functions, or statistical criteria (e.g., associated p-value). Annotation associates to each gene a set of functional information, such as biological processes related to a gene, and cross reference to biological databases. Statistical and data mining analysis aim to identify biologically meaningful genes, e.g., by finding differentially expressed genes among two groups of patients on the basis of their expression values, in case-control studies. In biological interpretation, extracted genes are correlated to the biological processes in which they are involved, e.g., a set of under-expressed genes may be related to the insurgence of a disease. Main challenges of microarray data analysis are discussed in Guzzi and Cannataro (2011). In the following, relevant software tools for gene expression preprocessing and analysis are briefly described.

Affymetrix Power Tools

Affymetrix Power Tools (APT) is a set of command line programs implementing various algorithms for preprocessing both gene expression and SNP Affymetrix microarray data (www.affymetrix.com). Considering gene expression data, the APT command line tool to normalize and summarize an Affymetrix microarray dataset is `apt-probeset-summarize`, and it provides different summarization algorithms, such as the Robust Multi-array Average (RMA) and the Probe Logarithmic Intensity Error (PLIER) algorithms. A possible command line to normalize and summarize an Affymetrix microarray dataset is `apt-probeset-summarize -a rma -d HuEx-1_0-st-v2.cdf -o output -cel-files list.txt`, where `rma` specifies the RMA summarization algorithm, `-d HuEx-1_0-st-v2.cdf` specifies the Human Exon 1.0 st library, `-o output` specifies the output folder, and `-cel-files`

`list.txt` specifies the input folder, where `list.txt` specifies the list of input CEL files. Considering SNP genotyping data, the APT command line tool to preprocess DMET data is `apt-dmet-genotype` that allows the extraction of genotype call (e.g., the individuation of the corresponding nucleotide) for each probeset. Using the `apt-dmet-genotype` command line, it is possible to control main preprocessing parameters, such as the algorithm used to determine the genotype call.

Affymetrix Expression Console

Expression Console is a software tool provided by Affymetrix that implements probe set summarization of Affymetrix binary CEL files and provides both summarization and quality control algorithms. A main advantage of Expression Console is the quality control, but it is not extensible for the preprocessing of multivendor datasets.

Micro-CS

Micro-CS or μ -CS (Microarray CEL file Summarizer) is a software tool for the automatic normalization, summarization, and annotation of Affymetrix gene expression data that adopts a client-server architecture (Guzzi and Cannataro 2010). The μ -CS client is deployed as a plug-in of the TIGR M4 platform or as a Java stand-alone tool. It encloses the Affymetrix Power Tools code and allows users to read, preprocess, and analyze binary microarray gene expression data, providing the automatic loading of preprocessing libraries and the management of intermediate files. The μ -CS server automatically updates a repository of preprocessing and annotation libraries by connecting in a periodic way to the Affymetrix libraries repository. Then, it provides to the μ -CS client the correct and more recent libraries needed for preprocessing the microarray data. The μ -CS server is implemented as a web service. Users can preprocess microarray data without the need to locate, download, and invoke the proper preprocessing tools and chip-specific libraries. Thus, main advantages of using μ -CS are avoiding wasting time for finding correct libraries, reducing errors due to incorrect

parameter settings or for using old libraries, and guarantee of analysis quality by providing the most updated annotation libraries.

dChip

dChip (DNA-Chip Analyzer) is a stand-alone program for summarizing Affymetrix gene expression data. dChip offers both preprocessing and analysis functions, performs the model-based intensity normalization only, and is available for Windows platform only. Compared to μ -CS, dChip does not download automatically the needed libraries nor the annotation of preprocessed data. To preprocess gene expression data with dChip, users need to manually download libraries, to perform the summarization method, and finally to manually download annotation libraries to annotate results. dChip is publicly accessible at www.dchip.org.

RMAExpress

RMAExpress is a stand-alone program for summarizing Affymetrix gene expression data (rma-express.bmbolstad.com). RMAExpress performs only the RMA normalization, is available for Windows platform, and must be compiled for running on the Linux platform. Compared to μ -CS, RMAExpress does not download automatically the needed libraries nor perform the annotation of files. To preprocess gene expression data with RMAExpress, users need to manually download libraries, to perform the summarization method (RMA), and finally to manually download annotation libraries to annotate results.

easyExon

easyExon (Chang et al. 2008) is a software pipeline for preprocessing and analysis of exon array data. easyExon can manage either raw binary CEL files, by transparently calling Affymetrix APT tools, or already summarized files. easyExon integrates external tools such as the Affymetrix Power Tools (APT) for the data preprocessing and the Integrate Genome Browser (IGB) for the biological interpretation of results. A drawback is related to the fact that it focuses only on exon array data.

Analysis of Microarray Data: SNPs

Single nucleotide polymorphisms (SNPs) are a common form of polymorphism in the human genome. Several genotyping platforms for detecting SNPs are widely used for human evolution research and for association studies of complex diseases (Wollstein et al. 2007). Preprocessing and analysis of SNPs aim to identify genetic variations that may be related with diseases. Genome-wide Association Studies (GWAS) investigate all the genome of a large population for finding variations that are statistical significant. The workflow of analysis of GWAS starts with the translation of microarray raw images into the genotype, i.e., the nucleotide sequence. After determining the sequence of genes, statistical models evaluate the significance of the presence or absence of specific variations. GWAS experiments generate big data (e.g., a study may require more than a terabyte of data), and main challenges are the efficient storage and processing of data that require big storage systems and high-performance computational platforms for the analysis. In the following relevant software tools for SNP genotyping data, preprocessing and analysis are briefly described.

DMET Console

The Affymetrix DMET Console is a stand-alone application that analyzes the intensity data (CEL files) from Affymetrix DMET Plus arrays and determines the genotype for each marker. DMET Console generates genotype calls (CHP files) for datasets of intensity data generated by the Affymetrix DMET Plus arrays, and it translates the genotypes to haplotype alleles that are reported using standardized star allele nomenclature. DMET Console tool returns a table containing, for each probeset and for each sample, the detected SNP or NoCall (i.e., the platform has not revealed the nucleotide with a sufficient confidence). The Affymetrix DMET Console (Sissung et al. 2010) is similar to `apt-dmet-genotype`, but it has a graphical user interface and is able to combine all the .CHP files of an experiment to obtain a unique table for all samples.

DMET-Analyzer

The workflow of analysis of a DMET dataset comprises the following steps (Arbitrio et al. 2016b): (i) biological samples are collected and treated to perform microarray experiments; (ii) the DMET microarray experiment is performed producing a raw microarray data file (.CEL file) for each sample; (iii) raw microarray data files are preprocessed by the `apt-dmet-genotype` command line tool, or by the DMET Console software tool, that produce as output respectively a single preprocessed files (.CHP) or a table of SNPs that represent the whole preprocessed dataset; and (iv) discovery of statistically significant differences in SNPs distribution among sample classes, e.g., in case-control studies. DMET-Analyzer (Guzzi et al. 2012) performs the automatic association analysis among the variations in the genomes of patients and their clinical conditions, e.g., a different response to drugs. For each detected SNP, and for each probe, DMET-Analyzer checks the association among the presence of SNPs and the classes, using the statistical Fisher's test. It provides the Bonferroni and false discovery rate (FDR) multiple test corrections, to improve the statistical significance of results. Each significant SNP detected by the DMET platform and underlined by DMET-Analyzer has an entry into dbSNP, allowing scientists to further study interesting SNPs into dbSNP. As the number of patients enrolled in pharmacogenomics studies increases, parallel and cloud computing may be used to face storage and performance issues. In particular, coreSNP (Guzzi et al. 2014) and Cloud4SNP (Agapito et al. 2013a) are, respectively, the parallel- and cloud-based versions of DMET-Analyzer.

Analysis of Mass Spectrometry Data: Protein Identification

Preprocessing and analysis of mass spectrometry proteomics data regard the following main goals: (i) protein identification, i.e., the identification of the amino acid sequence of the proteins contained in a sample; (ii) protein quantification, i.e., the identification of the absolute or relative amount of the proteins contained in a sample; and (iii) biomarker discovery, i.e., the discovery of

discriminant features in spectra able to discriminate samples coming from healthy or diseased people. Mass spectrometry protein identification methods (Perkins et al. 1999; Nesvizhskii 2007) include peptide mass fingerprinting (PMF) from simple mass spectrometry (MS) spectra and protein identification from peptide peaks obtained through tandem mass spectrometry (MS/MS), also called peptide fragmentation fingerprinting (PFF). In PMF, after a specific enzymatic cleavage of a protein and a mass spectrometry measurement of the resulting peptides, the masses of generated peptides form a map in the spectra called peptide mass fingerprinting. Protein identification is obtained by comparing such spectra against a database of masses of theoretical peptides obtained by in silico digestion. In PFF, a peptide/protein (precursor ion) is selected, isolated, and fragmented using tandem mass spectrometry (MS/MS). The fragmentation permits the de novo sequencing, or the masses of the fragments are compared against a database of masses of theoretical peptides obtained by in silico digestion.

MASCOT

MASCOT (Perkins et al. 1999) performs protein identification through PMF and scores results using the MOWSE (MOlecular Weight SEArch) algorithm. Spectra generated by the user are compared against the theoretical spectra, obtained by an enzymatic digestion of protein sequence in a reference database. For each observed peak in a spectrum, the system calculates the probability that a match between a peak and a peptide is purely random. DMET Console is available here www.matrixscience.com.

swissPIT

swissPIT (Swiss Protein Identification Toolbox) (Quandt et al. 2009) runs workflows of analysis of mass spectrometry data on the Swiss BioGRID infrastructure. swissPIT uses different peptide identification tools so the user can submit proteomics data to multiple analysis tools to improve the protein identification process. A single-input data may be submitted to the same tool and analyzed using different parameter settings,

or it can be submitted to different tools. Such computations are executed in parallel on a high-performance computing infrastructure, i.e., the Swiss BioGRID, by using a web-based interface.

EIPeptDi

The ICAT-labeling method allows the identification and quantification of proteins present in two samples. Nevertheless, when the ICAT is coupled to LC-MS/MS, the analysis pipeline presents a drawback: the insufficient sample-to-sample reproducibility on peptide identification. This results in a low number of peptides that are simultaneously identified in different experiments. The EIPeptDi tool (Cannataro et al. 2007) improves peptide identification in a set of spectra, by using a cross validation of peaks commonly detected in different spectra in tandem mass spectrometry. As a result, EIPeptDi increases the overall number of peptides identified in a set of samples.

Analysis of Mass Spectrometry Data: Protein Quantification

Protein quantification aims to infer the relative abundance of proteins. Algorithms include label-based methods that mine data coming from labeled samples, and label-free methods, that analyze the spectra of non-labeled samples. Label-based methods include ASAPRatio, XPRESS, and ProICAT, described in the following, while label-free methods include MSQuant, XCMS, OpenMS, and PeptideProphet.

ASAPRatio

The automated statistical analysis on protein ratio (ASAPRatio) (Li et al. 2003) tool computes the relative abundances of proteins from ICAT data. It preprocesses spectra with a smoothing filter, subtracts background noise from each spectrum, computes the abundance of each couple of corresponding peptides, groups all the peptides that belong to the same protein, and finally computes the abundance of the whole protein.

XPRESS

The XPRESS tool (Han et al. 2001) computes the relative abundance of proteins, from an ICAT-

labeled pair of samples, by reconstructing the light and heavy profiles of the precursor ions and determining.

Analysis of Mass Spectrometry Data: Biomarker Discovery

Biomarker discovery is a key technique for the early detection of diseases and thus for increasing patient survival rates. Biomarker discovery in spectra data aims to find a subset of features of the spectra, i.e., peaks or identified peptide/proteins, able to discriminate the spectra in classes (usually two classes), e.g., spectra belonging to healthy or diseased subjects. Main biomarker discovery algorithms first use spectra preprocessing algorithms to clean and reduce dimension of data, and then apply classification to preprocessed spectra, where classification may be obtained with statistical or data mining methods. A main challenge in biomarker discovery from spectra is the high number of features, i.e., peaks or peptides, compared to the low number of samples.

BioDCV

BioDCV (Cannataro et al. 2007) is a grid-based distributed software for the analysis of both proteomics and genomics data for biomarker discovery. BioDCV solves the selection bias problem that is the discovery of the correct discriminating features, with a learning method based on support vector machines. BioDCV allows to setup complex predictive biomarker discovery experiments on proteomics data.

Trans-Proteomic Pipeline

The Trans-Proteomic Pipeline (TPP) (Deutsch et al. 2010) is a complete suite of software tools, managed by the Seattle Institute of Systems Biology, that supports the complete pipeline of proteomic data analysis. The TPP pipeline contains tools for spectra conversion in standard formats, probabilistic peptide identification, protein quantification, validation, and biological interpretation of results.

Swiss Grid Proteomics Portal

The Swiss Grid Proteomics Portal, now called iPortal, offers several tools for data preprocessing

and analysis and allows to define data analysis workflows combining them (Kunszt et al. 2015). It offers three main portlets (i.e., predefined workflows): quality control, proteomics identification, and proteomics quantification workflows. The portal uses the P-GRADE method to submit workflows to different grid systems or to remote and local resources.

MS-Analyzer

MS-Analyzer is a biomarker discovery distributed platform to classify mass spectrometry proteomics data on the grid (Cannataro and Veltri 2007). It uses ontologies and workflows to support the composition of spectra preprocessing algorithms and data mining algorithms implemented as services. MS-Analyzer implements various spectra preprocessing algorithms and encapsulates several data mining and visualization tools that are classified through two ontologies. The data mining ontology models data analysis and visualization tools, while the proteomics ontology models spectra data and preprocessing algorithms. An ontology-based workflow editor and scheduler allows the easy composition, execution, and monitoring of services on the grid or on a local cluster of workstations. Users can browse the ontologies for selecting the preprocessing and analysis tools suitable to the input spectra data, then compose a workflow using drag and drop functions, and finally execute the workflow on the Grid or on a cluster. The user can design different analysis experiments using a parameter sweep approach (the same workflow is executed in many instances in parallel where each instance has different parameter settings) or using different preprocessing algorithms. This allows to evaluate preprocessing effectiveness in terms of performance (e.g., binned vs not-binned spectra) and in terms of data analysis quality (e.g., classification accuracy when changing the preprocessing type).

Analysis of Protein Interaction Networks: Protein Complexes Prediction

The analysis of the biological properties of protein interaction networks (PINs) can be done

considering the topological properties of the corresponding graph, or by finding relevant substructures in the graph, or comparing the topology of different graphs. Main algorithms analyze the topological properties of a network and extract its global and local properties that are used to infer biological knowledge. For instance, the finding of small subgraphs that are statistically overrepresented may indicate proteins with specific functions. The finding of highly connected subregions may indicate protein complexes. In the following, some tools for the analysis of PINs are described.

The Molecular Complex Detection Algorithm

The molecular complex detection algorithm (MCODE) (Bader and Hogue 2003) was one of the first approaches to extract protein complexes from a protein interaction network. The main idea of MCODE is that protein complexes, i.e., dense sub-networks, are clusters in the graph; thus, it finds complexes by building clusters. MCODE presents three main steps: (i) it weights all vertices considering local network density, where the local area is a subgraph named *k*-core; (ii) then the algorithm uses this resulting weighted graph to extend each subgraph, starting from the highest weighted vertex; When no more vertices can be added to the complex, this task is repeated considering the next highest weighted subgraph; and (iii), finally, protein complexes are filtered considering the number of nodes of each subgraph.

The Markov Cluster Algorithm

The Markov Cluster algorithm (MCL) (Enright et al. 2002) performs graph clustering through the simulation of a stochastic flow in the network and by analyzing the flow distribution. The main idea of MCL is to consider a biological network as a transportation network where there is a random flow. MCL simulates the evolution of the flow as Markov processes, and after a number of iterations, MCL separates network regions with a high flow from regions with low flow.

IMPRECO

IMPRECO (IMproving PREdiction of COMplexes) (Cannataro et al. 2010a) is a parallel tool

for the prediction of protein complexes. It is a meta-predictor; in fact it executes in parallel three prediction algorithms (MCL, MCODE, RNSC) on the input network and then integrates their results trying to predict complexes not predicted by the previous predictors and to improve the overall quality measures of the prediction.

Analysis of Protein Interaction Networks: Local Alignment

As sequence alignment is used to evaluate if similarity among biological sequences (DNA or proteins) is due by chance or by evolution, protein interaction network alignment aims to study the conservation of the interactome of organisms or the conservation of protein complexes among species. Network alignment algorithms comprises two main classes: *global alignment* that finds large common sub-networks covering all the input networks and optimizing a global function based on topology considerations and *local alignment* that finds similar small subregions optimizing a similarity function based on functional similarity, such as homology. Local alignment of interaction networks searches for similar or equal subgraphs in two or more networks (Berg and Lassig 2004). The graph alignment, conceptually similar to the sequence alignment, is based on a scoring function that measures the similarities of two subgraphs that in turn is used to measure the global comparison of interaction networks, by measuring the similarity of mutually similar subgraphs. Local alignment algorithms comparing two or more networks analyze the conservation or divergence of the interaction patterns among different species and give as output a set of conserved subgraphs.

Mawish

Mawish (Koyutürk et al. 2005) is a pairwise local alignment algorithm that finds high similar subgraphs. The algorithm builds an alignment among two networks starting from orthologous nodes. In Mawish the network alignment problem formulates as a graph optimization problem with the aim to build an alignment graph with the maximum score. Mawish includes the following

steps: (i) matching of the orthologs nodes belonging to two networks (a similarity score tables among nodes is built); (ii) growing of the alignment (starting from a pair of similar nodes, the neighborhood of both nodes in the input networks is expanded to small local regions of high similarity using a greedy heuristic); and (iii) evaluation (the aligned subgraphs are evaluated using a statistical approach).

AlignNemo

AlignNemo is a local alignment method that uses and integrates both homology and topology information (Ciriello et al. 2012). AlignNemo finds subgraphs of the networks that have relationship in biological function and in the topology of interactions. The integration algorithm of AlignNemo, which combines homology and topology information, allows better precision and recall performance, compared to other local alignment methods.

AlignMCL

AlignMCL is a local alignment algorithm that finds conserved sub-networks in protein interaction networks (Mina and Guzzi 2012). AlignMCL first builds an alignment graph through the merging of the input protein interaction networks and then mines it to find conserved sub-networks by using the Markov Cluster (MCL) algorithm. AlignMCL is an evolution of AlignNemo, where the mining strategy of AlignNemo, not suitable for big networks, is substituted by the Markov Cluster algorithm that allows better performance. To improve its usability, authors developed a version of AlignMCL as a Cytoscape plug-in that can be used transparently to align protein interaction networks loaded and visualized on Cytoscape.

GLAlign

GLAlign (Global Local Aligner) is a local alignment algorithm that integrates global and local alignment (Milano et al. 2016). The idea of GLAlign is to use the topological information obtained by performing a global alignment of the input networks, to improve the local alignment. In

particular, the information about the global alignment results is used to guide the building of the local alignment. GLAlign uses the MAGNA++ global alignment and the AlignMCL local alignment.

Analysis of Protein Interaction Networks: Global Alignment

Global alignment algorithms find a mapping that involves all the nodes of the input interaction networks. Such algorithms find a relation among all the nodes of the two input networks and may introduce new nodes (dummy nodes) if it is not possible to match some nodes. Opposite to local alignment that finds small regions of similarity or conserved motifs, global alignment finds a mapping that involves all nodes and optimizes a cost function.

MAGNA

At the basis of the MAGNA (Maximizing Accuracy in Global Network Alignment) algorithm (Saraph and Milenković 2014), there is the following consideration about the limits of several global alignment algorithms. In fact, many global alignment methods first compute node similarities to identify the high-scoring alignments with respect to the overall node similarity and then evaluate the accuracy of the alignments by using criteria that consider the number of conserved edges. Thus, they first build the alignment and then verify the number of conserved edges that may be not optimal. Starting from this consideration, MAGNA takes care of edge conservation when the alignment is built and not at the end of the alignment, trying to maintain a good quality of node mapping. The core of MAGNA is a genetic algorithm that simulates a population of alignments that change over time and allows the survival to those alignments that improve accuracy. Other than optimizing the number of conserved edges, MAGNA also optimizes other alignment accuracy measures, such as the combination of node and edge conservation.

MAGNA++

MAGNA++ (Maximizing Accuracy in Global Network Alignment via both node and edge conservation) (Vijayan et al. 2015) extends MAGNA with some important improvements: the possibility to optimize simultaneously edge conservation (with respect to any one of three different measures) and node conservation, improved performance through parallel computing, easy to use graphical user interface, and availability of the source code.

SANA

SANA (Simulated Annealing Network Alignment) is a global network alignment algorithm that uses a new stochastic search algorithm based on simulated annealing (Mamano and Hayes 2017). Authors show that SANA optimizes several popular objective functions improving them with respect to available existing search algorithms. At the basis of the SANA algorithm, there is the consideration that it is difficult to find optimal solutions to the network alignment problem because it is NP-hard. To face the complexity of the problem, authors model the network alignment problem as an optimization problem that is composed by two independent parts: an objective function used to measure the quality the alignment and a search algorithm used to enumerate or find all the possible alignments. The authors also point out that search algorithms may be deterministic or stochastic. The solution to the problem is thus the alignment corresponding to the best value of the objective function.

Visualization of Protein Interaction Networks

Visualization is about the visual drawing of data and is an important analysis step in scientific research. Protein-protein interaction networks are important resources for studying organisms, and their graphic representation may highlight relevant sub-networks or motifs such as protein complexes. However, PIN visualization presents several open problems: very high number of nodes and connections (tens of thousands), heterogeneity of nodes (proteins), heterogeneity of edges (interactions), and availability of

annotations enriching proteins and interactions but complicating their visualization. Many software tools for the visualization of biological networks and specifically PINs have been developed recently. Initial tools were devoted to visualization only, but recent tools offers additional functions for network analysis. The work (Agapito et al. 2013b) analyzes the main software tools for PINs visualization considering these main criteria: technology, interoperability, layout algorithms, rendering algorithms, and available network analysis functions, such as clustering or graph mining. Some tools offer 2D and 3D network visualization through many layout algorithms. Others tools support the integration of network data with annotations. Some tools are dedicated to specific functions such as the study of dynamic aspects of biological processes and analysis and visualization of pathways. An interesting approach is provided by tools like Cytoscape (Yeung et al. 2008) that may be incrementally enriched with novel functions for PIN analysis, through the development of plug-ins by the scientific community. Another trend is the increasing use of parallel computing to improve the performance of the visualization engine that in some cases provides near real-time response time and very high interactivity, as in NAViGaTOR (Brown et al. 2009).

Conclusions

The efficient storage, preprocessing, integration, and analysis of omics and clinical data, is today the main bottleneck of the bioinformatics analysis pipeline. To face those challenges, well-known architectures and algorithms are adapted to the specific issues of big data (e.g., data compression for storage (Cannataro et al. 2001), high-performance distributed computing (Cannataro and Talia 2003; Cannataro et al. 2013), peer-to-peer architectures for improving availability (Cannataro et al. 2008)), or novel computational models are gaining a central role (e.g., Cloud (Calabrese and Cannataro 2015) and RESTful architectures (Agapito et al. 2017), Internet of Things, GPU computing). After introducing big omics data in bioinformatics, the

chapter summarized main biological databases and described main data analysis pipelines available to analyze omics data.

[Time series prediction](#)

Definitions

Time series forecasting is the process of making predictions of the future values of a time series, i.e., a series of data points ordered by time, based on its past and present data/behavior.

Overview

Forecasting is part of the broader area of time series analytics. It is a vital and commonly used tool for planning and decision-making. Forecasting fits a model to a given time series and uses it to infer the future values of this time series. For this task, a lot of methods and approaches have been proposed, ranging from simple statistical models to complex and computation intensive machine learning approaches. The biggest challenge in time series forecasting is to identify the optimal combination of model and parameters for a given time series. The process of conducting time series forecasting can be illustrated using the method proposed by Box et al. (2008). Although it was designed for the application of *autoregressive (integrated) moving average (AR(1)MA)* models,

the fundamental approach is widely applicable. The procedure is defined by three stages that are iterated:

1. **Model selection:** Stationarity and seasonality are determined, while autocorrelation and partial autocorrelation plots are used to identify the autoregressive and moving average terms.
2. **Parameter estimation:** In order to find the model coefficients that provide the best fit to the data, sophisticated estimation approaches, e.g., maximum likelihood estimation, are used.
3. **Model checking:** The accuracy of the model is evaluated. If the model does not satisfy the given requirements, the process is restarted at the first stage and tries to identify a better model.

The original process has been extended in recent work (e.g., Makridakis et al. 1998) where a preliminary data preparation stage and a final model application stage have been added. Data preparation transforms and differentiates the data in order to make modeling easier. Model application is the actual computation of forecast values.

Key Research Findings

The topic of time series forecasting is an established field of research offering a variety of modeling techniques. These can be structured into *univariate forecasting methods* and *multivariate forecasting methods*. In addition there exist *techniques for handling incomplete time series* and more recent *machine learning approaches*.

Univariate Forecasting Methods

Univariate forecasting concentrates on individual time series, i.e., predictions are created for one time series, and a model is trained for each time series.

The most simple univariate forecasting method is the so-called *naïve* or *persistence* approach. With this approach, a prediction is equal to the last observed value. In time series notation, $\hat{y}_{T+h} = y_T$, where y_T is the last

observed value of the past data y_1, \dots, y_T and \hat{y}_{T+h} is the forecast for time $T + h$, with forecast horizon h . This method is generally used to provide a baseline for the comparison and evaluation of more sophisticated forecasting models. Another simple technique is the *average* approach, which uses the mean of the past data as prediction $\hat{y}_{T+h} = \bar{y}_T = (y_1 + \dots + y_T)/T$. The *drift* approach uses the average change over time (called drift) in the observed data and adds to the last observed value to create a forecast $\hat{y}_{T+h} = y_t + \frac{h}{T-1} \sum_{t=2}^T (y_t - y_{t-1}) = y_t + h \left(\frac{y_t - y_1}{T-1} \right)$.

Out of the more sophisticated univariate forecasting methods, the *ARIMA* model (McCarthy et al. 2006; Box et al. 2008) is the most well-known. The ARIMA uses three concepts for the modeling of a time series: autoregression **AR**, integration **I**, and moving average **MA**. These different concepts provide the ARIMA model with a high degree of adaptability to different time series characteristics, making it applicable in a wide range of use cases. The modeling begins with the integration step, in which the time series is differentiated to eliminate trend and seasonal characteristics to make it stationary, i.e., its expectation value and variance are constant over time. In the next step, the two predictive model parts AR and MA are applied. The autoregressive part models future time series values based on the most recent historical time series values. The moving average part models future values based on error terms which are the result of the simulated prediction of the available time series history. Both model parts are further distinguished into nonseasonal and seasonal variants. A seasonal model has to be applied if a seasonal pattern is present in the time series. For every analyzed time series, the degree of differentiation has to be determined, and the right number of AR and MA components has to be identified in order to create the optimal ARIMA model. Some guides on how to find the right ARIMA model for a specific time series have been published in Robert Nau (2016) and Box et al. (2008).

Another commonly used univariate technique is exponential smoothing, also known as the Holt-Winters model (McCarthy et al. 2006; Holt 2004). This model uses the exponential window

function to apply a smoothing mechanism on the entire time series. In doing so, exponentially decreasing weights are assigned to all observed values over time, i.e., the farther back in time a value was observed, the smaller its weight. The simplest form of exponential smoothing is $s_t = \alpha \cdot y_t + (1 - \alpha) \cdot s_{t-1}$ where α is the *smoothing factor* with $0 < \alpha < 1$. As such, the smoothed time series is a weighted average of the current observation y_t and the previous smoothed time series s_{t-1} where α controls the smoothing effect and thus the impact of recent changes. To create a forecast, the smoothed statistic is used with the last observed value $\hat{y}_{T+h|T} = \alpha \cdot y_T + (1 - \alpha) \cdot s_{T-1}$. The model is also capable of handling time series with trend (*double exponential smoothing*) and seasonal (*triple exponential smoothing*) characteristics. This is done by introducing additional components that take potential trend and seasonal behavior into account. These components are smoothed themselves and added to the forecast calculation using individual smoothing factors.

Two more recent additions to this class are *multivariate adaptive regression splines* (MARS) (Friedman 1991) and *gradient boosting machines* (GBM) (Friedman 2001). MARS uses a set of external influences of which it automatically extracts the most relevant ones to forecast the currently analyzed time series. Furthermore, it is capable of modeling nonlinear relationships between the external influences and the target series. The GBM model uses an ensemble of weak predictors, typically regression trees, to combine their predictions into the final forecast for the analyzed time series. The input for the decision trees may be historical data of the time series itself or external influences.

Multivariate Forecasting Methods

Multivariate forecasting techniques focus on the analysis and prediction of multiple time series within one model. The most commonly referenced approaches are VARIMA models (Riise and Tjøstheim 1984; Tiao and Box 1981). Like ARIMA, they are based on the concepts of autoregression and moving averages but apply them to a set of time series. In doing so, they model

how the time series in a data set influence each other. Each time series is modeled based on its own past data, the past data of all other time series of the set, and an error term. Assuming a simple two-dimensional VARIMA model with two time series $y_t^{(1)}$ and $y_t^{(2)}$, the model equations are:

$$y_t^{(1)} = c_1 + a_{11}y_{t-1}^{(1)} + a_{12}y_{t-1}^{(2)} + \varepsilon_1$$

$$y_t^{(2)} = c_2 + a_{21}y_{t-1}^{(1)} + a_{22}y_{t-1}^{(2)} + \varepsilon_2$$

where c is a constant value and ε is an error term. The model parameters c and a must be estimated. Econometric models build up on this idea and add external influences which affect the time series that should be predicted but are not affected themselves by other time series (Chatfield 2000).

Techniques for Incomplete Time Series Data

The forecasting of time series requires complete historic data. Gaps and missing values generally prevent the creation of a forecasting model. For this reason, approaches for handling incomplete or intermittent time series have been discussed in the forecasting literature. Croston's method is the most widely used approach for this kind of data and was designed for intermittent time series of nonnegative integer values (Croston 1972; Shewhart and Hyndman 2005). The model involves two exponential smoothing processes. One models the time period between recorded (non-zero) observations of the time series, while the other is used to model the actual observed values. As Croston's method models single time series only, it belongs to the class of univariate techniques. It is mentioned in this separate category because it was especially developed for the context of incomplete time series data. While Croston's method is able to calculate forecasts for incomplete time series, missing values have to occur regularly in order to be properly modeled. This can be problematic in application scenarios, where regular patterns of missing observations are not given.

Another possibility to deal with incomplete time series is to exploit the often hierarchical structure of large data sets (Friedner 2001). For this, time series are transferred to a more coarse

grained aggregation level by the application of an aggregation function, e.g., the sum. For example, time series representing the energy consumption of many individual consumers are aggregated to a higher aggregation level representing a whole city or a certain district. With this, missing observations can be compensated as observation gaps in one time series can be covered by observations from other time series. In addition, the influence of noisy data is reduced as fluctuations of different time series can equalize themselves. However, this approach is not guaranteed to solve the problem of incomplete data entirely. Observation gaps can persist even at high aggregation levels, e.g., if only few time series are available for aggregation. In addition, aggregation leads to a loss of detail and hampers the calculation of forecasts on more fine-grained levels of data.

Machine Learning Approaches

Techniques from the area of machine learning can also be applied to the topic of forecasting. Two well-known representatives are neural networks (Faraway and Chatfield 1998) and support vector regression (Basak et al. 2007). In the context of forecasting, both techniques are mostly used to solve regression problems, i.e., the dependence of a time series value on its predecessors, just as the AR component of the ARIMA model. These approaches can be considered as univariate techniques as they generally focus on single time series. However, they also form a class of their own as they utilize a different modeling approach. While typical univariate techniques model the time series as a whole, machine learning approaches often separate the sequence of observations into tuples containing an influenced historical observation and the observation(s) that influence it. These tuples are then used to train a model which solves the regression problem. This makes machine learning approaches more robust against missing values and also allows some techniques to model nonlinear dependencies in the observed data. On the downside, these methods have a reduced modeling versatility (e.g., no trend or season models) and are computationally expensive due to the higher number of parameters that have to be optimized.

Applications of Time Series Forecasting

Time series forecasting is an important tool for planning and decision-making in many application domains. A typical domain for forecasting is commerce, where predictions of sales quantities are used to observe market development and steer companies accordingly. Over the last decades, renewable energy production with its integration in the energy market has established itself as a major application domain for time series forecasting. Due to the fluctuating nature of renewable energy sources, considerable planning is necessary in order to guarantee stable energy supply and grid operation. A lot of research effort is and has been spent on the development of accurate models for the forecasting of energy demand and energy production of renewable energy sources (Arrowhead 2015; GOFLEX 2017). In recent years, the *Internet of things (IOT)* (Vermesan and Friess 2013) has become another major application domain for time series forecasting. The IOT trend has led to a wide range deployment of embedded sensors into physical devices ranging from home appliances to vehicles and even facilities. All these sensors create time series, and the prediction of these time series is of interest in many domains. For example, the German “Industry 4.0” initiative aims at the integration of IOT data in manufacturing. There, key performance indicators are forecasted in order to plan production and maintenance schedules.

Future Directions for Research

While time series forecasting has been studied extensively, a lot of research continues to be done in this field. One major direction for research is the development of forecasting models for certain application domains. This means that specific domain knowledge is directly integrated into the forecast model in order to improve forecast accuracy. Another major research direction considers the handling and utilization of large-scale time series data. The data gathering trend in general and IOT in particular have made large sets of re-

lated time series data (e.g., smart meters installed in the same city, pressure sensors on multiple tools of the same type) more and more available. Thus, the integration of such “peer” time series into multivariate forecasting models has become an important research question.

Big Data and Exascale Computing

Amelie Chi Zhou¹ and Bingsheng He²
¹Shenzhen University, Shenzhen, China
²National University of Singapore, Singapore, Singapore

Definitions

Big data refers to data sets which have large sizes and complex structures. The data size can range from dozens of terabytes to a few petabytes and is still growing. Big data is usually characterized with three Vs, namely the large Volume of data size, high Variety of data formats and fast Velocity of data generation.

The importance of big data comes from the value contained in the data. However, due to the three Vs, it is challenging to obtain the value from big data fastly and efficiently. Thus, designing big data systems which analyze big data according to the features of the data is important.

Overview

In the past few decades, clusters, grids, and cloud computing systems have been used to address the challenges on big data processing. Those systems use large numbers of commodity machines interconnected using commodity Ethernet networks to improve system scalabilities horizontally. Various programming models have also been proposed to efficiently distribute big data processing jobs onto those systems, such as MapReduce (Dean and Ghemawat 2004) and Apache Beam (Apache 2017). Based on the programming models, many big data processing systems have been designed to execute and manage data processing jobs with different features in parallel, such as Hadoop (Apache 2011), Yarn (Vavilapalli et al. 2013), and Spark (Zaharia et al. 2010) for batch jobs; Spark Streaming (Zaharia et al. 2013), Storm (Toshniwal et al. 2014), and Flink (Friedman and Tzoumas 2016) for stream jobs; and Apache Beam for both batch and stream jobs.

On the other hand, HPC communities have been developing powerful supercomputers. Exascale computing has already been on the schedule. As the computational requirement of big data applications increases, researchers envision that exascale computing and big data will converge and interact with each other (Reed and Dongarra 2015).

Exascale Computing

Exascale computing refers to computing systems capable of at least one exafLOPS, i.e., 10^{18} floating point calculations per second. The need of going to exascale becomes imperative with the emerging of big data applications. Especially for extreme-scale scientific applications such as climate modeling (Fu et al. 2017b) and earthquake simulation (Fu et al. 2017a), it can easily take years to complete one simulation if executed on a single core, not to imagine that scientists usually need to run the same simulation for multiple times to evaluate the impact of different parameters.

However, going toward exascale computing is not easy, and the challenges come from both hardware and software aspects. From the hardware side, with the millions of cores in one computer system, the power consumption and resilience problem have become especially important. From the software side, several major challenges must be resolved, such as achieving extreme parallelism to utilize the millions of cores efficiently, energy efficiency, fault tolerance, and I/O efficiency for data-intensive computations.

Current Efforts Toward Exascale Computing

Researchers have made great efforts to address the hardware and software challenges of exascale computing.

Energy efficiency. The US Department of Energy (DOE) has set a power budget of no more than 20 MW for an exaflop, forcing co-design innovations in both hardware and software to improve the energy efficiency of exascale computing. On the hardware side, many-core processor design gets more popular in exascale computing to increase the ratio of computational power to power consumption. New technologies such as Intel's Running Average Power Limit (RAPL) are introduced to monitor and control various power and thermal features of processors. The energy efficiency of other hardware components, such as memory and interconnect, is also enhanced to improve the overall efficiency of the systems. On the software side, simulation codes and parallel programming models need to be modified accordingly to better adapt to the new architectural features of future exascale computing systems.

Resilience and fault tolerance. With the large system scale, failures due to hardware and software reasons have become the norm rather than the exception in exascale computing systems. Current efforts have been made on both hardware and software aspects to solve the resilience problem. On the hardware side, system-on-chip designs are proposed to integrate hardware components onto a single chip to reduce the hard error rate. Techniques have also been introduced

to reduce the error rate of each individual component on chip, such as adding redundant cores in processors and using powerful error correction codes in unreliable message channels to reduce the likelihood of failures/errors. On the software side, debugging in exascale is extremely hard as some scalability bugs occur only intermittently at full scale. The current solution is mainly using application-based checkpoint/restart technique (Cappello et al. 2014). Another solution is again introducing redundancy in the software and using replication to reduce the likelihood of software failures. Emerging nonvolatile memory can also be used to reduce the checkpointing overhead (Gao et al. 2015).

The current efforts on developing high-performance computers (HPC) have led to a number of petascale computers. Since 1993, the TOP500 project lists the world's 500 most powerful nondistributed computer systems twice a year. The ranking is mainly based on measuring a portable implementation of the high-performance LINPACK benchmark. Currently, China's Sunway TaihuLight HPC holds the No. 1 position in the TOP500 ranking (released in November 2017), and it reaches 93.015 petaFLOPS on the LINPACK benchmarks and has a theoretical peak performance of 125.436 petaFLOPS. This means that to reach exascale computing, we still need to increase the computation power of existing HPC systems by at least ten times. Table 1 shows the specifications of the first five supercomputers on the latest TOP500 list.

Many countries are planning to have their exascale computers in the next 5 years. For example, according to the national plan for the next generation of high-performance computers, China will have their first operational exascale computer by 2020. The US Exascale Computing Project plans to have capable exascale systems delivered in 2022 and deployed in 2023.

Convergence of Big Data and Exascale Computing

Although the powerful computation capability of supercomputers seems a perfect fit for big data

Big Data and Exascale Computing, Table 1 Specifications of the top five supercomputers in the world (released in November 2017)

processing, there's a big gap between the two. This is mainly because the design of HPC aims for vertical scaling (i.e., scale-up which means adding more resources to individual nodes in a system), while many big data processing systems require good horizontal scalability (i.e., scale-out which means adding more nodes in a system). Research on how to fill the gap and to lead to the convergence between the two fields is necessary.

Current Efforts Toward Convergence

Various projects and workshops have been proposed to foster the convergence. For example, the BigStorage (EU 2017) European project aims to use storage-based techniques to fill the gap between existing exascale infrastructures and applications dealing with large volume of data. The Big Data and Extreme Computing (BDEC) workshop is jointly organized by over 50 universities, research institutes, and companies in the United States, the European Union, China, and Japan. It started from 2013 and has been looking for pathways toward the convergence between big data and extreme computing. Technically, there are mainly two pathways to prompt the convergence, namely, introducing new exascale architecture compatible for existing big data analytics softwares and introducing new data analytics software for exascale computing platforms.

On the first pathway, current cloud providers are offering high-performance instance types with high-performance processors, lots of memory, and fast networking for computation- and data-intensive applications. The underlying

infrastructures of these instance types are also different from traditional ones which are mostly based on commodity machines. For example, it is recently announced that Cray will bring its physical supercomputers into Windows Azure cloud, for users to easily get access to HPC in cloud.

On the second pathway, scientists are improving the parallelism of data-intensive simulations such as earthquake simulations to better utilize the power of supercomputers. As I/O is important to the overall performance of big data in HPC, new components such as Burst Buffer are introduced in Parallel File System to improve the I/O efficiency of big data in HPC. The traditional workloads in HPC systems are mostly write-intensive, while many big data applications are read-intensive. Burst Buffer has been adopted in storage systems as a prefetcher for read-intensive data analytics jobs to optimize their I/O performances.

Challenges and Opportunities

We see a clear trend and need of the convergence between big data and exascale computing. On the one hand, HPC cloud is emerging in major cloud providers such as Windows Azure, Amazon EC2, and Tencent Cloud to provide high-performance computing resources or even exclusive physical resources for data-intensive applications. On the other hand, new softwares such as Burst Buffer and I/O scheduling algorithms are proposed for optimizing big data applications on the traditional parallel supercomputers. Although these efforts

have offered great opportunities for the convergence, challenges also exist.

Challenges on converging big data and exascale computing mainly lie in the exascale software and hardware co-design. Currently, most efforts on improving the scalability of large-scale simulations in HPC systems are hardware-specific, namely, the optimizations for improving the parallelism of simulation codes are designed for a specific HPC hardware architecture (e.g., Fu et al. 2017a,b). Due to the architectural difference of HPC systems (refer to Table 1), a portable interface for building big data analytics jobs and automatically parallelizing them on HPC systems is needed.

Definitions

Fog Computing A model of distributed computing comprising of virtualized, heterogeneous, commodity computing and storage resources for hosting applications, analytics, content, and services that are accessible with low latency from the edge of wide area networks where clients are present while also having back-end connectivity to cloud computing resources.

Overview

Fog computing is an evolving computing paradigm that offers resources that lie between the edge devices and the cloud data center. It is motivated by the need to process high speed and large volumes of Big Data from Internet of Things with low latency. This article discusses the characteristics Fog computing, data-driven applications on it, and future research problems.

Background

Ever since computers could connect over a network, computing paradigms have undergone cyclical phases on *where* within the network the computation is performed. While the original mainframes till the 1970s were large, centralized time-sharing machines accessed by multiple users through remote terminals, the personal computers (PCs) of the 1980s heralded local processing for individuals (Nelson and Bell 1986). The growth of local area networks (LAN), the Internet, and the World Wide Web (WWW) brought about client-server models in the 1990s where many clients could access content hosted on individual servers, though most of the processing was still done on the PC (Sinha 1992). Web services and e-commerce of the 2000s lead to the growth of *cloud computing*, where computation once again skewed to centralized data centers, but with server farms rather than single servers hosting services that were consumed by PCs (Hwang et al. 2013). A complementary phenomenon in that decade was peer-to-peer (P2P) systems where PCs distributed across the Internet would work collaboratively for content sharing, to tackle bandwidth limitations of the Internet (Milojicic et al. 2002). Both cloud computing and P2P signaled the arrival of the *Big Data* age, where the ability to collect large enterprise, scientific and web datasets, and media content put an emphasis on being able to share and process them at large scales.

The decade of 2010 is seeing a similar cyclical shift but at a faster pace due to several technology advances. Starting with a more centralized cloud

computing model hosting thousands of virtual machines (VMs), we have seen the rollout of pervasive broadband Internet and cellular network communication combined with the rapid growth of smartphones as general-purpose computing platforms backed by cloud computing. *Internet of Things (IoT)* is yet another paradigm, enabled by the convergence of these other technologies (Gubbi et al. 2013). Sensors and constrained devices connected to the Internet are being deployed to support vertical IoT domains such as personal fitness using wearables, smart utilities using metering infrastructure, and even self-driving cars. Both smartphones and IoT mark the advent of *Edge Computing* (or mobile cloud computing). Here, ubiquitous devices numbering in the billions are present at the edge of the wide area network (WAN) that is the Internet and host applications that either operate locally or serve as lightweight clients that publish data to or consume content from cloud services (Garcia Lopez et al. 2015; Fernando et al. 2013).

The limitations of an edge-only or a cloud-only model were recognized by Satyanarayanan et al., who introduced the concept of *cloudlets* (Satyanarayanan et al. 2009). These are resource-rich servers, relative to edge devices, that could host VMs while also being closer in the network topology to the edge devices, relative to cloud data centers. They are designed to overcome the constrained resources available on edge platforms while reducing the network latency expended in being tethered to the cloud for interactive applications. *Fog computing* generalizes (and popularizes) the notion of cloudlets.

The term “fog computing” was coined by Cisco and first appears publicly in a talk by Flavio Bonomi, Vice President and Fellow at Cisco Systems, as part of the *Network-Optimized Computing at the Edge Of the Network Workshop*, colocated with International Symposium on Computer Architecture (ISCA), in 2011 (Bonomi 2011). This was further described as extending the concept of cloud computing to the edge of the network to support low-latency and geodistributed applications for mobile and IoT domains (Bonomi et al. 2014). Since then, fog

computing has been evolving as a concept and covers a wide class of resources that sit between the edge devices and cloud data centers on the network topology, have capacities that fall between edge devices and commodity clusters on clouds, and may be managed ad hoc as a smart gateway or professionally as a computing infrastructure (Varshney and Simmhan 2017; Vaquero and Rodero-Merino 2014; Yi et al. 2015).

Motivations

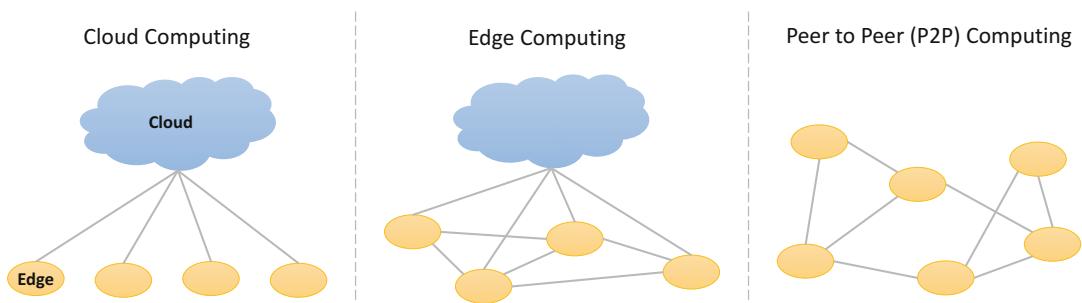

Fog computing is relevant in the context of *wide-area distributed systems*, with many clients at the edge of the Internet (Donnet and Friedman 2007). Such clients may be mobile or consumer devices (e.g., smartphone, smart watch, virtual reality (VR) headset) used interactively by humans or devices that are part of IoT (e.g., smart meter, traffic cameras and signaling, driverless cars) for machine-to-machine (M2M) interactions. The client may serve both as *consumers* of data or actuators that receive control signals (e.g., fitness notification on smart watch, signal change operation on traffic light), as well as *producers* of data (e.g., heart rate observations from smart watch, video streams from traffic cameras) (Dastjerdi and Buyya 2016).

There are two contemporary models of computing for applications and analytics that use data from, or generate content and controls for, such clients at the edge of the Internet (Simmhan 2017), as illustrated in Fig. 1. In a *cloud-centric model*, also called cloud computing, data from these clients is sent to a central data center where the processing is done and the

responses, if any, are sent back to the same or different client(s) (Simmhan et al. 2013; Cai et al. 2017). In an *edge-centric model*, or edge computing, part (or even all) of the processing is done at the data source with the rest done on the cloud (Beck et al. 2014; Anand et al. 2017).

These have their relative advantages. Cloud computing outsources computing infrastructure management to providers, who offer elastic access to seemingly infinite compute resources on-demand which can be rented by the minute. They are also cheaper due to economies of scale at centralized locations (Cai et al. 2017). Edge computing leverages the compute capacity of existing captive devices and reduces network transfers, both of which lower the costs. There may also be enhanced trust and context available closer to the edge (Garcia Lopez et al. 2015).

While fog computing is still maturing, there are many reason why its rise is inevitable due to the gaps in these two common computing approaches. The *network latency* from the edge client to the cloud data center is high and variable, averaging between 20 and 250 ms depending on the location of the client and data center (He et al. 2013). The *network bandwidth* between the edge and the cloud, similarly, averages at about 800–1200 KB/s. Both these mean that latency-sensitive or bandwidth-intensive applications will offer poor performance using a cloud-centric model due to the round-trip time between edge and cloud (Satyanarayanan et al. 2009, 2015). Another factor is the connectivity of devices to the Internet. Mobile devices may be out of network coverage periodically and cause

Big Data and Fog Computing, Fig. 1 Connectivity between resources in cloud, edge, and P2P models

cloud-centric applications to degrade or loose functionality (Shi et al. 2016).

Edge computing while avoiding issues of network time suffers from operating on constrained devices that have limited battery, compute, and memory capacities (Barbera et al. 2013). This reduces application performance and limits sustained processing that can drain the battery. These devices may also be less robust and their network connectivity less available (Aral and Brandic 2017).

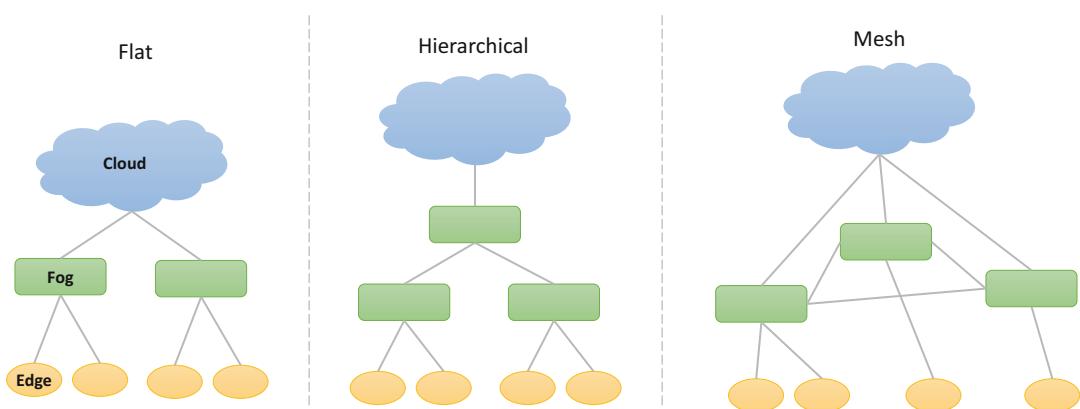

Fog computing serves as a computing layer that sits between the edge devices and the cloud in the network topology. They have more compute capacity than the edge but much less so than cloud data centers. They typically have high uptime and always-on Internet connectivity. Applications that make use of the fog can avoid the network performance limitation of cloud computing while being less resource constrained than edge computing. As a result, they offer a useful balance of the current paradigms.

Characteristics

Fog computing is an evolving model of computing. Hence, its perceived characteristics are broad, based on diverse viewpoints of the research community and industry (Varshney and Simmhan 2017). It is generally agreed that a defining characteristic of fog computing is its smaller network distance from the edge, but mul-

iple **network topology architectures** exist, as shown in Fig. 2 (Aazam and Huh 2014; He et al. In Press; Hou et al. 2016). Some models consider there to be a *flat* fog layer that sits, say, at 1-hop from the edge devices and allows connectivity to the cloud. Each fog device may be responsible for a collection of edge devices that connect to it. This zone of responsibility may be based on logical grouping or spatial regions. Others consider a *hierarchical* approach where fog devices form layers, where each layer is further away from the edge device and responsible for fog/edge devices that fall within its sub-tree, with the cloud forming the root. Alternatively, there are *mesh* designs where fog resources can communicate with each other as well as the cloud, with each edge device assigned to a single fog. A variation of this does not distinguish between edge and fog devices, and any of these may communicate with each other or the cloud. This approaches an edge-centric or P2P model.

The **resource capacity** in the fog can vary. At one end, Raspberry Pi devices with 1 GHz processors, 1 GB RAM, and 100 Mbps Ethernet may serve as a gateway fog resource for lower-end edge devices. On the other hand, fog resources could be provisioned as “micro” or “nano” data centers with clusters of servers or even accelerators present (Garcia Lopez et al. 2015). Individual fog devices can also have heterogeneous capacities (Chiang and Zhang 2016).

Big Data and Fog Computing, Fig. 2 Different interaction models in fog computing

Fog resources tend to be more **reliable and available** than edge resources, though lacking the robust fail-over mechanisms in the cloud that is possible due to a large resource pool. This makes them well-suited to serve as a layer for persisting data and services for the short and medium term. Fog resources themselves may be deployed in a stationary environment (e.g., coffee shop, airport, cell tower) or in a mobile platform (e.g., train, cab) (Chiang and Zhang 2016). This can affect the network connectivity of the fog with the cloud, in case it uses cellular networks for Internet access, and even its energy footprint (Jalali et al. 2017).

Fog **deployment models** are still emerging. These resources may be deployed within a public or a private network, depending on its end use. Smart city deployments may make them available to utility services within the city network (Yannuzzi et al. 2017), while retail shops and transit services can make them available to their customers. A wider deployment for public use on-demand, say, by cellular providers, cities, or even cloud providers, will make it comparable to cloud computing in terms of accessibility. These have implications on the operational costs as well (Viquer and Rodero-Merino 2014).

The fog resources may be made available as-a-service, similar to cloud resources. These may be virtualized or non-virtualized infrastructure (Bittencourt et al. 2015), with containers offering a useful alternative to hypervisor-based VMs that may be too heavyweight for lower-end fog resources (Anand et al. 2017). However, there is still a lack of a common platform, and programming models are just emerging (Hong et al. 2013; Ravindra et al. 2017). Most applications that use the fog tend to be custom designed, and there has only been some theoretical work on scheduling applications on edge, fog, and cloud (Brogi and Forti 2017; Ghosh and Simmhan In Press).

Role of Big Data

One of the key rationales for deploying and using fog computing is Big Data generated at the

edge of the network. This is accelerated by IoT deployments. Traditional web clients which just consume services and content from the WWW saw the growth of *content distribution networks (CDN)* to serve these with low latency. The data from IoT sensors is instead generating data at the clients that is being pushed to the cloud (Cai et al. 2017). In this context, fog computing has been described as acting like an inverse CDN (Satyanarayanan et al. 2015).

A large swathe of IoT data comes as *observational streams*, or time-series data, from widely distributed sensors (Naas et al. 2017; Shukla et al. 2017). These data streams vary in their rates – once every 15 min for smart utility meters, every second for heart rate monitoring by a fitness watch to 50 Hz by phasor measurement units (PMU) in smart power grids – and the number of sensors can range in the millions for city-scale deployments. These are **high-velocity** data streams that are latency sensitive and need online analytics and decision-making to provide, say, health alerts or manage the power grid behavior (Simmhan et al. 2013). Here, fog computing can help move the decision-making close to the edge to reduce latency.

Another class of **high-volume** data that is emerging is from video streams from traffic and surveillance cameras, for public safety, intelligent traffic management, and even driverless cars (Aazam et al. 2016). Here, the bandwidth consumed in moving the data from the edge to the cloud can be enormous as high-definition cameras become cheap but network capacity growth does not keep pace (Satyanarayanan et al. 2015). The applications that need to be supported can span real-time video analytics to just recording footage for future use. Fog computing can reduce the bandwidth consumed in the core Internet and limit data movement to the local network. In addition, it can offer higher compute resources and accelerators to deploy complex analytics as well.

In addition, **telemetry data** from monitoring the health of the IoT fabric itself may form a large corpus (Yannuzzi et al. 2017). Related to this is provenance that describes the source and processing done on the distributed devices that may be

essential to determine the quality and veracity of the data. Fog can help with the collection and curation of such ancillary data streams as well.

Data archival is another key requirement within such applications (Cai et al. 2017; Vaquero and Roderer-Merino 2014). Besides online analytics, the raw or preprocessed observational data may need to be persisted for medium or long term to train models for machine learning (ML) algorithms, for auditing to justify automated decisions, or to analyze on-demand based on external factors. Depending on the duration of persistence, data may be buffered in the fog either transiently or for movement to the cloud during off-peak hours to shape bandwidth usage. Data can also be filtered or aggregated to send only the necessary subset to the cloud.

Lastly, **metadata** describing the entities in the ecosystem will be essential for information integration from diverse domains (Anand et al. 2017). These can be static or slow changing data or even complex knowledge or semantic graphs that are constructed. They may need to be combined with real-time data to support decision-making (Zhou et al. 2017). The fog layer can play a role in replicating and maintaining this across distributed resources closer to the edge.

There has been rapid progress on Big Data platforms on clouds and clusters, with frameworks like Spark, Storm, Flink, HBase, Pregel, and TensorFlow helping store and process large data volumes, velocities, and semi-structured data. Clouds also offer these platforms as a service. However, there is a lack of programming models, platforms, and middleware to support various processing patterns necessary over Big Data at the edge of the network that can effectively leverage edge, fog, and cloud resources (Pradhan et al. In Press).

Examples of Applications

The applications driving the deployment and need for fog computing are diverse. But some requirements are recurrent: low latency processing, high volume data, high computing or storage needs, privacy and security, and

robustness. These span virtual and augmented reality (VR/AR) applications and gaming (Yi et al. 2015), Industrial IoT (Chiang and Zhang 2016), and field support for the military (Lewis et al. 2014). Some of the emerging and high-impact applications are highlighted below.

Smart Cities

Smart cities are a key driver for fog computing, and these are already being deployed. The Barcelona city's "street-side cabinets" offer fog resources as part of the city infrastructure (Yannuzzi et al. 2017). Here, audio and environment sensors, video cameras, and power utility monitors are packaged alongside compute resources and network backhaul capacity as part of fog cabinets placed along streets. These help aggregate data from sensors, perform basic analytics, and also offer WiFi hot spots for public use. As an example, audio analytics at the fog helps identify loud noises that then triggers a surveillance camera to capture a segment of video for further analysis. Similar efforts are underway at other cities as well (Amruthur et al. 2017). These go toward supporting diverse smart city applications for power and water utilities, intelligent transport, public safety, etc., both by the city and by app developers.

One of the major drivers for such city-scale fog infrastructure is likely to be *video surveillance* that is starting to become pervasive in urban spaces (Satyanarayanan et al. 2015). Such city or even crowd-sourced video feeds form *meta-sensors* when combined with recent advances in deep neural networks (DNN). For example, feature extraction and classification can count traffic and crowds, detect pollution levels, identify anomalies, etc. As such, they can replace myriad other environment sensors when supported by real-time analytics. Such DNN and ML algorithms are computationally cost to train and even infer and can make use of fog resources with accelerators (Khochare et al. 2017).

Healthcare

Wearables are playing a big role in not just personal fitness but also as assistive technologies in healthcare. Projects have investigated the use

of such on-person monitoring devices to detect when stroke patients have fallen and need external help (Cao et al. 2015). Others use eye-glass cameras and head-up displays (HUDs) to offer verbal and cognitive cues to Alzheimer's patients suffering from memory loss, based on visual analytics (Satyanarayanan et al. 2009). Predictive analytics over brain signals monitored from EEG headsets have been used for real-time mental state monitoring (Sadeghi et al. 2016). These are then used to mitigate external conditions and stimuli that can affect patients' mental state.

All these applications require low latency and reliable analytics to be performed over observations that are being collected by wearables. Given that such devices need to be lightweight, the computation is often outsourced to a smartphone or a server that acts as a fog resource and to which the observational data is passed for computation. There are also decisions to be made with respect to what to compute on the wearable and what to communicate to the fog, so as to balance the energy usage of the device.

Mobility

Driverless cars and drones are emerging application domains where fog computing plays a key role (Chiang and Zhang 2016). Both these platforms have many onboard sensors and real-time analytics for autonomous mobility. Vehicular networks allow connected cars to communicate with each other (V2V) to cooperatively share information to make decisions on traffic and road conditions (Hou et al. 2016). These can be extended to share compute capacity to perform these analytics. This allows a collection of parked or slow-moving vehicles to form a fog of resources among proximate ones. These may complement occasional roadside units that offer connectivity with the cloud. Here, the entities forming the fog can change dynamically and requires distributed resource coordination.

Drones are finding use in asset monitoring, such as inspecting gas pipelines and power transmission towers at remote locations (Loke 2015). Here, a mobile base station has a digital control tether with a collection of drones that follow a preset path to collect observational data. The

drones have limited compute capacity to increase their endurance and need to prioritize its use for autonomous navigation. So they typically serve as "data mules," collecting data from sensors along the route but doing limited onboard processing (Misra et al. 2015). However, when situations of interest arise, they can make use of their local capacity, resources available with nearby drones, or with fog resources in the base station, while the trip is ongoing. This can help decide if an additional flypast is necessary.

Research Directions

Fog computing is still exploratory in nature. While it has gained recent attention from researchers, many more topics need to be examined further.

Fog Architectures. Many of the proposed fog architectural designs have not seen large-scale deployments and are just plausible proposals. While city-scale deployments with 100s of fog devices are coming online, the experiences from their operations will inform future design (Yannuzzi et al. 2017). Network management is likely to be a key technical challenge as traffic management within the metropolitan area network (MAN) gains importance (Vaquero and Rodero-Merino 2014). Unlike static fog resources, mobile or ad hoc resources such as vehicular fog will pose challenges of resource discovery, access, and coordination (Hou et al. 2016; He et al. In Press). Resource churn will need to be handled through intelligent scheduling (Garcia Lopez et al. 2015). Resources will also require robust adaptation mechanisms based on the situational context (Preden et al. 2015). Open standards will be required to ensure interoperability. To this end, there are initial efforts on defining reference models for fog computing (Byers and Swanson 2017).

Data Management. Tracking and managing content across edge, fog, and cloud will be a key challenge. Part of this is the result of devices in IoT acting as data sources and compute

platforms, which necessitates coordination across the cyber and physical worlds (Anand et al. 2017). The generation of event streams that are transient and need to be processed in a timely manner poses additional challenges to the velocity dimension of Big Data (Naas et al. 2017). Data discovery, replication, placement, and persistence will need careful examination in the context of wide area networks and transient computing resources. Sensing will need to be complemented with “sensemaking” so that data is interpreted correctly by integrating multiple sources (Preden et al. 2015).

Programming Models and Platforms. Despite the growth of edge and fog resources, there is a lack of a common programming abstraction or runtime environments for defining and executing distributed applications on these resources (Stoica et al. 2017). There has been some preliminary work in defining a hierarchical pattern for composing applications that generate data from the edge and need to incrementally aggregate and process them at the fog and cloud layers (Hong et al. 2013). They use spatial partitioning to assign edge devices to fogs. The ECHO platform offers a dataflow model to compose applications that are then scheduled on distributed runtime engines that are present on edge, fog, and cloud resources (Ravindra et al. 2017). It supports diverse execution engines such as NiFi, Storm, and TensorFlow, but the user couples the tasks to a specific engine. A declarative application specification and Big Data platform are necessary to ease the composition of applications in such complex environments.

Related to this are application deployment and resource scheduling. VMs are used in the cloud to configure the required environment, but they may prove to be too resource intensive for fog. Some have examined the use of just a subset of the VM’s footprint on the fog and migrating this image across resources to track the mobility of user(s) who access its services (Bittencourt et al. 2015). Resource scheduling on edge, fog, and cloud has also been explored, though often validated just through simulations due to the lack of access to large-scale fog setups (Gupta et al. 2017; Zeng et al. 2017). Spatial awareness

and energy awareness are distinctive features that have been included in such schedulers (Brogi and Forti 2017; Ghosh and Simmhan In Press). Formal modeling of the fog has been undertaken as well (Sarkar and Misra 2016). Quality of Experience (QoE) as a user-centric alternative metric to Quality of Service (QoS) is also being examined (Aazam et al. 2016).

Such research will need to be revisited as the architectural and application models for fog computing become clearer, with mobility, availability, and energy usage of resources offering unique challenges (Shi et al. 2012).

Security, Privacy, Trust. Unlike cloud computing where there is a degree of trust in the service provider, fog computing may contain resources from diverse and ad hoc providers. Further, fog devices may not be physically secured like a data center and may be accessible by third parties (Chiang and Zhang 2016). Containerization does not offer the same degree of sand-boxing between multiple tenant applications that virtualization does. Hence, data and applications in the fog operate within a mix of trusted and untrusted zones (Garcia Lopez et al. 2015). This requires constant supervision of the device, fabric, applications, and data by multiple stakeholders to ensure that security and privacy are not compromised. Techniques like anomaly detection, intrusion detection, moving target defense, etc. will need to be employed. Credential and identity management will be required. Provenance and auditing mechanisms will prove essential as well. These will need to be considered as first-class features when designing the fog deployment or the application.

Definitions

Intelligent Transportation System is regarded as a smart application encompassing the promising features of sensing, analysis, control, and communication technologies in order to improve

the safety, reliability, mobility, and efficiency of ground transportation.

Big Data is an evolving and emerging terminology describing a voluminous amount (*terabytes, petabytes, exabytes, or even zettabyte*) of structured, unstructured, and semi-structured data which could be mined for information.

Overview

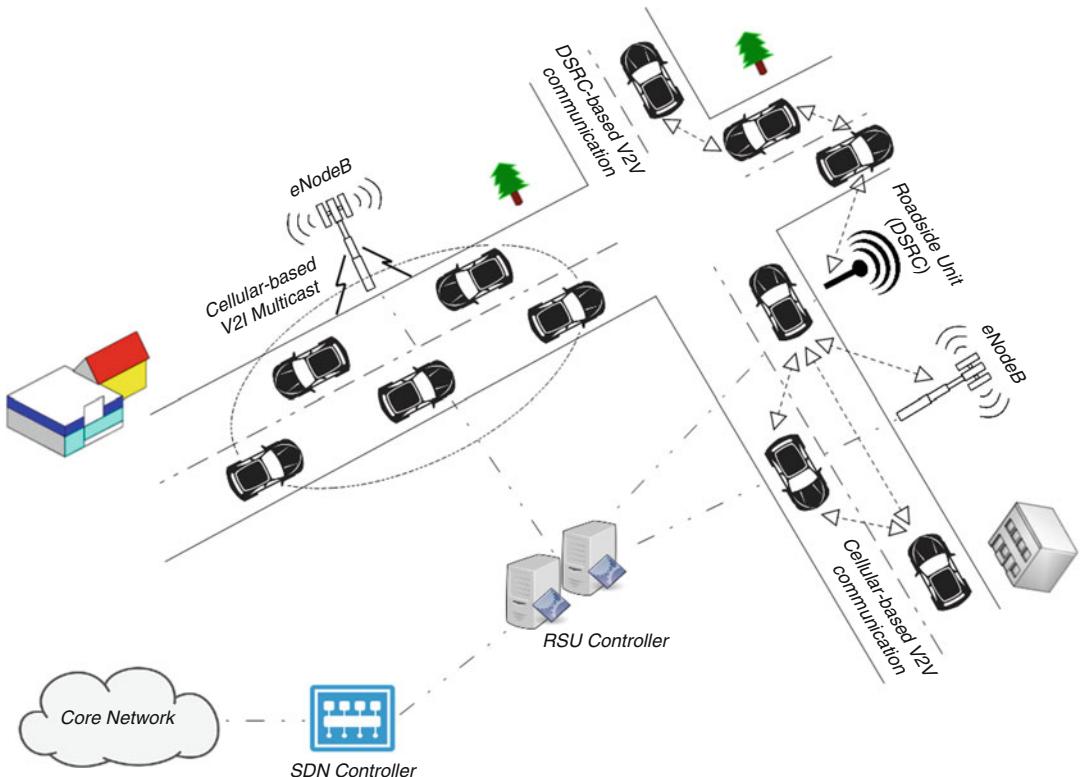

The evolution of Big Data in large-scale Internet-of-Vehicles has brought forward unprecedented opportunities for a unified management of the transportation sector, and for devising smart Intelligent Transportation Systems. Nevertheless, such form of frequent heterogeneous data collection between the vehicles and numerous applications platforms via diverse radio access technologies has led to a number of security and privacy attacks, and accordingly demands for a ‘secure data collection’ in such architectures. In this respect, this chapter is primarily an effort to highlight the said challenge to the readers, and to subsequently propose some security requirements and a basic system model for secure Big Data collection in Internet-of-Vehicles. Open research challenges and future directions have also been deliberated.

Introduction

Over the past few decades, a rapid increase in the number of vehicles (both passenger and commercial) across the globe has pushed the present-day transportation sector to its limits. This has thus caused the transportation systems to become highly ineffective and relatively expensive to maintain and upgrade overtime (Contreras et al. 2017). According to one recent estimate (British Petroleum 2017), the number of vehicles on the road has already surpassed 0.9 billion and is likely to be doubled by the end of year 2035. This massive increase in the number of vehicles has not only led to extreme traffic congestion(s) in dense urban environments and hinders economic growth in several ways but also transpires

in a number of road fatalities. The World Health Organization (2017) estimates that around 1.25 million people across the world die each year and millions more get injured as a result of road accidents, with nearly half of them being vulnerable road users, i.e., pedestrians, roller skaters, and motorcyclists. Approximately 90% of these road accidents occurs in low- and middle-income economies as a result of their poor infrastructures. From a network management perspective, this results in serious deterioration of quality of service for numerous safety-critical and non-safety (i.e., infotainment) applications and in degradation of quality of experience of vehicular users. Thus, there exists a significant room for improvement in the existing transportation systems in terms of enhancing safety, non-safety (i.e., infotainment), and efficiency aspects; and if properly addressed, this would ultimately set tone for highly efficacious intelligent transportation systems indispensable for realizing the vision of connected vehicles.

The paradigm of vehicular communication has been studied and thoroughly analyzed over the past two decades (Ahmed et al. 2017). It has rather evolved from traditional vehicle-to-infrastructure (V2I) communication to more recent vehicle-to-vehicle (V2V) communication and vehicle-to-pedestrian (V2P) communication, thus laying the foundations for the futuristic notion of vehicle-to-everything (V2X) communication (Seo et al. 2016). While cellular networks have been mostly relied upon for V2V communication due to its extended communication range (i.e., theoretically up to 100 km) and extremely high data rates, its high cost and low reliability in terms of guaranteeing stringent delay requirements do not make it as an ideal mode of communication in highly dynamic networks. On the contrary, the evolution of dedicated short-range communication (DSRC) as a two-way short-to-medium range wireless communication for safety-based V2V applications has been a subject of attention in recent years for engineers and scientists as a result of its efficacious real-time information exchange between the vehicles. While a number of challenges still hinder the effective deployment

Big Data and Privacy Issues for Connected Vehicles in Intelligent Transportation Systems, Fig. 1
Heterogeneous vehicular networking architecture

of DSRC-based vehicular networks, the US Department of Transportation (US DoT) is actively pursuing the same as one of its major research priority for various public safety and traffic management applications including, but not limited to, forward collision warnings, blind intersection collision mitigation, (approaching) emergency vehicle warnings, lane change assistance, and for anticipated traffic and travel conditions (Lu et al. 2014). A topological diagram of next-generation heterogeneous vehicular networks is depicted in Fig. 1.

In addition to both cellular networks and DSRC, numerous other radio access technologies (RATs) are currently being explored for vehicular communication. Since the number of sensors deployed onboard the vehicles (and on roadside infrastructure) is anticipated to increase by manifold primarily due to the introduction of connected and autonomous vehicles, it is neces-

sary to deploy a wireless communication system with the ability to transmit a large amount of data at high data rates. Since DSRC typically allows vehicles to transmit data up to a range of 1 km and with a practical data rate of 2–6 Mbps, and while data rates for cellular networks are also limited to 100 Mbps in high mobility scenarios, the ITS community has also gained momentum for exploring the possibility of millimeter wave communication (mmWave) for vehicular networking. mmWave is expected to offer gigabit-per-second data rate; however, issues such as efficacious channel modeling, security, and beam alignment still pose a considerable challenge to its implementation (Va et al. 2016). Further higher-frequency bands in the frequency spectrum are also gaining attention, and terahertz communication for vehicular networks is also on the cards of researchers in academia and wireless industry, thus paving the way for fifth-generation (5G) and

beyond fifth-generation (beyond 5G) wireless networking technologies (Mumtaz et al. 2017).

However, none of these aforementioned technologies possess a potential to fully realize the breadth of vehicular safety and non-safety applications simultaneously and especially when their requirements are in conflict with one another. The ideal approach thus is to ensure a synergy of several RATs so as to provide an appropriate heterogeneous vehicular networking platform in order to meet the stringent communication requirements. Heterogeneity is an important and timely topic but beyond the scope of this work. Since a vehicular network encompasses numerous heterogeneous data sources (i.e., not only from heterogeneous RATs but also from diverse sort of sensing equipment), the amount of data generated is not only huge but also poses a significant challenge to the network's security and stability. Therefore, this chapter, in contrast to other commonly published surveys and chapters, primarily focuses on secure Big Data collection in vehicular networks (interchangeably, referred to as *Internet of Vehicles* in this chapter).

Toward Big Data Collection in Vehicular Networks

In the near future, several substantial changes are anticipated in the transportation industry especially in light of the emerging paradigms of Internet of Things (IoTs), cloud computing, edge and/or fog computing, software-defined networking, and more recently Named Data Networking, among many others. Such promising notions have undoubtedly strengthened and contributed to the industrial efforts of devising intelligently connected vehicles for developing safe and convenient road environments. Furthermore, with the rapid evolution of high-speed mobile Internet access and the demand for a seamless ubiquitous communication at a much affordable price, new vehicular applications/services are emerging. The European Commission estimates that around 50–100 billion smart devices would be directly connected to the Internet by the end of year 2019, and approximately 507.5 ZB/year of data would be

produced due to the same (Sun and Ansari 2016). Moreover, today the smart vehicles have emerged as a multisensor platform, as the usual number of intelligent sensors installed on a vehicle is typically around 100, and this number is anticipated to increase to 200 by year 2020 (Choi et al. 2016). The data streams generated via these sensors are not only high in volume but also possess a fast velocity due to highly dynamic nature of vehicular networks. Moreover, information generated from numerous social networking platforms (i.e., Weibo, Facebook, Twitter, WhatsApp, WeChat) are regularly accessed by the vehicular users and generate a lot of traffic data in real time. This data is spatiotemporal in nature due to its dependence on time and geographical location of vehicles. Also, since the trajectory of vehicles is usually reliant on the road distribution across a huge geographical region, the collected information is also heterogeneous, multimodal, and multidimensional and varies in its quality. This context is pushing the concept of traditional vehicular ad hoc networks to large-scale Internet of Vehicles (IoVs), and all of this collected data converges as Big Data in vehicular networks which ultimately is passed via the core networks to both regional and centralized clouds.

Nevertheless, today's Internet architecture is not yet scalable and is quite inefficient to handle such a massive amount of IoV Big Data. Also, transferring of such data is relatively time-consuming and expensive and requires a massive amount of bandwidth and energy. Moreover, real-time processing of this collected information is indispensable for a number of safety-critical applications and hence demands for a highly efficient data processing architecture with a lot of computational power. As vehicular networks are highly distributive in nature, a distributed edge-based processing is recommended over traditional centralized architectures. However, such distributed architectures mostly have limitations of compute and storage and therefore are unable to cache and process a huge amount of information. Last but not the least, it is quite significant to design a secure mechanism which ensures that collection of IoV Big Data is trusted and not tampered with. There is a huge risk of fraudulent

messages injected by a malicious vehicle that could easily endanger the whole traffic system(s) or could potentially employ the entire network to pursue any dangerous activity for its own wicked benefits. Thus, *how to effectively secure the Big Data collection in IoVs deserves researching*. In this context, this chapter is of high importance so as to bring to forth the significance of such challenges for the attention of academic and industrial research community.

Security Requirements and System Model for Secure Big Data Collection in IoVs

Big Data primarily has three main characteristics, (a) volume, (b) variety, and (c) velocity, and this is also referred to as 3Vs (Guo et al. 2017). Vehicles usually collect a massive amount of data from diverse geographical areas and with various heterogeneous attributes, thus ultimately converging to IoV Big Data with variation in its size, volume, and dimensionality. The analytics of such Big Data can help network operators to optimize the overall resource(s) planning of next-generation vehicular networks. It would also facilitate the national transportation agencies to critically analyze and subsequently mitigate the dense traffic problems in an efficient manner, in turn making the lives of millions of people comfortable and convenient. These are some of the potential advantages that have lately encouraged the vehicles' manufacturers to build large-scale Big Data platforms for the intelligent transportation systems. However, all of this data analytics and subsequent decision making becomes impractical if any malicious vehicle is able to inject data in the IoV Big Data stream which would have severe implications for both safety and non-safety vehicular applications. In terms of safety applications, any maliciously fed information may lead to false trajectory predictions and wrong estimation of a vehicle's neighboring information in the near future which could prove quite fatal for passengers traveling in both semi-autonomous and fully autonomous vehicles. In terms of non-safety applications, this could not

only lead to a considerable delay in the requested services but also exposes a user's privacy data to extreme vulnerabilities (Singh et al. 2016; Zheng et al. 2015). Thus, any secure IoV information collection scheme should adhere to the following requirements so as to guarantee the secure Big Data collection:

Data Authentication – to verify the identities of the vehicles or vehicular clouds (i.e., vehicles with similar objectives and in vicinity of one another form vehicular clouds for resource-sharing purposes)

Data Integrity – to ensure that the transmitted data has been delivered correctly without any modification or destruction, as this would ultimately become part of the Big Data stream

Applications/Services Access Control – to warrant that each respective vehicle has access to the applications/services it is only entitled for

Data Confidentiality – to guarantee a secure communication among vehicles participating in a networking environment

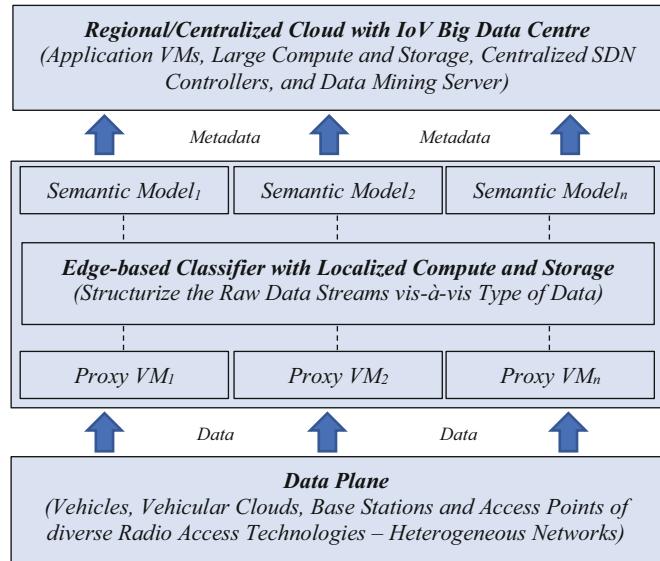

Data Non-repudiation – to ensure that any particular vehicle could not deny the authenticity of another vehicle

Anti-jamming – to prevent intrusion attempts from malicious vehicles which may partially or completely choke the entire network

An ideal approach to tackle these requirements would be via a hierarchical edge-computing architecture as depicted in Fig. 2. Each vehicle (or a vehicular cluster), along with their respective vehicular users, is associated with their private proxy VMs situated in the edge node which not only collects the (raw) data streams from their registered network entities via their respective base stations or access points but also classifies them into various groups depending on the type of data and subsequently generates metadata which is passed to regional/centralized IoV Big Data centers. The metadata encompasses certain valuable information, i.e., geographical locations of vehicles and corresponding timestamps, type of vehicular applications accessed or infotainment services and contents requested, and a pattern recognition identifier that checks for any irregularities in data stream against various

Big Data and Privacy Issues for Connected Vehicles in Intelligent Transportation Systems,

Fig. 2 Edge computing architecture for secure IoV
Big Data collection

prescribed network operator policies and also by comparing it with previously known patterns. In this way, a suspicious content could be filtered out at the edge without passing it to the regional/centralized storage. The metadata only contains valuable information without violating a user's privacy. Also, as several vehicles and vehicular users requests similar type of applications/services and pass identical information about their surroundings (i.e., provided if they are in vicinity of one another), intelligent content similarity schemes should be employed in order to avoid any duplication that may lead to excessive computational overheads both at the edge and at the regional/centralized cloud level.

Thus, in this way, not only the computational overheads can be considerably reduced but the amount of IoV Big Data that needs to be cached can also be significantly minimized. It is therefore pertinent to mention that (both) instantaneous and historical data is of critical importance in making intelligent decision making in IoV architectures. Nevertheless, it is also not practically possible to store all of the historical IoV Big Data for an infinite time due to storage issues globally. Thus, it is of extreme importance to not only secure the collection of IoV Big Data but to also ensure that the said data streams should not be excessively cached but disposed after a

certain time. Our envisaged architecture hence proposes to structure the raw data streams into valuable metadata, which not only consumes less resources in making a requisite decision but also takes less storage space in contrast to raw data streams.

Open Research Challenges and Future Directions

Unlike traditional IoT entities which are generally static in nature, IoV is a highly dynamic organism, and this feature makes it quite difficult to effectively deploy the next-generation intelligent transportation system platforms, at least in their current form. Since vehicles usually traverses at quite high geographical speeds, their neighborhood also changes dynamically. Thus, it is challenging to accurately apprehend a vehicle's current and anticipated surrounding neighborhood on run-time basis. A major problem is that by the time the IoV information has been captured, analyzed, and presented to network operators or interested vehicles/vehicular users, the real-time situation has already changed, and the IoV data recently presented has become obsolete. Thus, IoV standalone might not make any essence in the long run; rather, it has to be further optimized with an emerging yet promising paradigm of

software-defined networking which through its centralized controllers (possessing a globalized topological view) addresses the trajectory and neighborhood estimation problems to a much greater extent.

The other issue pertains to density of the vehicular networks. If each individual vehicle starts communicating with its edge (i.e., for reporting status information or requesting vehicular applications or infotainment services), this could transpire in a network broadcast storm that may severely deteriorate the overall network performance, and consequently the service-level objectives may not be fulfilled. In this respect, a notion of vehicular cloud has been proposed in order to mitigate the said threat. However, for this purpose, efficacious *vehicular cloud formation schemes* have to be envisaged. Although the concept of vehicular cloud is much similar to that of a cluster formation in sensor networks or more precisely to vehicular platoons in vehicular ad hoc networks, the actual challenge here is again the dynamic nature of vehicular networks due to which vehicular clouds could make and break at a rapid pace resulting in overall wastage of network resources. Also, it is important that no malicious vehicle becomes part of the vehicular cloud, as this could easily become fatal for the entire IoV environment.

Finally, with a recent push for openness of IoV data sharing among diverse cloud service providers, it has become quite imminent that each cloud service provider should protect its infrastructures from a diverse range of malicious attacks by employing specialized access controls, isolation, encryption, and sanitization techniques. Hence, the input data from other cloud service providers need to pass via a validation process so that any malicious, faulty, or compromised data may be timely detected and subsequently blocked in order to protect the data integrity of the whole IoV ecosystem.

Big Data and Recommendation

Giancarlo Sperlì

Department of Electrical Engineering and Information Technology, University of Naples “Federico II”, Naples, Italy

Synonyms

Data management; Information filtering; Knowledge discovery

Definitions

Recommender systems have been introduced to facilitate the browsing of items' collection assisting users to find “what they need” within this ocean of information that match their preferences or needs.

Overview

This chapter firstly provides an overview of traditional recommender systems and successively it analyzes how the large amount of data, namely “Big Data”, produced by heterogeneous sources changed the traditional approaches with particular attention on the On-line social networks (OSNs) context.

Introduction

The increase of data produced by heterogeneous data sources, due to the large amount of connected devices, led to the definition of the big

data concept. Big data is a field concerning the storage, management, and analysis of large and heterogeneous amount of data which require the development of new methodologies and technologies for their management and processing. Thus, as defined by “The McKinsey Global Institute” Manyika and Chui (2011) “*Big data refers to data sets whose size is beyond the ability of typical database software tools to capture, store, manage and analyze.*”

In the last years, people are able to produce and share digital data (such as text, audio, images, and video) at an unprecedented rate due to the continuously progress in consumer electronics and to the widespread availability of Internet access. For facilitate browsing of large multimedia repositories and for providing useful recommendation, several algorithms and tools have been proposed. Such tools, usually referred to as recommender systems, collect and analyze usage data in order to identify user interests and preferences that allows to suggest items that meet users' needs.

Recommender Systems

Recommender systems have been introduced to facilitate the browsing of items collections, assisting users to find “*what the need*” within this ocean of information. On one hand, users want to have personalized results, and, on other hand, they are not willing to spend too much time to specify their personal information. In the mid-1990s, early works of Resnick et al. (1994) about recommender systems have been proposed to address the problem of information overloaded with the aim to provide useful suggestions based on users' preferences about items that could be of interest (Ricci et al. 2011a).

Recommendation algorithms have been used in several fields, such as *e-commerce Web sites*, in which information about a customer's interests are used to generate a list of recommended items. Other applications exploit the features of item that customers purchase, the feedback on the quality of the product, and the seller trustworthiness and explicitly rate to provide useful sug-

gestions. Moreover, they can use other attributes, such as viewed items, demographic data, subject interests, and favorite artists. *Recommender systems* automatically identify relevant information for a given user, learning from available data (user actions, user profiles). In particular, a *recommender system* supports users to identify the most interesting items, helping people confused by multiple choices analyzing the behavior of the people who have similar interests to them.

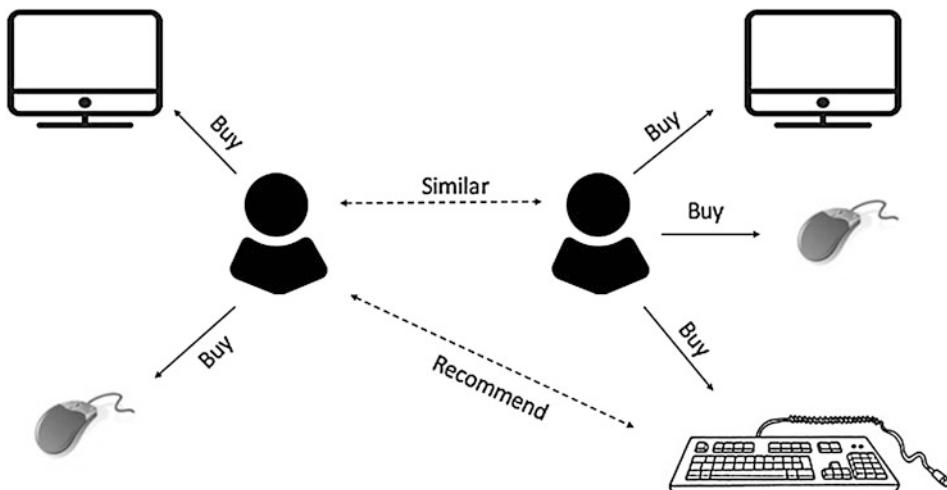

In a traditional model of *recommender system*, there are two types of entities: “*user*” and “*item*”. Users (often customers) have associated metadata (or content) such as age, gender, race, and other demographic information. Items (often products) also have metadata such as text description, price, weight, etc. Different interactions can be made between these two types of entity: user *A* downloads/purchases movie *B*, and user *X* gives a rating 5 to the product *Y* and so on.

The last-generation architecture of recommender systems is composed by one or more of the following stages (Ricci et al. 2011b; Colace et al. 2015): when a given user *i* is browsing a particular items’ collection, the system initially determines a set of useful *candidate* items $O_i^c \subset O$ based on user preferences and needs (*pre-filtering stage*); successively it assigns *score* (or a *rank*) $r_{i,j}$ to each item o_j in O_i^c , computed by analyzing the characteristics of each item

(feedbacks, past behaviors, and so on) (*ranking stage*); finally, it selects a subset of the item best suited (*post-filtering stage*).

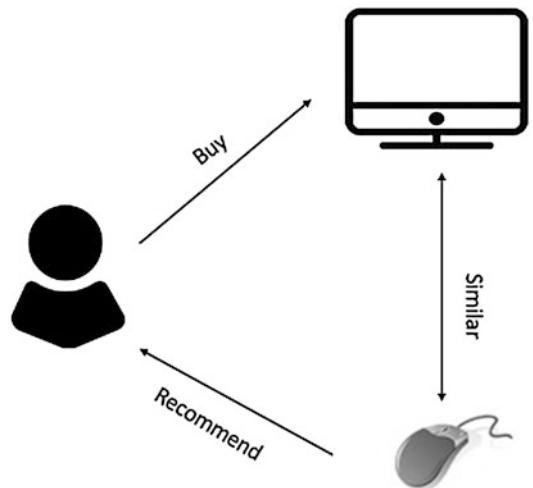

The recommender system approaches are usually classified into the following three categories:

- *Collaborative Filtering*: these systems rely solely on user’s preferences to make recommendations. Until a new item is rated by an appropriate number of users, the recommender system would not be able to provide meaningful recommendations. This problem is known as *cold-start* problem due to an initial lack of ratings. This approach is divided into (Fig. 1):
 - *Memory-based* approaches identify interesting items from other similar users’ opinions by performing the nearest neighbors on a rating matrix. This heuristics make rating predictions based on the entire collection of previously rated items by the users.
 - *Model-based* approaches use the collection of ratings to learn a model, which is then used to make ratings’ prediction.
- *Content-based filtering* approaches provide their suggestion based on the content of items, described as a set of tags, and the user profiles. The user may be recommended items similar

Big Data and Recommendation, Fig. 1 Collaborative filtering

**Big Data and
Recommendation, Fig. 2**
Content-based filtering

- to the ones the user preferred in the past. These approaches have some limitations; indeed the tags are explicitly associated with the items that the systems recommend. Another limitation is that two different items are indistinguishable if they are represented by the same tags. Furthermore, if there is a new user with few ratings, it would not be able to produce accurate recommendations (Fig. 2).
- *Hybrid-filtering based* approach combines both *content-based filtering* and *collaborative filtering* approaches to produce a recommendation. It is possible to classify the hybrid recommender system into the following four categories: (i) approaches that combine the prediction of collaborative and content-based methods; (ii) approaches that integrate some features of content-based into a collaborative approach; (iii) approaches that include some collaborative characteristics into a content-based approach; and (iv) approaches that integrate main characteristics of both models.

The technology behind *recommender systems* has evolved over the past 20 years into a rich collection of tools that enable researchers to develop effective recommender algorithms. Nowadays, the online shopping retails (such as *Amazon*, *Netflix*, etc.) are examples of recommender systems that analyze historical behaviors representing user information related

to past actions to propose additional products or services that enhance the customer satisfaction.

An approach that models recommendations as a social choice is proposed by Albanese et al. (2013). In particular, the authors combine intrinsic features of multimedia, past behaviors of users, and overall behavior of entire community of the users. Moreover, in Zhao et al. (2016), the authors propose a social recommendation framework based on an unified preferences learning process that integrates item content features with collaborative user-item relationships. Finally, Bartolini et al. (2016) propose a recommendation framework that manages heterogeneous data sources to provide context-aware recommendation techniques supporting intelligent multimedia services for the users.

Recommender Systems and Online Social Networks

The development of online social networks (OSNs) led to increase the amount of information on the Web. Different approaches have been proposed to include the information (i.e., users' relationships, behaviors, etc.) of OSNs in the recommender system for properly handling large amount of multimedia contents showing big data features, mainly due to their high change rate, huge volume, and intrinsic heterogeneity.

Big data in social networks (big social data) have been used to customize recommender systems in order to provide appropriate suggestions to users according to their needs and preferences. Also many e-commerce sites use social recommendation system to infer similarity between user purchase behaviors to recommend products that can improve the recommendation process in social networks. It is based on social network information, refers to trust and friendship among users (social relationship that resulted from common interests among users). In particular it is necessary to consider multi-attribute of products and users into the recommendation model. Furthermore, it allows to consider new different features for computing the similarity between two users. These features have three main properties:

1. *Contents generated by users* refer to all contents that are created by the users themselves and their meta-information.
2. *Relationship information* constitutes a social circle representing directly linked or connected relationships between users.
3. *Interaction information* refers to messages or contents exchanged between users.

Leveraging the information contained in OSNs, Qian et al. (2014) propose an unified personalized recommendation model based on probabilistic matrix factorization that combines three social factors: personal interest, interpersonal interest similarity, and interpersonal influence. The last two factors can enhance the intrinsic link among features in the latent space to deal with cold-start problem. In Sun et al. (2015), the authors propose recommender systems based on social networks, called *RSboSN*, which integrates social network graph and the user-item matrix to improve the prediction accuracy of the traditional recommender systems. In particular, a clustering algorithm for the *user-item-tag* matrix is used to identify the most suitable friends for realistic recommendation tasks. Moreover, Colace et al. (2015) propose a collaborative user-centered recommendation approach that combines preferences (usually in the shape of

items metadata), opinions (textual comments to which it is possible to associate a sentiment), behavior (in the majority of cases logs of past items observations made by users), and feedbacks (usually expressed in the form of ratings) with items features and context information for supporting different applications using proper customizations (e.g., recommendation of news, photos, movies, travels, etc.). In Amato et al. (2017) it is proposed a *recommending system* for big data applications based on a collaborative and user-centered approach. The recommendations are made based on the interactions among users and generated multimedia contents in one or more social networks.

In the last years, different recommendation techniques have been proposed in the literature for supporting several kinds of applications in *multimedia social networks*, in which nodes could be users or multimedia objects (photos, video, posts, and so on), and links between nodes could be assumed different meaning (publishing, endorsement, and so on). These systems exploit information extracted by these networks to improve the accuracy of recommendation, and they provide new types of suggestions; for instance, they can recommend not only items but also groups, friends, events, tags, etc. to users through algorithms that it is possible to classify into the following three different classes.

The first one is composed by a set of algorithms leveraging graph as data model in which nodes and edges represent, respectively, single social entities and the relationships among them. Jiang et al. (2015b) propose a modified version of *random walk* on a star-structured heterogeneous network, a particular network centered on social domain which is connected with other domains (i.e., video, Web posts, etc.). The aim of this approach is to predict user-item links in a target domain leveraging the items in auxiliary domains.

Algorithms that try to learn user and item preferences, through factorization of the related rating matrices, compose the second class. Jamali and Lakshmanan (2013) propose *Heteromf*, a context-dependent matrix factorization model that considers jointly two types of latent

factors: general latent factors for each entity type and context-dependent latent factors for each context in which entities are involved.

The third class is constituted by algorithms that model the interactions among users and items as “latent topics,” improving the recommendation process with other types of information. To such purposes, Yuan et al. (2013) propose a probabilistic model to exploit the different types of information (such as spatial, temporal, and activity data) extracted from social networks to infer behavioral models for users. In turn, Pham et al. (2016) propose an algorithm able to measure the influence among different types of entities, with the final aim to achieve higher recommendation accuracy and to understand the role of each entity in recommendation process.

Recommender Systems and Location-Based Social Networks

In addition to the described approaches, the rapid growth of cities led to develop recommendation systems based on points of interest (*POIs*). People, in everyday life, decide *where to go* according to their personal interests. Thus, *POI recommendation* helps users to filter out uninteresting places and reduce their decision-making time. Furthermore, the continuous increase in the use of smartphones led to the emergence of a new type of social network called location-based social networks (LBSNs); the main characteristic of these networks is to integrate the user’s location into the well-known OSN capabilities. With the development of *location-based social networks* (LBSNs) (i.e., FourSquare, Gowalla, etc.), *POI* recommendation on LBSNs (Gao et al. 2015) has recently attracted much attention as the latter provides an unprecedented opportunity to study human mobile behaviors for providing useful recommendations in spatial, temporal, social, and content aspects. These systems allow users to make *check in* at specific POIs with mobile devices and leave tips or share their experience with other users. These facets result in a W^4 (*who, when, where, what*) information layout, corresponding to four distinct information layers.

Content information on LBSNs could be related to a user check-in action; in particular, there are three types of content information:

B

- POI properties related to an action of check in, for example, by observing a POIs description as “vegetarian restaurant”; it is possible to infer that the restaurant serves “vegetarian food” and users who check in at this business object might be interested in the vegetarian diet.
- User interests related to user comments about a particular POI.
- Sentiment indications also related to users comments on a given POI.

The technological development led to see online social network an important means on which make business, allowing firms to promote their products and services and users to provide feedbacks about their experiences. In Zhang et al. (2016), the authors propose an approach based on matrix factorization that exploits both the attributes of items and social links of users to address the cold-start problem for new users by utilizing the social links between users. In particular, Kernel-based attribute-aware matrix factorization (KAMF) method is developed to discover the nonlinear interactions among attributes, users, and items. A recommender system that integrates community-contributed photos, social, and location aspects is proposed by Jiang et al. (2016) for providing a personalized travel sequence recommendation. In this system, similarities between user and route package are used to rank famous routes, whose top one are optimized by analyzing social similar users’ travel records. Moreover, Amato et al. (2014) propose a touristic context-aware recommendation system, based on the experience of previous users and on personal preferences of tourists, which combines information gathered by several heterogeneous sources. Eventually, an author topic model-based collaborative filtering (ATCF) method, based on user preference topics (i.e., cultural, cityscape, or landmark) extracted from the geo-tag constrained textual description of photos, is proposed by Jiang et al. (2015a) to provide *POI* recommendation for social users.

Recommender Systems and Event-Based Social Networks

Nowadays, the Web has grown into one of the most important channels to communicate social events, leading to the rise of a new type of OSN, called event-based social networks (ESBNs) (i.e., Meetup, Plancast, etc.), in which users join in social groups to attend events. Event-based social networks (EBSNs) are online social networks where users can create, promote, and share upcoming events of any kind with other users. The large amount of events available in EBSNs confuses users' ability to choose the events that best fit their interests. In Macedo et al. (2015), the authors propose a context-aware approach to event recommendation that exploits the following different signals that have a positive influence on the user's decision about attending an event: social signals based on group membership, location signals based on the user home distance to each event, and temporal signals derived from the users time preferences. The event participation decisions are analyzed by Ding et al. (2016) considering the interactions on the well-known ESBN Meetup. Successively the authors propose a technique that combines user features from multiple channels to recommend users to new events. In Gao et al. (2016), *SogBmf*, a Bayesian latent factor model that jointly considers social group influence and individual preferences, is proposed for improving the event recommendation performance.

Big Data Application in Manufacturing Industry

Amit Mitra¹ and Kamran Munir²

Introduction

Today data on customers or clients of companies is one of the key resources that adds to the valuation of an organization. Often data is not only generated by customers who are buying from organizations but increasingly because of feedback that they may share on various social media platforms about their experiences of buying. So, traditional approaches where data collection was mainly based on conducting surveys of customer experiences are increasingly becoming a thing of the past. On the one hand, people prefer to refrain from participating in surveys as these may be time-consuming; on the other the amount of time spent on social media platforms has been on the rise. Given such an environment, it is commonplace for organizations to collect data through touch points that customers use when ordering or choosing products and services. Therefore, data generation is not limited to responses to survey questions but more because of touch points and social media posts. In this ever-growing and dynamic need to deal with variety of

formats far exceeds the capacities of traditional modelling approaches. Traditional modelling approaches tend to suit predictive analysis more than those in contexts where a great deal of data is being generated at every moment's activity.

Like every new technological innovation, the importance of big data has burgeoned with the use of different kinds of media for personal as well as business communication. In the wake of such a growth of big data, there has also been skepticism as to what constitutes it (Sha and Carotti-Sha 2016). As mentioned above, the most common distinction by which big data can be characterized is that it cannot be stored using traditional data structures. Further the quantity of big data keeps on increasing as action takes place in real time. So, when an aircraft engine runs, then it generates real-time data over every moment that it is running. Such a dynamic dimension, as well as its profligacy, is something that distinguishes the nature of big data generation from standard data.

In tandem with this, over the last decade, there has been an exponential growth in the reliance on customer-generated data in every industry and every walk of life. In a world where instantaneous access and response to data directly influence prospects of a company, sales of business intelligence software have far outstripped sales of traditional software. Just like human capacity is being replaced by software agents, similarly there is a noticeable shift from reliance on stored data onto accessing and processing real-time data. Such real-time data is also getting generated as customers engage in consuming products and sellers are eager to curate these experiences so that they can be mimicked to increase familiarity and thus the custom of the consumer. The latter in most situations is voluminous, and as it is being generated through various sources, it requires nonstandard mechanisms of processing. So traditional formats of storing and analysis using RDBMS are increasingly found to be wanting in their capacities (Gandomi and Haider 2015). According to Davenport (2014), big data is going to play a critical role in among others “every industry that uses machinery, every industry that has physical facilities, and every industry that

involves money.” Obviously, the manufacturing industry is certainly going to be an environment which will be generating substantial amounts of data as it is no exception to the characteristics mentioned by Davenport (*ibidem*). The manufacturing industry is likely to be critically impacted upon by the presence of a great deal of data that would need to be processed using NoSQL.

Data Characteristics

The diagram in Fig. 1 is aimed to illustrate the voluminous nature of big data and the ensuing types of data structures that are compatible with it. The diagram illustrates the increasingly unstructured nature of growth of big data.

From a management perspective, the advent of big data has made it impossible to think of businesses in the same way as in the past. Whereas traditional approaches have used analytics to understand and fine-tune processes to keep management informed while alerting them to anomalies (business intelligence is driven by the idea of “exception reporting”). In contrast big data has flipped such an analytical orientation on its head. The central view of big data is that the world and the data that it describes are in a state of change and flux; those organizations that can recognize and react quickly have the upper hand in this space. The sought-after business and IT capabilities are discovery and agility, rather than stability (Davenport 2014). Table 1 below projects a few

key differences between big data and traditional analytics.

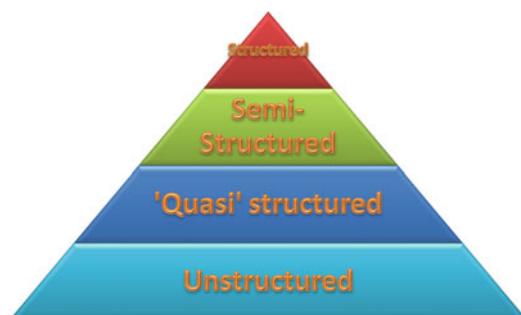

The dimension of primary purpose of big data in Table 1 reveals how the entire industrial world is reorienting itself with regard to customer data. The traditional information management approach has been to use analytics to cater to better internal decision-making through creation of reports and presentations that advise senior executives on internal decisions. In contrast data scientists are today involved in data-driven products and services through the creation of customer facing and customer touching applications.

Manufacturing Industry Transaction Processing

Given that discovery and agility are drivers that would enable manufacturing organizations to innovate and differentiate, data or big data would be at the heart of these endeavors. So in the manufacturing industry, not only manufactured products but also manufacturing equipment would increasingly contain data-producing sensors. Ability of devices that carry out, for instance, machining, welding, and robotic functions, would be reporting on their own performance and need for service. Being networked, most of these devices can be monitored and controlled from a central control hub.

Value addition in the manufacturing industry could also come about through connections with big data-fueled supply chains that would ensure supplies are available to support manufacturing while at the same time ensuring that only optimal amounts of goods are manufactured. Admittedly, discrete manufacturing companies have addressed this issue, whereas there is still a distance to go for process- or flow-based manufacturing like in the oil and natural gas sectors.

Foresight of troubleshooting products going forward along with the ability to outline expectations is critical in the manufacturing industry. Evidently, such foresight is based on accessing and evaluating a great deal of data (Marr 2016). Some of this is user generated, and some of this

Big Data Application in Manufacturing Industry,

Big Data Application in Manufacturing Industry, Table 2 Types of NoSQL data stores

Type	Typical usage	Examples
Key-value store – a simple data storage system that uses a key to access a value	Image stores Key-based file systems Object cache Systems designed to scale	Berkeley DB Memcached Redis Riak DynamoDB
Column family store – a sparse matrix system that uses a row and a column as keys	Web crawler results Big data problems that can relax consistency rules	Apache HBase Apache Cassandra Hypertable Apache Accumulo
Graph store – For relationship intensive problems	Social networks Fraud detection Relationship-heavy data	Neo4j AllegroGraph Bigdata (RDF data store) InfiniteGraph (objectivity)
Document store – Storing hierarchical data structures directly in the database	High-variability data Document search Integration hubs Web content management Publishing	MongoDB (10Gen) CouchDB Couchbase MarkLogic eXist-db Berkeley DB XML

Source: Adapted from McCreary and Kelly (2013).

is generated by intelligent agents such as Internet of Things (IoT) nodes.

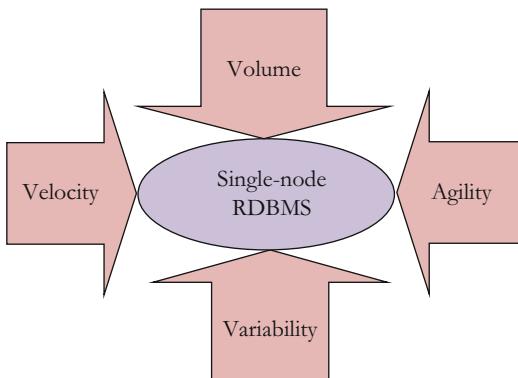

Analytics and Decision Support Requirements

As we all know, SQL is an acronym for Structured Query Language which is used to query data stored in rows and columns of databases. So SQL is used to create, manipulate, and store data in traditional formats with fixed rows and columns. However, a San Francisco-based developer group interested in issues surrounding scalable open-source databases first coined the term NoSQL (McCreary and Kelly 2013). In essence, NoSQL may be defined as:

NoSQL is a set of concepts that allows the rapid and efficient processing of data sets with a focus on performance, reliability, and agility. (McCreary and Kelly 2013; pg 4.)

It is clear from Table 2 above that there are a range of areas where NoSQL may be deemed to be a more reliable tool to process data in comparison to standard SQL. So considering data sources, key-value stores provide accommodation for a wide range of usage areas that are commonplace in the way data seems to get generated on different platforms.

Just like customer relationship management requires a completely different perspective of data storage on customers, similarly NoSQL storage envisages a change in the mindsets of data

Big Data Application in Manufacturing Industry,
Fig. 2 Impact of NoSQL business drivers. (Source: Adapted from McCreary and Kelley (2013))

handling. The diagram in Fig. 2 below projects this altered perspective.

In Fig. 2 above, the different business drivers, viz., volume, velocity, variability, and agility, are likely to apply gradual pressure on standard single CPU systems that could eventually lead to surfacing of cracks in the system's ability to handle increased processing expectations. In a real-world scenario of the manufacturing context, large amounts of data on production, of materials handling, and of supply chains all would be arriving fairly rapidly. Volume and velocity refer to the quantity and the speed at which such data would be getting generated, and so there would be increasing need to cope with these heightened requirements within restricted time horizons. Today's successful manufacturing companies would need to swiftly access data from sources that are not necessarily reducible into rows and columns. So, there may be recorded conversations, there may be Facebook posts, and there may be video recordings that would need to be considered by the manufacturing systems to make sure that business intelligence is sufficiently factored in to the manufacturing system to then cater to the continually changing expectations of the clientele. As a matter of fact, customer expectations are so quick changing that a manufacturing company can very easily find itself forced out of an industry if competitor application of NoSQL is more effective and insightful and leads to a better

match with customer expectations. The range of data types in big data is what is captured by variability of the data sets. Finally, for many manufacturing organizations, success in the market would be governed by how quickly they are able to respond to customer expectations. Such speed of response, represented by agility factors, would be reliant on the speed of successfully processing the different types of data that are going into the system.

Organization Readiness and Affordability

Manufacturing organizations may not be technologically or with regard to existing human capacity be able to modernize sufficiently quickly and integrate large volumes of data that is produced within the industrial environment. So there needs to be capacity that should be in place to accept and process these data sets. The approach that would be most appropriate would be to gradually phase in capacity to process big data. In the context of manufacturing data, organizations need to handle data using RDBMS, big data involving various formats as well as hybrid data. Using NoSQL to process big data is undoubtedly the most appropriate option for manufacturing organizations.

As an example, the levels of cost reduction achieved through big data technologies are incomparable to other alternatives in the present context. As a matter of fact, MIPS (millions of instructions per second – that is how fast a computer system crunches data) and terabyte storage for structured data are now most cheaply delivered through big data technologies like Hadoop clusters. For instance, a small manufacturing company considering storage of 1 terabyte for a year was £28 k for a traditional RDBMS, £3.9 k for a data appliance, and only £1.6 k for a Hadoop cluster – and the latter had the highest speed of processing data under most circumstances (Davenport 2014). Clearly, the cost-benefit trade-offs of not acquiring big data capabilities could potentially manifest in losing competitive advantage in the manufacturing industry.

Data Privacy and Security

As more data is available, stored in non-relational databases accessible online, and increasingly shared with third parties, the risk of data breaches also increases. Big data thus raises a number of privacy and security questions related to the access, the storage, and the usage of personal/user-related data. In the context of manufacturing companies, they share data on, among others, materials and processes with third-party organizations such as supply chain partners. So there will continue to be risks of exposure of sensitive identity attributes and other confidential information to the wider public. Additionally, for manufacturing organizations, data breaches may result in brand damages (i.e., loss of customers and partners' trust/loyalty, loss of intellectual property, loss of market share, and legal penalties and fines in case of noncompliance with privacy regulation). To deal with the abovementioned privacy risks, NoSQL has all the inbuilt capabilities of RDBMS (like GRANT, REVOKE, COMMIT, ROLLBACK for transactions). Therefore NoSQL is intrinsically suitable for encrypting data, access control, and data anonymization.

There are a couple of types of data that are sought after by external competitors of manufacturing companies. One type is raw data which is accessed by adversaries to compromise the interpretation/analysis process, e.g., injecting false data into raw data or stealing a large volume of sensitive (financial/identity) data. The second type of data that is accessed by adversaries is the different data sets that have already been analyzed as well as the actionable intelligence that analysts may have extracted from the data.

Conclusions

The discussion so far has touched upon various facets of data storage in general and big data in particular for manufacturing companies. Considering the future growth in both internal and external data that is likely to be generated, it follows that choosing NoSQL storage would be

an imperative. Circumstances of manufacturing companies would vary in the need of standard traditional RDBMS processing as well as NoSQL or hybrid data processing requirements. Hadoop, as a platform comprising of HIVE, enables NoSQL to be able to deal with all three requirements of manufacturing organizations. Considering exemplar costs, privacy, volume, variability, and agility requirements of the present and future contexts, it is clear that NoSQL is an inevitable necessity of manufacturing organizations. However, exponentially growing volume, variability, and agility of data requirement is a reality that all manufacturing companies need to cope with in order to survive in an increasingly data-driven industry where capacity to predict may make the difference between success and failure.

Big Data Architectures

Rodrigo N. Calheiros
School of Computing, Engineering and Mathematics, Western Sydney University, Penrith, NSW, Australia

Definitions

Big data architectures comprise an abstract view of systems that enable big data. It specifies the role of diverse components of the system, their

behavior, and how they interact with each other. Examples of roles of components include batch processing (i.e., handling the volume aspect of big data), stream processing (handling velocity), data management (handling variety) and modules enabling security, processing across geographically distributed locations, and other specific functions. Software architectures are not concerned on how modules are realized (implemented); thus, it is possible that two different realizations of the same architecture might be built with very different technology stacks. Specification of a software architecture helps in the definition of a blueprint containing the long-term vision for the future system and can help in directing development efforts and technical decisions during the system implementation.

Overview

According to Len Bass, “The software architecture of a system is the set of structures needed to reason about the system, which comprise software elements, relations among them, and properties of both” (Bass 2013). Therefore, rather than being a detailed description of how a system is built, a software architecture describes the diverse building blocks of the system and the relationship between them, keeping aside implementation details that, even if changed, do not change the vision described in the architecture.

The software architecture of a system is an ideal manner to communicate key design principles of the system, system properties, and even the decision-making process that led the system architecture to attain a certain shape.

The more complex the system, the bigger the need for a comprehensive documentation of its architecture. Thus, in the realm of big data, where there is a need to process large quantities of fast-arriving and diverse data on a system, it is important that a blueprint exists that documents what component of the system handles each of the aspects of big data, how these parts integrate, and how they work toward achieving their goals. This is the goal of big data architectures.

Over the years, several architectures were proposed that target the challenges of big data in dif-

ferent ways and that make different assumptions about how big data applications are structured and where the system is hosted. Although the term architecture is used in the literature to also describe implementation-specific approaches, we target here the most conceptual definition of architecture, independent of how it is realized. With this definition in mind, we review the most influential big data architectures in the next pages.

Lambda Architecture

The Lambda architecture (Marz and Warren 2015) is one of the first documented architectures for big data. It contains components that handle data volume and data velocity: it combines information from batch views and real-time views to generate results of user queries.

Conceptually, the architecture is divided in three layers: the *batch layer*, the *speed layer*, and the *serving layer* (Marz and Warren 2015). The role of the batch layer is to generate batch views that are a solution of the volume problem: the assumption in the architecture design is that, because batch views are computed from large volumes of data, it is likely that this computation will run for hours (or even days). Meanwhile, there will be still data arriving in the system (velocity) and queries being made by users. Thus, the answer needs to be built with the last available batch view, which may be outdated by hours or days.

An interesting characteristic of batch views is that they are immutable once generated. The next batch view is generated from the combination of all the data available in the system at the time the previous batch view was generated in addition to all the data that arrived since such a view was built (and that is available in the speed layer). Because batch views are continuously generated, problems with the data are corrected in the next batch view generated after the problem was detected and corrected, without requiring any other action by administrators.

To compensate staleness in the batch layer, the *speed layer* processes data, via stream computing, that arrived since the latest batch view was

generated. To be feasible, it performs incremental computation. Eventually, these views are incorporated by a new batch view and cease existing in the speed layer, thus making room for continuous incorporation of data on the system.

User interaction occurs in the serving layer, which incorporates the most recent batch view and the current views generated by the speed layer to answer to user queries. For this layer to meet its purpose of providing answer to queries in reasonable time, it needs to meet certain performance expectations, and thus data denormalization is not uncommon. Moreover, it should also support random reads on the data it contains so that answer to users can be sped up. Besides performance, other desired attributes of this layer, as pointed out by Marz and Warren, are fault tolerance and scalability (Marz and Warren 2015).

The architecture targets clusters or private clouds as its underlying architecture: a certain degree of data locality is necessary to enable efficient building of the batch views and queries by the speed layer. If data were to be distributed, extra modules would be necessary to combine local views generated in geographically distinct locations.

The Lambda architecture is general enough to be applied in many big data domains. The literature contains several realizations of the architecture, with open source and custom-made tools, in different domains (Magnoni et al. 2015; Schnizler et al. 2014). Nevertheless, this architecture also has some limitations. In particular, it is designed for computations that can be performed incrementally at the speed layer and that can benefit from random access or from different computations that can anticipate different user queries. When this does not hold, the applicability of the architecture is uncertain.

Big Data Architecture Framework (BDAF)

The Big Data Architecture Framework has been proposed by Demchenko et al. (2014) and has a more data-centric perspective of big data activities than the processing-centric view of the

Lambda architecture. It also addresses a different target environment: unlike the Lambda architecture that is more suitable to a local distributed system (e.g., a cluster or a private cloud), BDAF contemplates the fact that part of the data required for computation can be geographically distributed. Thus, if user queries need to be performed over such distributed data, computation will also need to be distributed, to occur where the relevant data is.

BDAF and Lambda also diverge in the aspect of data management. BDAF envisions a data management module that is separated from processing modules. This module addresses the “variety” dimension of big data (whereas the Lambda architecture addresses velocity and volume). It encompasses capabilities of data transformation, modeling, curation, and access. It also acknowledges the need to keep different views of data (i.e., different transformations over the same data) to serve as input to different analytics tasks.

Finally, BDAF also contains modules addressing security and coordination of distributed components, which is not necessary in the Lambda architecture because of the different target environment (centralized vs. distributed). This module is in charge of aspects such as federation (i.e., seamless access to resources that may be physically located in different infrastructure, thus avoiding the need for users to login or access each location individually), security, and interoperation (so the same operations can be carried out in different locations even if details on how to access such operations differ across locations).

In terms of applications, BDAF envisions different uses for the architecture. Some applications might just require batch processing, others just streaming, and others a combination of both. More complex programming such as workflows are also envisioned and supported in the architecture.

In a later publication (Demchenko et al. 2016), authors of BDAF mapped components of the architecture to the context of different big data scientific projects, demonstrating that the components of the proposed architecture match requirements of real systems.

In summary, BDAF is an architecture more concerned with data management aspects of big data and thus complements well the Lambda architecture, which has a bigger emphasis on processing capabilities with strong assertions on how data should be presented. However, its design is more complex to be able to address inherent issues with its complex target infrastructure.

BASIS

BASIS (Costa and Santos 2016) is a big data architecture that has been designed with a specific domain in mind, namely, smart cities. Nevertheless, the principles and design choices make it suitable to general domains as well.

Given its target context of smart cities, it is assumed that there are several sources of data to the system that needs to be transformed before being analyzed. This data enters the system via processing modules that include not only batch and stream (handling volume and velocity, as in the previous architectures) but also specific modules for data integration (handling variety). Other necessary components are APIs supporting ingestion of data from sensors and other particular devices and connectors to databases (enabling data to be persistently stored).

In its storage layer, BASIS encompasses modules supporting different types of data storage: file storage (called landing zone), distributed storage (for large volume), and three special-purpose storage modules, handling operational data, administrative data, and data to be made publicly available.

On top of this processing and storage infrastructure, the architecture contains a layer supporting arbitrary big data analytics tasks, which are accessed by applications that lay in the layer above, the topmost.

An implementation of the architecture is also presented by the authors to demonstrate the viability of the architecture. In terms of capabilities, BASIS is very similar to BDAF, but also differentiates itself in some aspects. The first one is that requirements for cross-site coordination and security are of smaller concern in BASIS,

as it is not design for the same level of distribution targeted by BDAF. However, BASIS has a stronger emphasis in enabling analytics as a service that can be composed by applications to provide specialized analytics to users, which is the main differential of BASIS compared to the other discussed architectures.

SOLID

SOLID (Cuesta et al. 2013) is a big data architecture for clusters that has been developed with the goal of prioritizing the variety dimension of big data over volume and velocity. As a result, many architectural decisions are made that differ significantly from the other approaches described so far.

The first key difference regards the expected data model. SOLID models data as *graphs*. The second key difference is that it mandates a specific data model, namely, RDF (Resource Description Framework (Manola et al. 2004)) to be used in the architecture.

Conceptually, SOLID is similar to the Lambda architecture with a few more components. The *merge layer* is responsible for batch processing (thus handling the volume aspect of big data). Similar to the case of Lambda architecture, it generates immutable views from all the data available until the moment the view is generated and stores the result in a database.

The *online layer* is conceptually equivalent to Lambda's speed layer, handling big data's velocity. It stores data received since the last dump to the merge layer. The *service layer* receives user queries and issues new queries to the online and index layers to build the answer to the query, and thus this is equivalent to Lambda's serving layer. Notice that, different from the Lambda architecture's serving layer, the online layer does not precompute views to be used to answer queries; it builds the answers on demand based on received requests.

Besides the three layers that are equivalent to Lambda layers, two other layers are present in SOLID: the first extra layer is the *index layer*, which generates indices that speed up

the access to the data items generated by the merge layer. The second one is the *data layer*, which stores data and metadata associated with the architecture, which is generated by the merge layer.

Quality-Centric Big Data Architecture for Federated Sensor Services

Ramaswamy et al. (2013) proposed a cloud-based big data architecture to support the Internet of Things (IoT) and all the data generated by IoT sensors. The key concern in the design of the architecture was enabling quality data to be obtained, stored, and accessed by end users. The objective of this vision is reducing the investment required to run IoT sensor networks: if the data of such sensors are valuable (timely and accurate) and it can be accessed by end users as a service, the cost of installing and maintaining such networks can be amortized among many users over time.

Data quality aspects considered by the architecture are not only performance metrics (latency, throughput) but also accuracy and variety. Moreover, the architecture requires components that can discover and add data feeds from sensors to the architecture. If this is the case, transformation in the data of added sensors may be necessary to conform with expectations from the architecture. Finally, mechanisms for billing are necessary, as one of the goals of the architecture is making the platform economically viable.

Conceptually, the platform contains not only modules for batch processing and stream analysis (such as Lambda's batch and speed layers, respectively) but also other components, pricing, network services, storage services, and sensor services, which virtualize and provide quality attributes to the corresponding elements, and also other modules with more specialized functions.

One of such specialized modules is the *DQ Monitor*. This module is responsible for managing the quality of data emerging from sensors (and therefore it communicates with the sensor service module). The *DQ Service Catalog* re-

ceives access from *brokers*, which act on behalf of users, to provide information about available sensors and corresponding data feeds.

B

M3Data

M3Data (Ionescu et al. 2016) is a cloud-based big data architecture that differs from the above architectures by envisioning a cycle for data processing that applies ETL (extract, transform, load) operations, similarly to classic business intelligence applications.

Some architectural components from M3Data are designed to support and interact with cloud infrastructures, whereas other components are designed to support actual operation on the data. The first group includes the *control layer*, which is responsible for operations such as installation and deployment of relevant software packages, and other self-explained layers such as *security layer*, *communication layer*, *processing layer*, *notification layer*, and *data transfer layer*.

The *flow control* module enables description and execution of complex dataflows, where users can describe operations to be carried out on data (such as cleansing, processing, transferring, and so on). Most importantly, this can be done graphically via a *dataflow studio* software.

M3Data also supports diverse data sources, including proprietary databases, file systems, FTP and email servers, and third-party applications. New data sources can be discovered and accessed, and its data can be indexed for future use. In fact, indexing and searching are important aspects of the architecture, with dedicated components for these tasks.

Another highlight of M3Data is support for autonomic computing, where the IT infrastructure is self-managed and can autonomously react to failures and other anomalies.

Summary of Architectures

Table 1 summarizes the key points of the evaluated architectures. It can be noticed that they

Big Data Architectures, Table 1 Summary of big data architectures

	Key application domain	Target infrastructure	Module for volume?	Module for velocity?	Module for variety?	Infrastructure-level modules?	Application-level modules?	Design highlights
Lambda (Marz and Warren 2015)	Queries over stream and stored data	Clusters	Yes	Yes	No	No	No	Immutable views Implemented by third parties
BDAF (Demchenko et al. 2014)	Geo-distributed queries	Geo-distributed clouds	Yes	Yes	Yes	Yes	Yes	Data-centric Support for multiple programming models
BASIS (Costa and Santos 2016)	Smart cities	Clusters	Yes	Yes	Yes	No	Yes	Supports different types of data stores Supports analytics as a service
SOLID (Cuesta et al. 2013)	Real-time systems	Clusters	Yes	Yes	Yes	No	No	Strong support for “variety” Module for indexing
Quality-centric (Ramaswamy et al. 2013)	Internet of Things (IoT)	Clouds	Yes	Yes	Yes	Yes	No	Modules to discover and aggregate data from new sensors
M3Data (Ionescu et al. 2016)	Data manipulation and querying	Clouds	Yes	Yes	Yes	Yes	Yes	Support for ETL operations Autonomous

differ in target domains, platforms, support for different features, and main features. It is evident that there is no one-size-fits-all solution for big data architectures, and the answer to the question of which one is the best depends on individual requirements.

Examples of Applications

A key application of big data architectures regards initial blueprints of big data solutions in a company or specific domain. In early stages of adoption, architects need to understand the re-

quirements of the system being designed, where it will be applied, what are the data sources, and what transformations and queries will occur in the data.

Once the above is identified, an architect needs to *select the big data architecture whose design and goals are closer to the system being conceived*. During this stage, two situations can be observed. In the first situation, it can be determined that some functionalities are missing in the candidate architecture. If this is the case, new capabilities will need to be designed and incorporated to the final system.

In the second case, the architect might identify that some elements of the architecture antagonize with needs/requirements of the system under development. In this case, a careful assessment needs to be carried out to identify the risks and costs involved in circumventing the antagonistic characteristics. Solutions to such situation can require complex logic and brittle software systems that may fail in achieving their goals. Therefore, architects should avoid selecting candidate architectures with antagonistic capabilities in relation to the needs of the system.

minimum knowledge about the underlying platform.

Future Directions for Research

- *Leveraging emerging computing platforms in new architectures.* Many of the discussed architectures were designed to benefit from public cloud computing platforms. This requires addition of new components on the architecture, but this decision empowers applications with elasticity and larger scale than achievable by cluster and private clouds. We are witnessing the emergence of new platforms such as edge computing and fog computing, which offer a compromise between local-only and cloud-only solutions. To enable big data architectures to benefit from such platforms, research is needed to identify the extra challenges incurred by these platforms and how it can be addressed in emerging architectures.
- *User-centric capabilities.* Existing architectures aim to solve abstract or specific problems with little or no focus on end users. Some architectures are data-centric, in which most of its components exist to operate on the data. Other architectures contain analytics and application modules, but none of them focus in the user experience. Therefore, research is needed to facilitate the interaction between end user and the system, so non-ICT specialist users can easily describe their desired operations, visualization, and reporting with

Definition

Deep Learning or also known as deep structured learning or hierarchical learning is a part of a broader family of Machine Learning methods

based on learning data representations (Bengio et al. 2013). Giving that Hordri et al. (2017) have systematically reviewed that the features of the Deep Learning are a hierarchical layer, high-level abstraction, process a high volume of data, universal model, and does not overfit training data. Deep Learning can be applied to learn from labeled data if it is available in sufficiently large amounts; it is particularly interesting to learn from large amounts of unlabeled/unsupervised data (Bengio et al. 2013; Bengio 2013), so it is also interesting to extract meaningful representations and patterns from Big Data. Since data keeps getting bigger, several Deep Learning tools have appeared to enable efficient development and implementation of Deep Learning method in Big Data (Bahrampour et al. 2015). Due to Deep Learning having different approaches such as convolutional neural network (CNN) and recurrent neural network (RNN), these Deep Learning tools are going to optimize different aspects of the development of Deep Learning approaches. The list of the Deep Learning tools includes but not limited to Caffe, Torch7, Theano, DeepLearning4j, PyLearn, deepmat, and many more. However, in this paper we will only focus on three tools such as Caffe, Torch7, and Theano since most of the researchers are using these tools according to the 2015 KDnuggets Software Poll.

Overview

Big Data generally refers to data that exceeds the typical storage, processing, and computing capacity of conventional databases and data analysis techniques. While Big Data is growing rapidly in the digital world in different shapes and sizes, there are constraints when managing and analyzing the data using conventional tools and technologies. Most conventional learning methods use shallow-structured learning architectures. Since the constraints are not an ordinary task, they require a collaboration of both developments of advanced technologies and interdisciplinary teams. Hence, Machine Learning techniques, together with advances in available computational power, have come to play an important role in Big

Data analytics and knowledge discovery (Chen and Lin 2014). Today, Deep Learning becoming a trend due to its techniques that use supervised and/or unsupervised strategies to automatically learn hierarchical representations in deep architectures for classification (Bengio and Bengio 2000; Boureau and Cun 2008).

One of the main tasks associated with Big Data Analytics is retrieving information (National Research Council 2013). Efficient storage and retrieval information are a growing problem in Big Data, primarily because of the enormous quantities of data such as text, image, video, and audio being collected made available across multiple domains. Instead of using raw inputs for indexing data, Deep Learning can be used to generate high-level abstract data representations to be used for semantic indexing. These representations can expose complex associations and factors (especially when the raw input is Big Data), which leads to semantic knowledge and understanding. While Deep Learning in providing an understanding of semantic and relational of the data, a vector representation (corresponding to the extracted representations) from data instances would provide faster searching and obtain information. With Deep Learning one can leverage unlabeled documents (unsupervised data) to have access to a much larger amount of input data, using a smaller amount of supervised data to improve the data representations and make it more relevant in learning task and specific conclusion.

Chen and Lin (2014) has discussed on how Deep Learning has also been successfully applied in industry products that take advantage of the large volume of digital data. Google, Apple, and Facebook are one of the companies that collect and analyze massive amounts of data everyday which aggressively make Deep Learning push forward to each related project. As in Efrati (2013), by utilizing Deep Learning and data collected by Apple services, the virtual personal assistant in iPhone, Siri, has offered a wide variety of services including weather reports, sports news, answer to user's questions, and reminder, while Google uses Deep Learning algorithms for massive chunks of messy data which are

obtained from the Internet for Google's translator, Android's voice recognition, Google's street view, and image search engine (Jones 2014). Microsoft also uses language translation in Bing voice search. IBM joins forces to build a brain-like computer by using Deep Learning to leverage Big Data for competitive advantage (Kirk 2013).

In summary, we could not find any related works on reviewing Deep Learning tools in Big Data analytics. Therefore, the purpose of the paper is to review the current top-listed tools of Deep Learning in Big Data applications. Findings may assist other researchers in determining the potential tools that going to be used in their study. The remainder of this paper is divided into following parts: in section “[Tools of Deep Learning Big Data](#),” we summarized each of the top three tools for Deep Learning. Moreover, we discussed the recent applications, languages, environments, and libraries for each tool. This is to ensure a good understanding on the concept of the common Deep Learning tools for Big Data that have been done over the years. Consequently, in section “[Comparative Study of Deep Learning Tools](#),” we created a comparative table of the properties of tools that have been discussed in section “[Tools of Deep Learning Big Data](#).” Finally, we have concluded this paper in the last section which is in section “[Future Directions for Research](#).”

Tools of Deep Learning Big Data

This section describes the foundation of this review by discussing several of tools of Deep Learning that have been applied with Big Data.

Caffe. Convolutional Architecture for Fast Feature Embedding or also known as Caffe is a Deep Learning framework made with expression, speed, and modularity in mind (Tokui et al. 2015). Caffe was originally developed at UC Berkeley by Yangqing Jia which is open sourced under BSD license. The code is written in clean, efficient C++ with CUDA used for GPU computation and nearly complete well-supported bindings to Python/Numpy and MATLAB (Jia et al. 2014; Tokui et al. 2015; Kokkinos

2015). Caffe becomes a preferable framework for research use due to the careful modularity of the code and the clean separation of network definition from actual implementation (Tokui et al. 2015). Several different types of Deep Learning architecture that Caffe support as mentioned in Caffe Tutorial (2018) are image classification and image segmentation. Caffe supports CNN, Regions with CNN (RCNN), long short-term memory (LSTM), and fully connected neural network designs.

According to Jia et al. (2014), Caffe stored data and communicates data in four-dimensional arrays called blobs. Blobs provide a unified memory interface, holding batches of images, parameters, or parameter updates. The data is transferred from one blob to another blob in the next layer. Based on Chetlur et al. (2014), in Caffe each type of model operation is encapsulated in a layer. Layer development comprises declaring and implementing a layer class, defining the layer in the protocol buffer model scheme, extending the layer factory, and including tests. These layers take one or more blobs as input and yield one or more blobs as output. Each layer has two key responsibilities for the operation of the network. There are (i) a *forward pass* that takes the inputs and produces the output and (ii) a *backward pass* that takes the gradients with respect to the parameters and to the inputs, which are in turn back-propagated to earlier layers. After that, Caffe does all the bookkeeping for any directed acyclic graph of layers, ensuring correctness of the forward and backward passes. A typical network begins with a data layer which is run on CPU or GPU by setting a single switch. The CPU/GPU switch is seamless and independent of the model definition.

Caffe is able to clear access to deep architectures which can train the models for fastest research progress and emerged the commercial applications. In 2015, Ahmed et al. (2015) has implemented deep network architecture using the Caffe Deep Learning framework which the research adapted various of layers from the framework and wrote their own layers that are specific to the deep network architecture. The convergences time for training the network is approxi-

mately 12–14 h. The architecture is implemented in NVIDIA GTX780 and NVIDIA K40 GPUs. Also, in 2015, Kokkinos (2015) has evaluated the performance of Caffe, cuDNN, and CUDA-convnet2 using the layer configurations which are commonly used for benchmarking convolutional performance and quoting average throughput for all these layers. This performance portability is crossed GPU architecture with Tesla K40. Tokui and co-workers (2015) have introduced Chainer, a Python-based, stand-alone, open-source framework for Deep Learning models (Caffe Tutorial 2018). Tokui claims that Chainer provides a flexible, intuitive, and high-performance means of implementing a full range of Deep Learning models. He then compared Chainer with Caffe using various CNNS. Based on the experiment, since Caffe is written in C++ and Chainer is written in Python, the total time required for trial-and-error testing in implementing and tuning new algorithms is likely to be similar for both frameworks. Still in 2015, Kokkinos combined a careful design of the loss for boundary detection training, a multi-resolution architecture and training with external data to improve an accuracy of the current state of the art (Chetlur et al. 2014). This detector is fully integrated into the Caffe framework and processes a 320×420 image in less than a second on an NVIDIA Titan GPU.

Torch7. Collobert et al. (2011) defined Torch7 as a versatile numeric computing framework and Machine Learning library that extends Lua (Collobert et al. 2011). By using Lua you can have a lightweight scripting language. Collobert and his team chose Lua because Lua is the only fastest interpreted language that they can find. Lua is easy to be embedded in a C application. They also chose Lua instead of Python because Lua is well-known in the gaming programmer community. Most packages in Torch7 or third-party packages that depend on Torch7 rely on its Tensor class to represent signals, images, and videos. There are eight packages in Torch7 which are (i) torch, (ii) lab and plot, (iii) qt, (iv) nn, (v) image, (vi) optim, (vii) unsup, and (viii) third-party. Lua also provides a wide range of algorithms for Deep Machine Learning and uses the scripting LuaJIT.

Torch7 is designed and developed to use Open Multi-Processing (OpenMP) directives for various operations in its Tensor library and neural network package (Collobert et al. 2011). This is due to the OpenMP which provides a shared memory CPU parallelization framework in C/C++ and Fortran languages on the almost operating system and compiler tool set. Hence, OpenMP normally requires minimal modification for integrating into an existing project. If the compiler is supported by OpenMP, Torch7 will automatically detect it and compile a high-level package that adds multi-threaded Tensor operations, convolutions, and several neural network classes. The number of threads to be used can be specified by either setting or environment variable to the desired number.

In 2015, Lane et al. (2015) have done the experiment in designing the raw feasibility of executing Deep Learning models. The paper also considered end-to-end model performance metrics of execution time and energy consumption, especially in terms of how these map to application needs. For the experiments, Torch7 has been used for training all the models in NVIDIA Tegra K1. The result of the experiments shows that Deep Learning is enabling to be ready to integrate with IOT, smartphones, and wearable systems. Shokri and Shmatikov (2015) have designed, implemented, and evaluated a practical system that enables multiple parties to jointly learn an accurate neural network model for a given objective without sharing their input datasets (Shokri and Shmatikov 2015). They used Torch7 packages as they mentioned that Torch7 has been used and extended by major Internet companies such as Facebook. Later in 2016, small towers of wooden blocks are created using a 3D game engine which the stability is randomized and renders them collapsing (Lerer et al. 2016), using Torch7 Deep Learning environment to integrate with Machine Learning framework directly into the UE4 game loop. Torch7 allowed fine-grained scripting and online control of UE4 simulations. Since Lua is the dominant scripting languages for games and many games including UE4 support, Torch7 is well-suited for game engine integration. The

simulations from Torch7 can be run faster than real time and help in large-scale training. Other than games, the author also said that Torch7 is useful for experiments in vision, physics, and agent learning.

Theano. Theano is a Python library that allows to define, optimize, and evaluate mathematical expressions involving multidimensional arrays efficiently (Al-Rfou et al. 2016; Goodfellow et al. 2013). Theano aims to improve both execution time and development time of Machine Learning applications, especially Deep Learning algorithm (Bergstra et al. 2011). By describing the mathematical algorithms as in functional language and profit from fast coding, Theano makes it easier to leverage the rapid development pattern encouraged by the Python language and depending on Numpy and Scipy. Theano also provides a language that is an actual implementation for describing expressions (Sherkhane and Vora 2017). Likewise, in Bastien's paper (2012), Theano uses CUDA to define a class of n -dimensional arrays located in GPU memory with Python binding (Bastien et al. 2012). Theano can automatically compute symbolic differentiation of complex expressions, disregard the variables that are not required to compute the final output, recycle partial results to avoid redundant computations, apply mathematical simplifications, calculate operations in place when possible to minimize the memory usage, and apply numerical stability optimization to overcome or minimize the error due to hardware approximations (Al-Rfou et al. 2016).

Theano defines a language to represent mathematical expressions and manipulate them. For example, Theano represents symbolic mathematical expressions as directed, acyclic graphs (Al-Rfou et al. 2016). These graphs are also bipartite, containing two kinds of nodes: variable nodes and apply nodes. Practically, for graph inputs and outputs, usually variables and intermediate values are going to be used. During the execution phase, values will be provided for input variables and computed for intermediate and output ones. The apply node has inputs and outputs, while the variable node can be the input to several

Big Data Deep Learning Tools, Table 1 Properties of Deep Learning tools (Boureau and Cun 2008)

Property	Caffe	Torch7	Theano

apply nodes but can be the output of at most one apply node. Since variables are strongly typed in Theano, the type of these variables must be specified at creation time. By calling Python functions on variables, the user can then interact with them in a direct and natural way. Due to the computation graph is acyclic and its structure is fixed and independent from the actual data, it can be a challenge to express loops symbolically. Therefore, Theano implements a special Op called Scan to abstracts the entire loop in a single apply node in the graph. The Scan node handles the communication between the external or outer computation graph it belongs to and the internal or inner graph. The Scan is also responsible to manage the bookkeeping between the different iterations.

Glorot et al. (2011) proposed a Deep Learning approach which learns to extract a meaningful representation of the problem of domain adaptation of sentiment classifiers (Glorot et al. 2011). All algorithms were implemented using the Theano library, while in 2016, Litjens and his team (2016) introduced Deep Learning as a technique to improve the objectivity and efficiency of histopathologic slide analysis. In this work, the convolutional neural network has been trained using the open source Deep Learning libraries which are Theano. However, in this work, due to the memory limitations of the GPU, some of the sized patches performed substantially worse on patch-based accuracy.

Comparative Study of Deep Learning Tools

This section provides a comparison of Deep Learning tools as in Table 1 below. Table 1 describes the general properties of Caffe, Torch7, and Theano. According to Bahrampour et al. (2015), these tools are the top three well-developed and widely used frameworks by the Deep Learning community. However, the comparison only focused on the speed of performance of the convolutional frameworks.

Future Directions for Research

Overall, Deep Learning tools that have been discussed in the previous sections may give the guideline to the other researcher on which tools that want to use in their study. We found that each of the tools is effective when the researchers use to match their study. Nevertheless, since the data keeps getting bigger, the technology also becoming more advanced. There might be new Deep Learning tools that can outperform the current tools.

Conclusion

In contrast between conventional Machine Learning tools and Deep Learning tools, Deep Learning has the advantages of potentially providing a

solution to Big Data analysis due to its extracting complex data representations from large volumes of unsupervised data. Deep Learning tool becomes valuable tools when it comes to Big Data analytics where the analysis data involving large volumes of raw data are unsupervised and uncategorized. The tools can be applied to managing and analyzing the data in Big Data analytics problem due to its features that can learn from hierarchical representation in deep architectures for classification. Hence, in this study, we have aimed and identified the top three tools of Deep Learning that can be useful to Big Data. The tools are Caffe, Torch7, and Theano. This study also has given a comparative study on the performance of the convolutional frameworks for each tool.

LMI is, it can be referred to the design and use of AI algorithms and frameworks to analyze data related to labor market (*aka* labor market information) for supporting policy and decision-making (see, e.g., UK Commission for Employment and Skills 2015; UK Department for Education and Skills 2004).

Classification system or taxonomy in the field of labor market refers to a taxonomy or a graph that organizes jobs into a clearly defined set of groups according to the tasks and duties undertaken in the job, as in the case of the International Standard Classification System ISCO (Organization IL 2017) and the US classification system O*NET (U.S. Department of Labor/Employment & Training Administration 2017). Recently, such systems have been improved to take into account also skills, competences, and qualifications, as the case of the European classification system ESCO (European Commission 2017).

KDD stands for knowledge discovery in databases. It is a framework firstly introduced by Fayyad et al. (1996) for extracting knowledge from huge mass of data. It specifies a number of steps – from data collection to data visualization – that form a guidance for any applications that intend to retrieve knowledge from data, as in the case of Big Data applications as well.

Web job vacancy is job advertisement composed of two text fields: a title and a full description. The former shortly summarizes the job position, while the full description field usually includes the position details and the relevant skills that an employee should hold.

Big Data Enables Labor Market Intelligence

Mario Mezzanica and Fabio Mercurio
Department of Statistics and Quantitative Methods – CRISP Research Centre, University of Milan Bicocca, Milan, Italy

Definitions

Labor market intelligence (LMI) is a term that is emerging in the whole labor market community, especially in the European Union. Although there is no unified definition of what

Overview

In the last years, several forces and factors have dramatically changed the nature and characteristics of the labor market, in both advanced and developing countries. Technical progress, globalization, and the reorganization of the production processes have radically modified the demand for certain skills, intensifying the need for continued

training, especially in those jobs that are highly specialized or heavily affected by digitalization.

On one hand several jobs are disappearing, while new jobs are emerging, some of which are simply a variant of existing jobs, others are genuinely new jobs that were nonexistent until few years ago. On the other hand, the quantity and quality of the demand for skills and qualifications associated to the new labor market have changed dramatically. New skills are needed not only to perform new jobs, but also the skill requirements of existing jobs have changed considerably.

The Need for LMI. In such a dynamic scenario, the problem of monitoring, analyzing, and understanding these labor market changes (i) timely and (ii) at a very fine-grained geographical level has become practically significant in our daily lives. *Which occupations will grow in the future and where? What skills will be demanded the most in the next years?* Those are just few questions with which economists and policy makers have to face with (see, e.g., the recent work by Frey and Osborne (2017) about occupations that might disappear due to the digitalization). Here, a key role is played by Big Data concerning labor market (e.g., job advertisements, cv posted on the Web, etc.). This data needs to be collected, organized, and manipulated for enabling a real-time monitoring and analysis of labor market dynamics and trends. In this way, labor market

needs can be analyzed without the time lags found in traditional administrative and survey data sources that may require several months for being available. In addition, a real-time analysis of Web labor market represents an anytime snapshot of the market demands, providing a useful source of information about specific job requirements, the offered contracts, requested skills (both hard and soft), the industry sector, etc., which are not covered in any surveys.

A Motivating Example. Table 1 shows two job vacancies extracted from specialized Web sites. Even though both advertisements seek for *computer scientists*, the differences in terms of job requirements, skills, and corresponding educational levels are quite evident. The first job vacancy (A) is looking for a software developer, while the second one (B) is searching for a less specialized candidate, i.e., an ICT technician. Indeed, in the latter case, the only requested abilities required are to be able to *use* some solutions and the knowledge of a programming language (nice to have) that is usually taught in some professional high schools.

The ability to catch such differences and to classify these two distinct occupational profiles (i) timely and (ii) according to a standard taxonomy is mandatory for analyzing, sharing, and comparing the Web labor market dynamics over different regions and countries. Here, job offer

Big Data Enables Labor Market Intelligence, Table 1
CEDEFOP project (Taken from Boselli et al. 2017b)

(A) **ICT Developer.** “Looking to recruit a software developer to join our dynamic R&D team to support work on Windows-based software for current and upcoming products. A flexible, self-starting attitude is essential along with a strong motivation to learn new skills as required. The ideal candidate will have at least 2–3 years experience working in a fast and dynamic small team. Experience in Python is the key requirement for my client. A degree in computer science/computer engineering is preferable, but other engineering/science graduates will be considered if they have software development experience.” [ISCO 2512: Software Developer]

Workplace: Milan

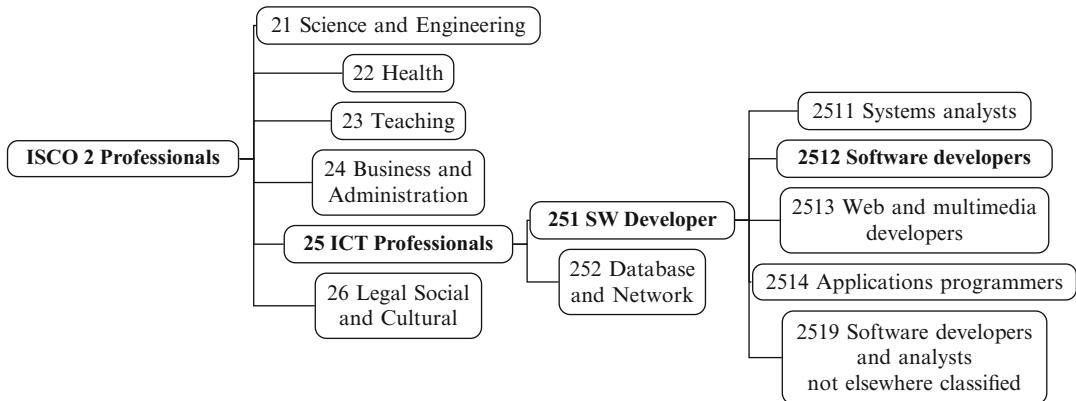

Contract type: Permanent

An example of real Web job vacancies as collected in the

(B) **Application Consultant.** “We are seeking for an application consultant that will support our internal SW engineers in the realization of ad hoc ERP software. The ideal candidate should have (at least) a high-level degree and 2+ years experience in using both Sharepoint-MS CRM and Magic. Coding skills on VB are appreciated.” [ISCO 3512: ICT user support technicians]

Workplace: Rome

Contract type: Unlimited term

Big Data Enables Labor Market Intelligence, Fig. 1 A branch of the ISCO classification tree for professionals

A was classified on the code 2512: *Software Developer* of the ISCO hierarchical classifier by labor market experts of The European Network on Regional Labour Market Monitoring (2017), while job offer B refers to 3512: *ICT user support technicians* (an example is provided in Fig. 1).

In addition, focusing on skills (both hard and soft) have to be identified from raw text and linked against the skill taxonomy (e.g., the ESCO taxonomy), while new emerging skills have to be recognized and returned as well. *Which are the most important in skill in these advertisements? Which are the most relevant skills in these job occupations?* These are just few questions that labor market analysts and specialists need to face to deeply understand the labor market at local, national, and international level and to design labor policies accordingly.

Research Findings

Literature on LMI. Labor market intelligence is an *emerging cross-disciplinary field of studies* that is gaining research interests in both *industrial* and *academic* communities. On one side, the task of extracting useful information from unstructured texts (e.g., vacancies, curricula, etc.) mainly focused on the e-recruitment process, by attempting to support or to automate the *resume* management by matching candidate profiles with job descriptions using language models and ma-

chine learning (Li et al. 2017; Zhu et al. 2016; Kokkodis et al. 2015; Verroios et al. 2015; Singh et al. 2010; Yi et al. 2007; Hong et al. 2013). On the other side, companies need to automatize human resource (HR) department activities; as a consequence, a growing amount of commercial skill-matching products have been developed in the last years, for instance, BurningGlass, Workday, Pluralsight, EmployInsight, and TextKernel (see, e.g., Neculoiu et al. 2016). To date, the only commercial solution that uses international standard taxonomies is Janzz: a Web-based platform to match labor demand and supply in both public and private sectors. It also provides API access to its knowledge base, but it is not aimed at classifying job vacancies. Worth of mentioning is Google Job Search API, a pay-as-you-go service announced in 2016 for classifying job vacancies through the Google Machine Learning service over O*NET, that is the US standard occupation taxonomy. Although this commercial service is still a closed alpha, it is quite promising and also sheds the light on the needs for reasoning with Web job vacancies using a common taxonomy as baseline.

Calls for Projects on LMI. Focusing on *public administrations and organizations*, there is a growing interest in designing and implementing real LMI applications to Web labor market data for supporting the policy design and evaluation activities through evidence-based decision-

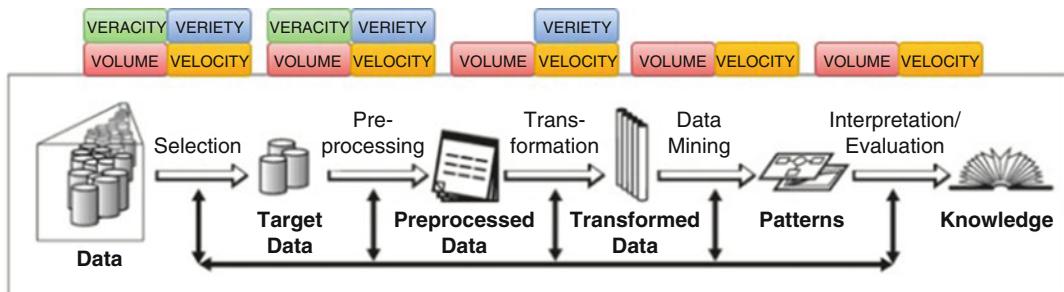

making. In 2010 the European Commission has published the communication “A new impetus for European Cooperation in Vocational Education and Training (VET) to support the Europe 2020 strategy” (CEDEFOP 2010) aimed at promoting education systems, in general, and VET, in particular. In 2016, the European Commission highlighted the importance of vocational and educational activities, as they are “valued for fostering job-specific and transversal skills, facilitating the transition into employment and maintaining and updating the skills of the workforce according to sectorial, regional, and local needs” (European Commission 2016a). In 2016, the EU and Eurostat launched the ESSnet Big Data project (EuroStat 2016), involving 22 EU member states with the aim of “integrating big data in the regular production of official statistics, through pilots exploring the potential of selected Big Data sources and building concrete applications.” Furthermore, in 2014 the EU CEDEFOP agency – aimed at supporting the development of European Vocational Education and Training – has launched a call-for-tender for realizing a system able to collect and classify Web job vacancies from five EU countries (CEDEFOP 2014). The rationale behind the project is to turn data extracted from Web job vacancies into knowledge (and thus value) for policy design and evaluation through a fact-based decision-making. Given the success of the prototype, a further call-for-tender has been opened for realizing the Web labor market monitor for the whole EU, including 28 EU country members and all the 24 languages of the Union (CEDEFOP 2016).

All these initiatives are quite effective and shed the light on the relevance of reasoning with labor market information for supporting business purposes in both private sector (e.g., *job matching*, *candidate profile*, etc.) and in the public one (e.g., *labor market analysis*).

KDD Applied to LMI

The extraction of knowledge from (Big) labor market data has been addressed using the KDD approach as baseline (i.e., knowledge discovery in databases). KDD is mainly composed of five steps, as shown by Fayyad et al. (1996). Clearly, this approach needs to be adapted to the domain of interest, enhancing one task or step in spite of another. To this end, Fig. 2 reports a graphical overview of the KDD framed within the LMI context, along with a number of labels that specify which Vs of the Big Data context is involved. Each step can be adapted to the Web labor market context as follows.

Step 1: Selection. Data sources have to be selected first. Each Web source has to be evaluated and ranked to guarantee the reliability of the information included (see, e.g., the work concerning the *believability* of data by Wang and Strong 1996). Just to give an example, this phase should take into account the vacancy publication date, the website’s update frequency, the presence of structured data, if there are any restrictions in downloading, etc. At the end of this process, a *rank* of reliable Web sources has been produced. As one might note, this step requires to deal with all the 4 Vs of Big Data that include also

Big Data Enables Labor Market Intelligence, Fig. 2 The KDD steps annotated to specify which Vs of Big Data is involved in each step. Figure built on top of the figure from Fayyad et al. (1996)

the *veracity*, intended as the biases, noise, and abnormality in data.

Step 2: Preprocessing. This includes the data cleaning task to remove noise from the data or inappropriate outliers (if any), deciding how to handle missing data, as well as identifying a function to detect and remove duplicated entries (e.g., duplicated vacancies, vacancy with missing values, etc.). Data quality and cleaning tasks are indeed mandatory steps of any data-driven decision-making approach for guaranteeing the believability of the overall process, intended as “the extent to which data is accepted or regarded as true, real, and credible” (see, e.g., Wang and Strong 1996; Redman 1998; Mezzanzanica et al. 2015; Batini et al. 2009).

Notice that the identification of duplicated job vacancies is far from straightforward. Indeed, job vacancies are usually posted on different website, and the *same* text is often reused to advertise a similar position. The former is a duplication while the latter not. The identification of appropriate features to correctly identify duplicates is crucial in the Web labor market domain. Notice that this step allows reducing the complexity of Big Data scenario, as the impact of the *veracity* dimension is mitigated through data quality and cleaning activities performed within this task.

Step 3: Transformation. This step includes the data reduction and projection tasks, which aim at identifying a unified model to represent the data, depending on the goal of the task. Furthermore, it may include the use of dimensionality reduction or transformation methods to reduce the effective number of variables or to find invariant representations for the data. Still in this case, this step reduces the complexity of the dataset by addressing the *variety* dimension. This step is usually performed by means of ETL techniques (extract, transform, and load) that aim at supporting the data preprocessing and transformation tasks in the KDD process. Roughly speaking, in the ETL process, the data extracted from a source system undergoes a set of transformation routines that analyze, manipulate, and then cleanse the data before loading them into a knowledge base (see,

e.g., Vassiliadis et al. 2002 for details on the ETL process). Notice that, at the end of this step, the *variety* issue related to Big Data is expected to be solved as a cleansed and well-defined model of the data is reached.

Step 4: Data Mining and Machine Learning.

This step requires to identify proper AI algorithms (e.g., classification, prediction, regression, clustering), searching for patterns of interest in a particular representational form on the basis of the analysis purposes. More specifically, in the context of LMI, it usually requires the use of text classification algorithms (ontology based, machine learning based, etc.) that builds a classification function to map a data item into one of several predefined classes. Here, items are represented by Web job offers, while the predefined classes are the one from a taxonomy (e.g., a proprietary one or a public one, as ESCO, O*NET, etc.). This is the core step of the KDD approach, even for LMI activity. Therefore, the task of job vacancy classification deserves to be formally described in terms of text categorization.

Text categorization aims at assigning a Boolean value to each pair $(d_j, c_i) \in D \times C$ where D is a set of documents and C a set of predefined categories. A *true* value assigned to (d_j, c_i) indicates document d_j to be set under the category c_i , while a *false* value indicates d_j cannot be assigned under c_i . In the LMI scenario, a set of job vacancies \mathcal{J} can be seen as a collection of documents each of which has to be assigned to one (and only one) occupation code of the taxonomy. Hence, classifying a job vacancy over a classification system requires to assign one occupation code to a job vacancy. This text categorization task can be solved through machine learning, as specified by Sebastiani (2002). Formally speaking, let $\mathcal{J} = \{J_1, \dots, J_n\}$ be a set of job vacancies and the classification of \mathcal{J} under the taxonomy consists of $|O|$ independent problems of classifying each job vacancy $J \in \mathcal{J}$ under a given taxonomy occupation code o_i for $i = 1, \dots, |O|$. Then, a *classifier* is a function $\psi : \mathcal{J} \times O \rightarrow \{0, 1\}$ that approximates an unknown target function $\dot{\psi} : \mathcal{J} \times O \rightarrow \{0, 1\}$.

Clearly, as this case requires to deal with a single-label classifier, $\forall j \in \mathcal{J}$ the following constraint must hold: $\sum_{o \in O} \psi(j, o) = 1$.

Step 5: Interpretation/Evaluation. Finally, this step employs visual paradigms to visually represent the resulting knowledge according to the user's purposes. In the LMI context, this step requires to take into account the user's ability in understanding the data and its main goal in the LMI field. For example, public administrations might be interested in identifying the most requested occupations in its local area; companies might focus on monitoring skills trend and identifying new skills for some occupations, so that they can promptly design training path for their employees, etc. In the last few years, a lot of work has been done for producing off-the-shelf visual libraries that implement several narrative and visual paradigms. A powerful example is D3js (Bostock et al. 2011), a data-driven responsive library for producing dynamic, interactive data visualization even in Big Data context (see, e.g., Bao and Chen 2014).

Examples of Application and Projects

As said above, LMI is an emerging field, in which the private sector plays a key role through many commercial solutions while public and academic applications/projects are fewer. Focusing on the latter, here two EU projects are reported as they are mature examples of how to use Big Data for LMI purposes.

Application 1: LMI for Decision-Making

In 2014, the CEDEFOP EU Agency invited academics to participate a call-for-tender aimed at collecting Web job vacancies from five EU countries and extracting the requested skills from the data. The rationale behind the project is to turn data extracted from Web job vacancies into knowledge (and thus value) for policy design and evaluation through fact-based decision-making. The system (Boselli et al. 2017a) is now running on the CEDEFOP data center since June 2016, gathering and classifying job vacancies

from five EU countries, namely, the United Kingdom, Ireland, Czech Republic, Italy, and Germany, through machine learning (Boselli et al. 2017b). To date, the system collected 7+ million job vacancies over the five EU countries, and it accounts among the research projects that a selection of Italian universities addressed in the context of Big Data (Bergamaschi et al. 2016).

This prototype allowed the CEDEFOP agency to have evidence of the *competitive advantage* that the analysis of Web job vacancy enables with respect to the classical survey-based analyses, in terms of (i) near-real-time labor market information; (ii) reduced time-to-market (iii) fine-grained territorial analysis, from countries down to municipalities; (iv) identification of the most requested skills; and (v) evaluation of skills impact to each ISCO profession.

Online Demo. To better clarify the final outcome of a LMI project, the reader can refer to the animated heat map showing the job vacancy collection progress over time available at <http://goo.gl/MQuIUn>. On the other side, an example of how the LMI knowledge might be made available to decision-maker is provided at <http://goo.gl/RRb63S>.

Application 2: LMI for Producing Official Statistics

Focusing on the statistical perspective related to the analysis of Big Data for LMI, the Eurostat – the official statistical office of the European Union – launched a project named ESSnet Big Data aimed at integrating Big Data about LMI in the regular production of official statistics, through pilots exploring the potential of selected Big Data sources and building concrete applications (EuroStat 2016). The project – started in late 2016 – is composed of 22 EU partners and strictly follows the KDD approach to collect data from Web portals previously ranked and cleanse and transform it for classifying data over standard taxonomies. Worth noting here is the important role that the *representativeness* of Big Data plays in this project, as participants aim at evaluating the ability of Big Data to be representative of the whole population (or a stratified sample) for being included in official EU statistics.

Future Directions for Research

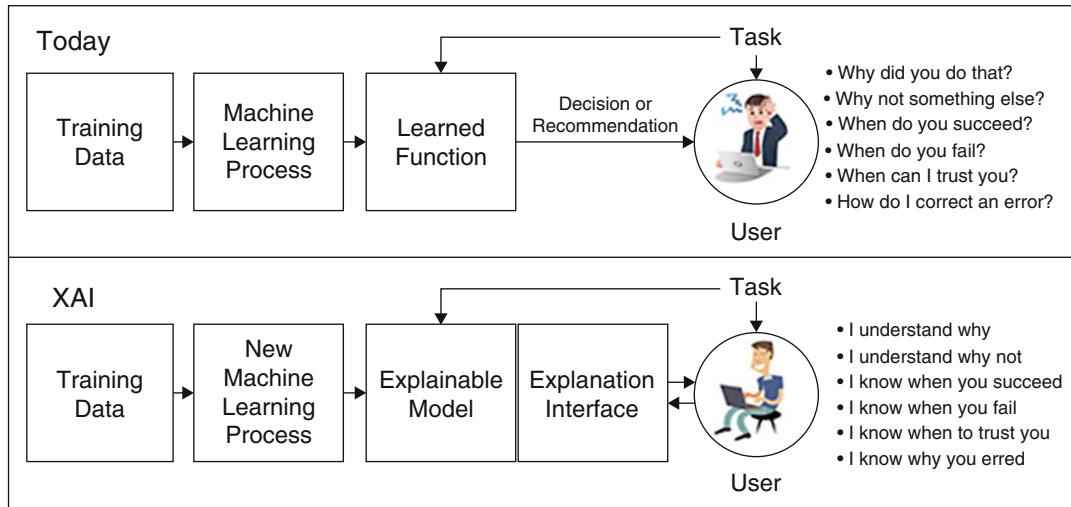

LMI is a cross-disciplinary research area that involves computer scientists, statisticians, and economists working together to make sense of labor market data for decision-making. In such a scenario, three distinct research directions can be identified for each area of interest, as discussed below.

K1: Making LMI Explainable. Explainable artificial intelligence (XAI) is an emerging branch of artificial intelligence aimed at investigating new machine learning models able to be completely explainable in contexts for which transparency is important, for instance, where these models are adopted to solve analysis (e.g., classification) or synthesis tasks (e.g., planning, design), as well as mission critical applications. DARPA recently launched the Explainable AI (XAI) program that aims to create a suite of AI systems able to explain their own behavior, focusing on ML and deep learning techniques. To date, indeed, most ML research models rarely provide explanations/justifications for the outcomes they offer in the tasks they are applied to. The need for explainable AI indeed is motivated mainly by the need for (i) trust, (ii) interaction, and (iii) transparency, as recently discussed in by Fox et al. (2017). This is also the reason behind the interest in XAI applications by academia and industrial communities (see, e.g., Biran and Cotton 2017; Ribeiro et al. 2016). Focusing on business contexts, as LMI is, autonomous decision-making can be framed as a set of economic problems that need to make evidence of the rationale behind the action suggested, so that the final decision can result believable to human decision-makers. Figure 3 would give a graphical overview of the main goal of XAI, that is, the development of AI-based systems able to explain their rationale, to characterize their strengths and weaknesses, as well as to convey an understand how they will behave in the future.

XAI in LMI. In the LMI field, indeed, ML-based approaches do not provide any explanations for their outcomes/predictions. This untransparent behavior may prevent the decision-

maker to consider reliable enough the analyses that have been computed, making the overall process ineffective. In essence, the use of XAI algorithms in LMI fits this challenging issue that DARPA identifies working on *machine learning problems to construct decision policies for an autonomous system to perform a variety of simulated missions* (DARPA 2017). Specifically, providing explanation of a job vacancy classifier would request to answer a question as *why a job vacancy J has been classified as financial manager rather than financial and insurance manager?*

To better understand what an explanation should be, Fig. 4 reports an example where the LIME tool proposed by Ribeiro et al. (2016) has been applied to retrieve the explanation of the example above, explaining a classifier that was previously trained on million English job vacancies. As one might note, the system provides the probabilities that lead the ML algorithm to classify the job vacancy on a given ISCO code. Furthermore, it also provides the contribution that each feature (here, word) has given to the classification process. We can observe that terms *finance* and *manager* positively contributed in classifying on financial manager (code 1211). Surprisingly, the system also reports that the term *finance* has a higher probability to classify a job vacancy on financial and insurance manager (code 1346), but the presence of term *manager* here contributed negatively in classifying on that code. Such a kind of result is quite useful for improving both transparency and interaction of ML systems in LMI applications. In essence, this real example sheds the light on what happens behind the scenes of a black-box classifier: Although the system correctly classifies the vacancy on the right code, the negative contribution that the term “*manager*” gives to the class with label 1346 is wrong and might have unpredictable effects on the classification in the future. On the other side, having such a kind of information would allow analyst to revise and refine the system, applying a sort of *explain and validate* approach to improve both the effectiveness and reliability of the machine learning-based system.

Big Data Enables Labor Market Intelligence, Fig. 3 Graphical overview of a XAI system (Taken from www.darpa.mil)

Big Data Enables Labor Market Intelligence, Fig. 4
An example of explanation for a ML-based system. ESCO codes are as follows. 1211,“financial manager”;

1346, “financial and insurance services branch managers”; 3313,“accounting associate professionals”; 2413, “financial analysts”

This, in turn, would allow final users to answer the following questions:

- Q1: Why did you classify J on that code?
- Q2: Which feature has lead you to classify J on code A rather than B?
- Q3: Which is the confidence score in your classification outcome?
- Q4: How robust your classification is to errors and changes in labor market?

Answering to these questions in a believable manner is a crucial step to make the decision-maker in state to *take reliable decisions and design effective policies* when the data is processed and managed by AI-based systems.

K2: Dealing with cross-language LMI. The problem of dealing with multilingual Web job

vacancy is growing in importance, mainly in the context of LMI for decision-making, where one of the main goal is to be able to share and compare labor market dynamics among different countries.

- Q1: How to compare labor market for different countries?
- Q2: How to deal with jargon and lexicon of different countries?
- Q3: How to deal with different labor market taxonomy of each country?

To this end, there is call by European Community in using the ESCO standard taxonomy that would provide a *lingua franca* to express occupations, skills, and qualifications over 28 official EU languages. Unfortunately, the use of ESCO does

not completely solve the issue related to multi-language job vacancies, as a *training/test set* has still to be created for each language. To cope with this issue, the community working on LMI is working on two distinct directions:

- Build a classifier for a text classification task in some target language T , given labeled training tests for the same task in a different source language S . Clearly, a function that maps word correspondence between languages T and S is required. This procedure is called *cross-language text classification*; see, e.g., Shi et al. (2010), Bel et al. (2003), and Olsson et al. (2005);
- Use unlabeled data from both languages and a word translation map to *induce* cross-lingual word correspondences. In this way, a cross-lingual representation is created enabling the transfer of classification knowledge from the source to the target language, aka *cross-language structural correspondence learning*; see, e.g., Prettenhofer and Stein (2011).

K3: Representativeness of Web Labor Market Information.

A key issue related to the use of Big Data for decision-making relies on their ability of being representative of the whole population. Indeed, while on one side labor market surveys can be designed for being representative of a certain population (sectors/occupations etc.), on the other side, representativeness of web data might not be evaluated easily, and this affects the reliability of statistics and analytics derived from it. This issue also affects the labor market intelligence field (e.g., some occupations, and sectors are not present in web advertisements). To cope with this issue, the question has been rephrased to assess whether a set of online job vacancies is a representative sample of *all* job vacancies *in a specified economic context*. Indeed, even though it should be considered finite, the population of job vacancies continuously changes, and this makes difficult to exactly determine it in stable manner. Indeed, jobs and people are usually reallocated in the labor market and in firms, respectively; tasks are split, restructured,

or partially switched, and recruitment strategies might have sectoral and occupational specificities (see, e.g., Gosling et al. 2004; Mang 2012). From a statistical perspective, samples of available Web vacancies are prone to problems of self-selection and/or non-ignorable missing mechanism (Little and Rubin 2014).

In such a scenario, several approaches have been taken by different authors in attempting to deal with representativeness issues related to the usage of online job vacancy data for analytical and policy-making purposes. Among others, a number of studies decided to focus on the segment of the labor market characterized by widespread access to the Internet (e.g., ICT) in the belief that they would be relatively well represented among the job applicants due to characteristics of Internet users and would therefore offer a representative data sample (Anne Kennan et al. 2006; Wade and Parent 2002). Notice that this approach has been considered as valid by EU commission and that in 2016 invited to contribute to a call-for-tender aimed at *obtaining data on job vacancies for ICT practitioners and other professional categories gathered by crawling job advertisements published in relevant online job advertisement outlets* (European Commission 2016b).

Recently, some researchers considered online data generalizable due to the dominant market share and very high reputation of the chosen portal among employers and employees (Kureková et al. 2012).

Nonetheless, the problem related to representativeness of Big Data concerning LMI data – that is important for including them in official statistics and data analytics – still remains an open issue.

Concluding Remarks

LMI is an emerging and cross-disciplinary field of study that draws competences from different disciplines, such as of computer science, statistics, and economics in order to make sense of Big Data in the labor market field. Though the rationale behind LMI is the *use* of labor market

data, the final goal that guides LMI activities may vary as the purpose of the users varies. Private companies aim at supporting the HR in recruitment activities, while analysts and public organizations would use LMI for studying the labor market dynamics and for designing more effective policies following a data-driven approach. In any case, all the approaches mentioned strictly rely on the KDD approach as baseline and massively employ AI algorithms for classifying occupations/resumes and extract occupations and skills. As for the AI in general, in the early future, the research on LMI will overcome some limitations that might prevent a steady use of Big Data in the LMI field, as the ability to *explain* and motivate to decision-makers how AI works behind the hood; the ability to deal with multiple languages, lexicon, and idioms with a limited effort; and the ability to be representative – or at least statistically relevant – of the whole population observed. These are the research directions identified by top players on LMI – mainly EU and US governments – for allowing Big Data to enable labor market intelligence.

Big Data for Cybersecurity

Definitions

Cybersecurity deals with the protection of computer systems; information and communication technology (ICT) networks, such as enterprise

networks, cyber-physical systems (CPS), and the Internet of Things (IoT); and their components, against threats that aim at harming, disabling, and destroying their software and hardware.

Overview

In the beginning of the Digital Revolution, the primary goal of computer hackers that attack ICT infrastructures and networks was just to receive recognition from like-minded people. Thus, the consequences have been mostly downtimes and the often costly need of recovering and cleaning up compromised systems. Therefore, the consequences were manageable with rather little effort. In the meantime, the ICT networks' relevance massively increased, and they became the vital backbone of economic as well as daily life. Since their importance and complexity continuously evolve, also cyberattacks against them become more complex and diverse and consequently difficult to detect. Today's modern attacks usually target on stealing intellectual properties, sabotaging systems, and demanding ransom money. Sophisticated and tailored attacks are called advanced persistent threats (APT) (Tankard 2011) and usually result in high financial loss and tarnished reputation.

Since usually the protection against sophisticated cyberattacks is difficult and highly challenging, (i) timely detection to limit the caused damage to a minimum, which can be achieved by applying smart *intrusion detection systems (IDS)*, and (ii) preventive actions, such as raising situational awareness, through analyzing and sharing *cyber threat intelligence (CTI)*, are of primary importance. Because of the continuously growing interconnection of digital devices, the amount of generated data and new malware samples per day grows with an exorbitant speed. Moreover, particular types of malware, such as worms, rapidly evolve over time and spread over the network in unpredictable ways (Dainotti et al. 2007; Kim et al. 2004). Thus, it gets more and more difficult to analyze all generated data that might include hints on cyberattacks and malicious system behavior. This is the reason why cybersecurity be-

came a *big data problem*. According to the four Vs feature of big data (Chen et al. 2014), big data is defined by (i) volume (large amount of data), (ii) variety (heterogeneous and manifold data), (iii) velocity (rapidly generated data that has to be analyzed online, i.e., when the data is generated), and (iv) value (extraction of huge value from a large amount of data).

This section deals with the two main research areas of cybersecurity that are related to big data: (i) intrusion detection, which deals with revealing cyberattacks from network traces and log data, and (ii) CTI analysis and sharing, which supports incident response and decision-making processes. Therefore, the section first splits into two main parts, which are structured the same way. Both first answer the question why the considered topic is a big data problem and then summarize the state of the art. Finally, future directions for the research of big data for cybersecurity are presented. Thus, it is also discussed how intrusion detection and CTI analysis and sharing can benefit from each other.

Intrusion Detection

Countermeasures and defense mechanisms against cyberattacks split into tools that aim at timely detection of attack traces and tools that try to prevent attacks or deploy countermeasures in time. Technical preventive security solutions are, for example, firewalls, antivirus scanners and digital rights, account management, and network segmentation. Tools that aim at detecting cyberattacks and therefore only monitor a network are called intrusion detection systems (IDS). Currently applied IDS mostly implement signature-based black-listing approaches. Black-listing approaches prohibit system behavior and activities that are defined malicious. Hence, those solutions can only detect already known attack patterns. Nevertheless these established tools build the vital backbone of an effective security architecture and ensure prevention and detection of the majority of threats. Nevertheless, the wide range of application possibilities of modern devices and the fast changing threat landscape

demand smart, flexible, and adaptive white-listing-based intrusion detection approaches, such as self-learning anomaly-based IDS. In contrast to black-listing approaches, white-listing approaches permit a baseline of normal system behavior and consider every deviation of this ground truth as malicious activity. Thus, it is possible to detect previously unknown attacks.

Intrusion Detection: A Big Data Problem

Because of the rapidly growing number of interconnected digital devices, also the amount of generated data increases. Thus, the *volume* of data that potentially can be analyzed for intrusion detection is enormous. Hence, approaches are required that can analyze and also correlate a huge load of data points. Furthermore, there is a wide *variety* of data types available for intrusion detection. The spectrum ranges from binary files over network traffic to log data, just to name a few. Additionally the representation of this data differs depending on the applied technologies, implementations, and used services, as well as operating systems, why analysis of data created in an ICT network comprising various different types of devices is not straightforward. Furthermore, the data is generated quickly, and the *velocity* is increasing with the number of connected devices. Thus, to provide online intrusion detection, i.e., the data is analyzed when it is generated, which ensures timely detection of attacks and intruders, big data approaches are required that can process rapidly large amounts of data. Since most of the generated data relates to normal system behavior and network communication, it is important to efficiently filter the noise, so only relevant data points that include information of high *value* for intrusion detection remain.

Intrusion Detection: Methods and Techniques

Like other security tools, IDS aim to achieve a higher level of security in ICT networks. Their primary goal is to timely detect cyberattacks, so that it is possible to react quickly and therefore reduce the window of opportunity of the attacker to cause damage. IDS are passive security mechanisms, which only detect attacks without

setting any counter measurements automatically (Whitman and Mattord 2012).

In 1980, James Anderson was one of the first researchers who indicated the need of IDS and contradicted the common assumption of software developers and administrators that their computer systems are running in “friendly,” i.e., secure, environments (James P Anderson 1980). Since the 1980s, the amount of data generated in ICT networks tremendously increased, and intrusion detection therefore became a big data problem. Furthermore, since Anderson published his report on IDS, a lot of research in this area has been done until today (Axelsson 2000; Sabahi and Movaghfar 2008; Liao et al. 2013; Garcia-Teodoro et al. 2009).

IDS can be roughly categorized as host-based IDS (HIDS), network-based IDS (NIDS), and hybrid or cross-layer IDS that make use of both data collected on hosts and monitored network traffic (Vacca 2013; Sabahi and Movaghfar 2008). There exist generally three methods that are used in IDS: (i) signature-based detection (SD), (ii) stateful protocol analysis (SPA), and (iii) anomaly-based detection (AD) (Liao et al. 2013).

- **SD (knowledge based)** uses predefined signatures and patterns to detect attackers. This method is simple and effective for detecting known attacks. The drawback of this method is it is ineffective against unknown attacks or unknown variants of an attack, which allows attackers to evade IDS based on SD. Furthermore, since the attack landscape is rapidly changing, it is difficult to keep the signatures up to date, and thus maintenance is time-consuming (Whitman and Mattord 2012).
- **SPA (specification based)** uses predetermined profiles that define benign protocol activity. Occurring events are compared against these profiles, to decide if protocols are used in the correct way. IDS based on SPA track the state of network, transport, and application protocols. They use vendor-developed profiles and therefore rely on their support (Scarfone and Mell 2007).

- **AD (behavior based)** approaches learn a baseline of normal system behavior, a so-called ground truth. Against this ground truth, all occurring events are compared to detect anomalous system behavior. In opposite to SD- and SPA-based IDS, AD-based approaches allow detection of previously unknown attacks. A drawback of AD-based IDS is the usually high false-positive rate (Garcia-Teodoro et al. 2009; Chandola et al. 2009).

Modern sophisticated and tailored attacks, such as APTs, where attackers try to hide their presence as long as possible and therefore try to circumvent detection by signatures and blacklists and respect benign protocol activity, require flexible approaches that provide broader security. A solution to that are white-listing approaches that make use of a known baseline of normal system/network behavior. Furthermore, it is impossible to define a complete set of signatures, because during normal usage, a network reaches only a small number of possible states, while the larger number remains unknown. Thus, while in case of white-listing, an incomplete baseline of normal system/network behavior would cause a larger number of false alarms, i.e., a bigger number of alarms that have to be further analyzed, and an incomplete blacklist leads to false negatives, i.e., undetected attacks. Thus, flexible AD approaches are required that are able to detect novel and previously unknown attacks. While SD and SPA solutions are usually easier to deploy than AD, they depend on the support of vendors. Hence, they mostly cannot be applied in legacy systems and systems with small market shares, which are often poorly documented and not supported by vendors, but often used in industry networks, such as industrial control systems and IoT.

The rapidly changing cyber threat landscape demands flexible and self-adaptive IDS approaches. Since networks grow fast and therefore also the amount of generated data, this task requires machine learning-based big data approaches that implement self-learning

AD-based IDS. These self-learning solutions usually learn during a training phase, or after they are deployed, a baseline of normal system/network behavior that then serves as ground truth to detect anomalies that expose attacks and especially invaders. Generally, there are three ways how self-learning AD can be realized (Goldstein and Uchida 2016):

1. **Unsupervised:** This method does not require any labeled data and is able to learn to distinguish normal from malicious system behavior while it is deployed without any training. It classifies any monitored data as normal or anomalous.
2. **Semi-supervised:** This method is applied when the training set only contains anomaly-free data and is therefore also called “one-class” classification.
3. **Supervised:** This method requires a fully labeled training set containing both normal and malicious data.

These three methods do not require active human intervention during the learning process. While unsupervised self-learning is entirely independent from human influence, for the other two methods, the user has to ensure that the training data is anomaly-free or correctly labeled. To implement self-learning AD, there are many machine learning algorithms (Witten et al. 2016) that can be applied for that big data task. Methods that are used for machine learning in cybersecurity are, for example (Buczak and Guven 2016):

- **Artificial neural networks (ANN):** Input data activates neurons (nodes) of an artificial network, inspired by the human brain. The nodes of the first layer pass their output to the nodes of the next layer, until the output of the last layer of the artificial network classifies the monitored ICT networks’ current state (Cannady 1998).
- **Bayesian networks:** Bayesian networks define graphical models that encode the probabilistic relationships between variables of interest and can predict consequences of

actions (Heckerman et al. 1998).

- **Clustering:** Clustering enables grouping of unlabeled data and is often applied to detect outliers (Xu and Wunsch 2005).
- **Decision trees:** Decision trees have a treelike structure, which comprises paths that lead to a classification based on the values of different features (Safavian and Landgrebe 1991).
- **Hidden Markov models (HMM):** A Markov chain connects states through transition probabilities. HMM aim at determining hidden (unobservable) parameters from observed parameters (Baum and Eagon 1967).
- **Support vector machines (SVM):** SVM construct hyperplanes in a high- or infinite-dimensional space, which then can be used for classification and regression. Thus, similar to clustering, SVM can, for example, be applied for outlier detection (Steinwart and Christmann 2008).

Cyber Threat Intelligence

The concepts of *data*, *information*, and *intelligence* differ from one another in terms of volume and usability. While data is typically available in large volumes, and describes individual and unarguable facts, information is produced when a series of data points are combined to answer a simple question. Although information is a far more useful output than the raw data, it still does not directly inform a specific action. Intelligence takes this process a stage further by interrogating data and information to tell a story (e.g., a forecast) that can be used to inform decision-making. Crucially, intelligence never answers a simple question; rather, it paints a picture that can be used to help people answer much more complicated questions. Progressing along the path from data to information to intelligence, the quantity of outputs drops off dramatically, while the value of those outputs rises exponentially (Chairman of the Joint Chiefs of Staff 2013).

Modern cybersecurity incidents manifest themselves in different forms depending on the attack perpetrators' goal, on the sophistication of the employed attack vectors, and on the

information system the attack targets. Large amounts of data are to be analyzed while handling such incidents in order to derive meaningful information on the relations existing among the collected data units, and eventually obtain cyber threat intelligence (CTI), with the purpose of designing suitable reaction strategies and timely mitigate the incident's effects.

CTI: A Big Data Problem

Hundreds of thousands of new malware samples are created every day. Considering the large amount of vulnerabilities and exploits revealed at a similar rate, there exists a large *volume* of data comprising information on cyber threats and attacks that can be analyzed to improve incident response, to facilitate the decision-making process, and to allow an effective and efficient configuration of cybersecurity mechanisms. Furthermore, the *variety* of the data is manifold. There exist, for example, many different standards describing vulnerabilities, threats, and incidents that follow different structures, as well as threat reports and fixes written in free text form. Because of the large amount of data on cyberattacks generated daily, the data that can be analyzed to derive intelligence is created with a high *velocity* and should be processed as fast as possible. Since large parts of the data are just available as free text and computer networks show a high diversity among each other, it is of prime importance to select and extract the information with the highest *value*.

From Raw Data to Cyber Threat Intelligence

Threat information may originate from a wide variety of internal and external data sources. Internal sources include security sensors (e.g., intrusion detection systems, antivirus scanners, malware scanners), logging data (from hosts, servers, and network equipment such as firewalls), tools (e.g., network diagnostics, forensics toolkits, vulnerability scanners), security management solutions (security information and event management systems (SIEMs), incident management ticketing systems), and additionally also personnel, who reports suspicious behavior,

social engineering attempts, and the like. Typical external sources (meaning external to an organization) may include sharing communities (open public or closed ones), governmental sources (such as national CERTs or national cybersecurity centers), sector peers and business partners (for instance, via sector-specific information sharing and analysis centers (ISACs)), vendor alerts and advisories, and commercial threat intelligence services.

Stemming from this variety of sources, it becomes evident that cyber threat intelligence can be (preferably automatically) extracted from numerous technical artifacts that are produced during regular IT operations in organizations:

- **Operating system** services application logs and provides insights into deviations from normal operations within the organizational boundaries.
- **Router, Wi-Fi, and remote services logs** provide insights into failed login attempts and potentially malicious scanning actions.
- **System and application configuration settings and states**, often at least partly reflected by configuration management databases (CMDBs), help to identify weak spots due to not required but running services, weak account credentials, or wrong patch levels.
- **Firewall, IDS, and antivirus logs and alerts** point to probable causes, however, often with high false-positive rates that need to be verified.
- **Web browser histories, cookies, and caches** are viable resources for forensic actions after something happened, to discover the root cause of a problem (e.g., the initial drive-by download).
- **Security information and event management systems (SIEMs)** already provide correlated insights across machines and systems.
- **E-mail histories** are essential sources to learn about and eventually counter (spear) phishing attempts and followed links to malicious sites.
- **Help desk ticketing systems, incident management/tracking systems, and people** provide insights into any suspicious events and

actions reported by humans rather than software sensors.

- **Forensic toolkits and sandboxing** are vital means to safely analyze the behavior of untrusted programs without exposing a real corporate environment to any threat.

B

There are multiple types of potentially useful information obtained from the data sources mentioned before for security defense purposes. Every type has its own characteristics regarding the objective (e.g., to facilitate detection, to support prosecution, etc.), applicability, criticality, and “shareability” (i.e., the effort required to make an artifact shareable because of steps required to extract, validate, formulate, and anonymize some piece of information). Depending on their content, cyber threat information can be grouped into the categories defined by NIST (2016) and OASIS (2017) and described below:

- **Indicators:** are technical artifacts or observables that suggest an attack is imminent or is currently underway or that a compromise may have already occurred. Examples are IP addresses, domain names, file names and sizes, process names, hashes of file contents and process memory dumps, service names, and altered configuration parameters.
- **Tactics, techniques, and procedures (TTPs):** characterize the behavior of an actor. A tactic is the highest-level description of this behavior, while techniques give a more detailed description of behavior in the context of a tactic, and procedures are an even lower-level, highly detailed description in the context of a technique. Some typical examples include the usage of spear phishing emails, social engineering techniques, websites for drive-by attacks, exploitation of operating systems and/or application vulnerabilities, the intentional distribution of manipulated USB sticks, and various obfuscation techniques. From these TTPs, organizations are able to learn how malicious attackers work and derive higher-level and generally valid detection, as well as remediation techniques, compared to

- quite specific measures based on just, often temporarily valid, indicators.
- **Threat actors:** contain information regarding the individual or a group posing a threat. For example, information may include the affiliation (such as a hacker collective or a nation-state's secret service), identity, motivation, relationships to other threat actors, and even their capabilities (via links to TTPs). This information is being used to better understand why a system might be attacked and work out more targeted and effective countermeasures. Furthermore, this type of information can be applied to collect evidences of an attack to be used in court.
 - **Vulnerabilities:** are software flaws that can be used by a threat actor to gain access to a system or network. Vulnerability information may include its potential impact, technical details, its exploitability, and the availability of an exploit, affected systems, platforms, and version, as well as mitigation strategies. A common schema to rate the seriousness of a vulnerability is the common vulnerability scoring schema (CVSS) (Scarfone and Mell 2009), which considers the enumerated details to derive a comparable metric. There are numerous web platforms that maintain lists of vulnerabilities, such as the common vulnerability and exposure (CVE) database from MITRE (<https://cve.mitre.org/>) and the national vulnerability database (NVD) (<https://nvd.nist.gov/>). It is important to notice that the impact of vulnerabilities usually needs to be interpreted for each organization (and even each system), individually, depending on the criticality of the affected systems for the main business processes.
 - **Cybersecurity best practices:** include commonly used cybersecurity methods that have demonstrated effectiveness in addressing classes of cyber threats. Some examples are response actions (e.g., patch, configuration change), recovery operations, detection strategies, and protective measures. National authorities, CERTs, and large industries frequently publish best practices to help organizations building up an effective cyber defense and rely on proven plans and measures.
 - **Courses of actions (CoAs):** are recommended actions that help to reduce the impact of a threat. In contrast to best practices, CoAs are very specific and shaped to a particular cyber issue. Usually CoAs span the whole incident response cycle starting with detection (e.g., add or modify an IDS signature), containment (e.g., block network traffic to command and control server), recovery (e.g., restore base system image), and protection from similar events in the future (e.g., implement multifactor authentication).
 - **Tools and analysis techniques:** this category is closely related to best practices, however focuses more on tools rather than procedures. Within a community it is desirable to align used tools to each other to increase compatibility, which makes it easier to import/export certain types of data (e.g., IDS rules). Usually there are sets of recommended tools (e.g., log extraction/parsing/analysis, editor), useful tool configurations (e.g., capture filter for network protocol analyzer), signatures (e.g., custom or tuned signatures), extensions (e.g., connectors or modules), code (e.g., algorithms, analysis libraries), and visualization techniques.
- Interpreting, contextualizing, and correlating information from different categories allow the comprehension of the current security situation and provide therefore threat intelligence (Skopik 2017). Independently from the type, there are common desired characteristics to make cyber threat intelligence applicable. Specifically, CTI should be obtained *timely*, to allow security operation centers to promptly act; it should be *relevant* in order to be applicable to the pertaining operational environment; it should be *accurate* (i.e., correct, complete, and unambiguous) and *specific*, providing sufficient level of detail and context; finally, CTI is required to be *actionable* to provide or suggest effective course of action.

Future Directions for Research

The following section discusses the future directions for research in the fields of intrusion detection and CTI, as well as how both might profit from each other. In the field of intrusion detection, already a lot of research and development have been done in the direction of signature-based IDS, with focus on black-listing. But today's evolving interconnection and the associated dependence on digital devices are the reason for sophisticated and tailored attacks, carried out by smart attackers who flexibly adjust their behavior according to the circumstances they face and therefore cannot be revealed and stopped by signature-based IDS and black-listing approaches which are only capable of revealing known attack vectors. Thus, the future research direction in cybersecurity related to big data tends toward anomaly-based intrusion detection and white-listing. The main challenges here will be reducing a usually high number of false positives that create a great effort for security analysts. Additionally, because networks grow fast and hardware devices and software versions change quickly, smart self-learning algorithms are required so that IDS can adapt themselves to new situations, without learning malicious system/network behavior and to keep the effort that has to be invested for configuration to a minimum.

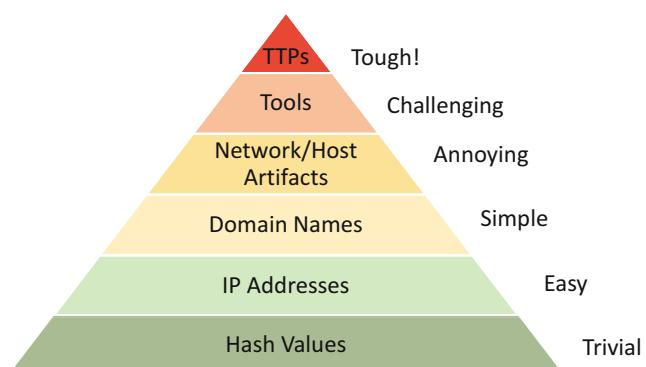

One solution to the aforementioned problems can be CTI. There exists already a considerable amount of research on how findings and observables, also from IDS outputs, can be combined

to provide insights into cybersecurity threats and attacks to finally correlate those information to gain CTI (Skopik 2017). However, since anomalies are just data without any context, and therefore do not carry any intrinsic information, the detected anomalies have to be interpreted first. To fulfill this task properly and timely, intrusion detection should be enriched with existing CTI. Thus, sharing acquired knowledge is mandatory. The “pyramid of pain” (Bianco 2014), shown in Fig. 1, demonstrates how much effort is required to acquire certain information, starting from a contextless anomaly. The goal is that stakeholders who demand a high level of security for their network infrastructures and are also able to afford the resources to analyze the large number of alerts generated by AD-based IDS solutions use their acquired knowledge to define signatures. These signatures, i.e., shareable and timely intelligence, can then be shared with further organizations on a broad basis. Hence, industry players beyond specialized security solution providers should be included in the threat intelligence creation to enable a faster reaction against new threats across whole industry sectors.

Finally, to reduce the effort of dealing with the large and quickly evolving amounts of data concerning cybersecurity, novel smart big data approaches will be required that make use of collected CTI to support and steer the configuration and deployment of cybersecurity tools, and to automatize as many tasks as possible, since the amount of generated data and the number of cyber threats and attacks keep continuously growing.

[Healthcare](#); [Well-being](#)

Definitions

Health is a state in which a person is not suffering from any illness and is feeling well. *Healthcare* refers to the various services for the prevention or treatment of illness and injuries on a comprehensive, ongoing basis. Leveraging the potential of ICTs and big data allows for addressing raising issues in the health sector, providing novel technological solutions for healthcare.

Overview

Healthcare is among the most important social and economic challenges that every country faces. Indeed, constant population growth influences healthcare demand, requiring more advanced scientific solutions to address raising issues. In fact, the growing cost of medical care impacts quality of life, and this issue is exacerbated in the case of chronic diseases. Today, clinicians, administrators, as well as researchers experience more and more pressure due to the growing expectations from both the private and the public sector. Leveraging big data paves the way to unprecedented opportunities for both reducing costs and improving quality of healthcare services (Murdoch and Detsky 2013).

Understanding the progress of information and communication technologies (ICTs) is crucial to be properly aware of the potential of big data in the health sector, as ICTs have allowed to improve access, efficiency, quality, and effectiveness of healthcare-related processes. At the beginning of the 1990s, the *e-health* concept was coined, broadly defining the application of ITCs – above all, the Internet – to the health sector. It has come in common use and has been subjected to both great public interest and unprecedented levels of research effort and investments, thus allowing e-health services to benefit from the uninterrupted development of novel technological solutions. As a result, over the years the specific characterization of the e-health concept has progressively evolved and specialized, according to the widespread range of opportunities raised by the evolution of the ICTs.

The advancements in broadband communications, the unprecedented spread of wireless and mobile communication technologies, as well as the raise of *mobile apps* allowed to implement the *anywhere-and-anytime* connectivity vision, which has become a solid reality for a growing number of scenarios. These technology advancements, together with mass market demand, led to the spread of *low-cost sensing devices*, suitable for a number of different goals. Such availability of computing resources at lower costs and higher integration scale fueled the *Internet of Things* paradigm, implementing the interconnection of uniquely identifiable smart objects and devices with advanced connectivity. The circumstances above also allowed huge-scale datacenters to be deployed all over the globe and accessible to the general public through the *cloud computing paradigm*.

The success of each of the technologies and paradigms mentioned above is utmost for supporting novel healthcare applications and services. Indeed, their fruitful mixture is reshaping modern healthcare, not only with technological prospects but also with promising economic and social ones: opportunities for gathering health-related big data from a growing number of sources are provided, together with continuous advancements in technological solutions for manipulating and capitalizing it.

Coherently, the scientific literature also highlights non-negligible changes in how the concept of e-health itself is intended. Indeed, riding the wave of the technological progress, a number of healthcare-related paradigms have been introduced emphasizing the beneficial impact of big data. *Mobile health*, *smart health*, and *personalized health* are compelling examples (Silva et al. 2015; Holzinger et al. 2015; Suzuki et al. 2013; Cowie et al. 2015; Viceconti et al. 2015; Omanović-Mikličanin et al. 2015). These paradigms are commonly referred to in the scientific literature and witness how big data play a primary role in the health sector:

- Mobile health, generally aiming at delivering healthcare services regardless of any mobility

- constraints, has found fundamental pillars in smartphones and mobile apps, these tools being able to gather and deliver different kinds of information (e.g., streams of physiological signs monitoring results or public health information);
- Smart health integrates ideas from ubiquitous computing and ambient intelligence, where related processes generate large amounts of data being collected over a network under daily life and that is potentially valuable to monitor, predict, and improve patients' physical and mental conditions;
 - Personalized health, sometimes referred to as *adaptive health*, is *user-centric*, i.e., it targets to take patient-specific decisions, rather than stratifying patients into typical treatment groups.

The remainder of the entry is composed of three main parts discussing, respectively:

- the main sources and types of information that compose the health-related big data scenario;
- the most significant use cases and applications of big data in the health domain;
- the related opportunities and raising issues.

Characterization of Health-Related Big Data

Larger amounts of data are becoming available to organizations (working at global, national, regional level) both gathered from novel applications (e.g., health and wellness monitoring ones) and obtained by applying analysis techniques on already existing – but not fully capitalized yet – information (e.g., clinical reports). Worldwide digital healthcare data was estimated to be equal to 500 petabytes in 2012 and is expected to reach 25,000 petabytes in 2020 (Cyganek et al. 2016; Sun and Reddy 2013). Being aware of the sources as well as types and characteristics of this data is fundamental for understanding the applications that rely on it as well as the unclosed opportunities.

Healthcare-related big data can come from both *sources internal to the organization* (such as health records and clinical decision support systems) and *sources external to the organizations* (such as government sources, laboratories, pharmacies, insurance companies, and health maintenance organizations).

Two primary types of health-related big data can be identified: *structured data*, which refer to those with defined data model (e.g., clinical databases), and *unstructured data*, with no defined schema or explicit semantics (e.g., natural language text as in doctor prescriptions). The latter require specialized analytical methods to extract the contained information and to transform it into computable form. However, it is worth noting that this categorization has not to be intended as absolute: for instance, structured databases may contain unstructured information in practice (e.g., free-text fields) and unstructured data may in fact have some structure (e.g., metadata associated with an image or markup embedded in a document).

Up to 80% of healthcare data has been estimated to consist of rich unstructured data either only partially exploited or not leveraged at all. Only the remaining 20% is estimated to reside in automated systems, such as hospital, radiology, and laboratory information systems (Fernandes et al. 2012). Accordingly, technological solutions to either automatically interpret such resources or assist people tasked with interpreting these data sources are critical, as allowing to scale up the analysis and consider a much broader set of data.

The main sources of the health-related information today available can be identified in:

- clinical data;
- medical and clinical references and publications;
- *omics* data;
- streamed data;
- social networking and web data;
- business, organizational, and external data.

Each of the categories above is briefly discussed in the following.

Clinical Data

Clinical information about individual patients, such as results of the medical tests, images, descriptions from clinicians, and prescriptions, are collected through records that may assume several forms and denominations. As witnessed by the scientific literature, the most popular ones are (Garets and Davis 2006; Smolij and Dun 2006):

- *Electronic health records* (EHR);
- *Electronic medical records* (EMR);
- *Personal health records* (PHR).

EHRs – according to the ISO 20514 standard definition – are repositories of information about the health status of a subject of care. More specifically, they are *longitudinal* electronic records of patient health information, reporting episodes of care *across multiple care delivery organizations* within a community, region, or state.

EMRs are real-time patient health records with access to evidence-based decision support tools, possibly used to aid clinicians in decision-making. EMRs are used by healthcare practitioners to document, monitor, and manage healthcare delivery *within a care delivery organization*.

PHRs are layperson-comprehensible, lifelong tools for managing relevant health information, promoting health maintenance and assisting with chronic disease management. They are directly managed by the citizens (or by their legal proxy) and may be subjected to various legal limitations.

Because of the complex, heterogeneous, fast-growing nature of these possibly unstructured data representations, they should be considered as one of the most complex data objects in the information processing industry (Cyganek et al. 2016). In addition, text, images (encompassing a huge spectrum of methodologies to be acquired), audio, and video streams are also commonly produced in clinical context and therefore require the development of specific strategies for the extraction and the summarization of the information they contain (Martin-Sánchez and Verspoor 2014).

Medical and Clinical References and Publications

Although structured resources are increasingly available, the scientific literature often represents the main source of data (e.g., for studies in biomedicine), to the extent that the published biomedical literature can be considered as the primary repository of biomedical knowledge (Martin-Sánchez and Verspoor 2014).

Given the growth of the literature, processes requiring manual effort to extract and organize the information do not scale and are therefore unsustainable. Accordingly, different entities have devoted themselves to developing text mining web tools for indexing and cataloging of biomedical information, as well as helping users quickly and efficiently search and retrieve relevant publications (Lu 2011). In addition, current practices often require available data to be compared against clinical reference data developed by private organizations and public institutions.

Omics Data

Large amounts of biological data in various forms (e.g., genomics, microbiomics, proteomics, metabolomics, epigenomics, transcriptomics, etc.) are today generated and collected at an unprecedented speed and scale (Chen and Snyder 2013). Indeed, new-generation high-throughput sequencing technologies enable the processing of billions of DNA or RNA sequences per day (Mardis 2011).

The cost of acquiring and analyzing this biomedical data is dramatically decreasing with the help of technology upgrades and the development of novel hardware and software for parallel computing. Moreover, the rapid development and the integration of high-throughput technologies – which have significantly improved the way of looking at cells, tissues, and organisms in physiological and pathological conditions – and computational frameworks enable to examine biological systems at unprecedented level of detail, for instance, making large population-scale projects feasible (Schmidt and Hildebrandt 2017). Integrating the vast amount of often complementary data produced

by the different NGS applications allows to gain more significant biological insights toward a complete understanding of the mechanisms driving gene expression changes in human genetic pathologies, rather than limiting to the interpretation of single data sets (Costa et al. 2013).

Streamed Data

Personal devices – mainly in the form of smartphones – have significantly penetrated into society in a relatively short period of time. In addition, the progress in wireless sensors, mobile communication technology, and stream processing enable to design and implement body area networks (BANs) consisting of intelligent devices (e.g., low-power, miniaturized, non-invasive, and lightweight wireless sensors, attached on or implanted in the body) able to monitor either the human body functions or the surrounding environment. These devices allow to monitor people's health status in real time, generating large amounts of data (Chen et al. 2014; Ullah et al. 2012).

Thanks to the above enablers, large amounts of heterogeneous medical information have become available in healthcare organizations, since smart and connected healthcare devices are increasingly adopted and contribute to generating streams of structured and unstructured data.

Social Networking and Web Data

Social media technologies are significantly changing the practice of medicine: social media sources, such as online discussion forums, social networking sites and feeds, as well as more general web resources (e.g., blogs and even search query logs), are proving to be valuable information resources (Waxer et al. 2013). In more details, according to recent surveys, social media are reshaping the nature of health-related interactions, changing the way healthcare practitioners review medical records and share medical information.

In addition, social network perspective provides a set of methods for analyzing the structure of social entities as well as a variety of theories to explain these structures, whose study

may lead to identify local and global patterns, locate influential entities, and examine network dynamics (Wasserman and Faust 1994).

Business, Organizational, and External Data

Other data, not strictly related to health, such as administrative, billing, and scheduling information, further enrich the list of potential sources, allowing to implement studies that encompass not exclusively medical aspects.

Herland et al. in their review identified four distinct levels to categorize health data (Herland et al. 2014):

1. *molecular-level data* (e.g., used in bioinformatics);
2. *tissue-level data* (e.g., used in neuroinformatics);
3. *patient-level data* (e.g., used in clinical informatics);
4. *population data* (e.g., used in public health informatics).

According to the proposed review, each study may leverage data from one or more levels to answer questions that can be clustered according to their nature in different groups, such as human-scale biology, clinical, or epidemic scale.

In the light of the overall characterization provided in this section – more specifically, due to its volume, velocity, and variety – the data available in the healthcare field satisfies the commonly agreed requirements to be qualified as big data (Raghupathi and Raghupathi 2014). Newer forms of data (e.g., imaging, omics, and biometric sensors readings) are fueling the growth of the volume of health-related data; the *velocity* of gathered data has increased with regular monitoring processes (e.g., blood pressure readings, electrocardiograms, and glucose measurements); the *variety* of structured and unstructured data is evident, emphasizing the challenging aspects.

To be in line with a fourth characteristic introduced by some big data practitioners (i.e., *veracity*), big data, analytics, and outcomes have to be error-free. Finally, enormous *value* is envisioned in the predictive power of big data, due

to recent results in fields such as public health, science, and medicine where the combination of omics and clinical data is expected to fuel precision and personalized medicine understanding the mechanisms of diseases and accelerating the individualization of medical treatments (Costa 2014)

Main Applications of Big Data in the Health Sector

According to [Murdoch and Detsky](#), big data may advance the mission of healthcare delivery in four different ways (Murdoch and Detsky 2013):

- expanding the capacity to generate new knowledge;
- helping with knowledge dissemination;
- translating personalized medicine initiatives into clinical practice;
- allowing for a transformation of health care by delivering information directly to patients.

In more general terms, advances in big data analytics help naturally transform research questions from being *descriptive* (e.g., *what has happened?*) to *predictive* (e.g., *what could happen?*) and *prescriptive* (e.g., *what should we do then?*) (Chang and Choi 2016). For instance, big data analytics in healthcare can contribute to evidence-based medicine, genomic analysis, pre-adjudication fraud analysis, device remote monitoring, and patient profile analyses.

As research advances, the scientific literature witnesses how big data science is able to improve quality, efficacy, as well as efficiency of healthcare services. In the following, a number of examples are reported, organized in the categories reported below:

- genomics;
- clinical decision support;
- personalized medicine;
- health and wellness monitoring;
- medical image processing.

Genomics

Analytics related to omics sequencing techniques is an inherently big data problem: for instance, sequencing procedures produces millions and billions of reads, omics data are highly diverse, while human genome consists of 21,000 protein-coding genes (Lander 2011).

The availability of these advanced tools has enabled researchers to study genetic markers over a wide range of population and to investigate genetic causes of physiological and pathological phenotypes, investigating cell/tissue/organism identities and molecular mechanisms of human diseases, also reducing the timescale of related analyses and improving reliability. Indeed, high-throughput sequencing technologies allow to improve process efficiency by more than five orders of magnitude since sequencing of the human genome was completed.

Big data applications in genomics cover a wide variety of topics, although this field is still in a nascent stage with applications in specific focus areas (e.g., cancer), because of cost and time (Belle et al. 2015).

For instance, delivering recommendations in a clinical setting also requires fast analysis of genome-scale big data in a reliable manner, and information derived through big data analytics applied to genetic data helps in delivering personalized care to patients.

Clinical Decision Support

Clinical decision support systems (CDSSs) are designed to impact clinician decision-making about individual patients and in real time. These systems have gained popularity with the increased focus on the prevention of medical errors and have been proposed as a key element to improve patient safety. The adoption of mobile devices and apps provides additional benefits in supporting decision-making, increasing access to point-of-care tools, and improving patient outcomes (Ventola 2014).

[Berner and La Lande](#) provided an overview of CDSSs, summarizing data about the use and the impact of this kind of systems in practice (Berner and La Lande 2007). They highlight how CDSSs

have the potential to change the way medicine is taught and practiced.

In this context, the adoption of data mining techniques facilitates unprecedented understanding of large healthcare data sets, helping researchers gain both novel and deep insights. Thus, new biomedical and healthcare knowledge can be uncovered, for instance, generating scientific hypotheses from large experimental data, clinical database, as well as scientific literature to support clinical decisions but also those related to administrative settings (Yoo et al. 2012).

In addition, the use of modeling techniques (e.g., logistic regression models, Bayesian networks, support vector machines, neural networks, and classification trees, etc.) has become highly developed. The obtained models are often leveraged to support the computation of risk scores (Martinez-Millana et al. 2015). However, the performance of models is subjected to various statistical and clinical factors (e.g., deficiencies in the baseline data or modeling methods used in the study, over-fitting, differences between patient characteristics, measurement methods, healthcare systems particularities, or data quality).

Personalized Medicine

The availability of valuable big data has a fundamental importance in the implementation of the personalized health paradigm that allows to put into practice the idea of personalized care and personalized medicine.

In more particulars, *P4 medicine* is radically changing the idea of medicine itself, as it is intended to be *predictive, preventive, personalized, and participatory* (Sobradillo et al. 2011; Hood and Flores 2012)

It is based on the comprehensive understanding that the biology of each individual – in contrast to the current approach of clustering patients into treatments groups according to their phenotype – aims at tailoring treatments to its characteristics, considering the genetic information of each individual as the main data source.

A comprehensive understanding of an individual's own biology (e.g., *personalized omics*) is

expected to address both health and disease and to impact on predisposition, screening, diagnosis, prognosis, pharmacogenomics, and surveillance (Chen and Snyder 2013).

This approach is expected to cut global health budgets, both by reducing the need for hospitalization and related costs and by minimizing the unnecessary adoption of drugs. This also leads to reducing the related side effects and avoiding the development of resistance to drugs (Nice 2016).

In this scenario, leveraging proper artificial intelligence solutions to handle and analyze the huge amount of available health data is crucial (Raghupathi and Raghupathi 2014).

Health and Wellness Monitoring

In the recent past, as physiological signal monitoring devices have become ubiquitous (e.g., IoT devices), there has been an increase in utilizing telemetry and continuous physiological time series monitoring to improve patient care and management (Belle et al. 2015). These solutions are carrying unprecedented opportunities for personalized health and wellness monitoring and management, allowing for the creation and the delivery of new types of cloud services (Jovanov and Milenkovic 2011) that can either replace or complement existing hospital information systems (Kulkarni and Ozturk 2011).

Streaming data analytics in healthcare consists in systematically using continuous time-varying signals, together with related medical record information. This information is usually analyzed through statistical, quantitative, contextual, cognitive, and predictive analytical disciplines. Enriching the data consumed by analytics makes the system more robust helping balance the sensitivity and specificity of the predictive analytics.

This kind of applications requires a platform with enough bandwidth to handle multiple data sources to be designed for streaming data acquisition and ingestion. According to (Patel et al. 2012), systems for patients' remote monitoring consist of three main building blocks:

- the sensing and data collection hardware to gather physiological and movement data (e.g., tiny either on-body or in-body biosensors and battery-free RFID tags);
- the communication hardware and software to relay data to a remote center;
- the data analysis techniques to extract clinically relevant information from physiological and movement data.

Several monitoring solutions gather clinical information (such as position, temperature, or breath frequency) via body sensors or mobile devices and integrate it in the cloud, leveraging cloud characteristics such as scalable processing capability, seemingly infinite storage, and high availability (Santos et al. 2016; Thilakanathan et al. 2014; Hossain and Muhammad 2015). Often, the cloud represents a flexible and affordable solution to overcome the constraints generated by either sensor technologies or mobile devices, and therefore a growing number of proposals take advantage of the cloud capabilities to remotely off-load computation- or data-intensive tasks or to perform further processing activities and analyses (Zhang et al. 2014; Tong et al. 2014; Chen 2014; Wang et al. 2014; Wan et al. 2013).

A variety of signal processing mechanisms can be utilized to extract a multitude of target features. Their specifics largely depend on the type of diseases under investigation. Integrating these dynamic streamed data with static data from the EHR is a key component to provide situational and contextual awareness for the analytics engine.

Medical Image Processing

Medical images are a frequent and important source of data used for diagnosis, therapy assessment, and planning. They provide important information on anatomy and organ function in addition to detecting diseases states. From a data dimension point of view, medical images might have 2, 3, or 4 dimensions, as medical imaging encompasses a wide spectrum of methodologies to acquire images (e.g., computed tomography, magnetic resonance

imaging, X-ray, molecular imaging, ultrasound, photoacoustic imaging, fluoroscopy, positron emission tomography-computed tomography, and mammography). The volume of medical images is growing exponentially, and therefore such data requires large storage capacities.

As both the dimensionality and the size of data increase, understanding the dependencies among the data and designing efficient, accurate, and computationally effective methods demand new computer-aided techniques and platforms. Often, image processing techniques such as enhancement, segmentation, and denoising in addition to machine learning methods are needed. In addition, efforts have been made for collecting, compressing, sharing, and anonymizing medical data.

The integration of medical images with other types of electronic health record (e.g., EHRs) data and genomic data can also improve the accuracy and reduce the time taken for a diagnosis.

Opportunities and Issues

An increasing number and variety of organizations are beginning to apply big data to address multiple healthcare challenges, transforming data to information, supporting research, and assisting providers to improve patient care. Notwithstanding the unprecedented benefits and opportunities, the adoption of big data analytics in the health scenario is strictly related to (and even amplifies) a number of typical ICT issues, extending them to this critical domain. Therefore, healthcare practitioners are commonly facing difficulties related to managing and capitalizing this huge amount of heterogeneous data to their advantage. According to the scientific literature, data privacy and security, system design and performance, data and systems heterogeneity, and data management are the most recurring issues to be addressed.

Considering the only recent emergence of big data analytics in healthcare, governance issues including security, privacy, and ownership have yet to be fully addressed (Jee and Kim 2013; Kruse

et al. 2016). Security, privacy, and confidentiality of the data from individuals are major concerns.

The availability of real-time analytics procedures is a key requirement for a number of applications, and it is often achieved relying on cloud platforms, able to provide proper reliability with uninterrupted services and minimum down-times (Ahuja et al. 2012).

Proper data management represents an open issue. After data generation, costs are incurred when for storing, securing, transferring, as well as analyzing it (Kruse et al. 2016). Indeed, data generation is inexpensive compared with the storage and transfer of the same (Costa 2014). The lack of proper skills further exacerbates these issues representing a significant barrier to the implementation of big data analytics in health domain.

While from the one hand the adoption of cloud-based solutions mitigates performance-related issues (also providing a good trade-off with costs), from the other hand, it raises concerns about data privacy and communication confidentiality because of the adoption of external third-party's softwares and infrastructures and related concerns of losing control over data (Ermakova et al. 2013).

Data heterogeneity and lack of structure are commonly considered obstacles and still represent open issues, as healthcare data is rarely standardized, often fragmented, or generated in legacy IT systems with incompatible formats. EHRs are known to not share well across organizational lines (Kruse et al. 2016). In more particulars, biological and medical data are extremely heterogeneous (more than information from any other research field) (Costa 2014). Additional challenges arise when filling the gap emerging between the low-level sensor output and the high-level user requirements of the domain experts. As a result, continuous data acquisition and data cleansing require to be performed.

Finally, health-related data analytics is also accompanied by significant ethical challenges, ranging from risks to individual rights (e.g., concerns about autonomy) to demand of transparency and trust (e.g., in public health practice) (Vayena et al. 2015).

The adoption of big data in the health field is very promising and is gaining more and more popularity, as it is able to provide novel insights from very large data sets as well as improving outcomes while reducing costs. Its potential is great but a number of challenges remain to be addressed.

Big Data Hardware Acceleration

► Computer Architecture for Big Data

Big Data in Automotive Industry

Awais Akram Mughal

Beijing Institute of Technology, Beijing, China

Definitions

Big Data in the automotive industry is an effort to highlight the significance and relation of Big Data Analytics in the emerging automotive industry. Automotive industry is no more a property of conventional original equipment manufacturers (OEMs), but IT companies are pouring into the industry and giving tough challenge to big brands. Big Data has played a significant role in a wide range of areas, for example, training algorithms for autonomous driving, data clustering, consumer studies, understanding the relationship between customer demand and technology impact, evaluation for better future strategies for R&D and sales, etc.

Overview

The arrival of the fourth industrial revolution has brought significant challenges for the industry (Bloem et al. 2014). Numerous industries which thrived in the past now face mere extinction. One such example is the emergence of touch screens in the mobile phones. This innovation literally wiped out numerous cellular OEMs when they failed to predict the change and couldn't meet the customer expectations in screen size, features, and quality. Automotive OEMs are no exception and are also exposed to similar challenges at all times. They are racing against fast-changing customer expectations from greater horsepower to more greener and cutting-edge disruptive technologies (Bloem et al. 2014; Deloitte 2014).

It is often overwhelming for the businesses to tackle large amounts of data to better identify, evaluate, and meet customer expectations. Big Data has proved to be a vital tool in handling such information and providing meaningful data

clusters that help lead to better strategies and products. Automotive OEMs often analyze vast amounts of data to understand their customer priorities when purchasing a car. In the recent few years, some of the other key developing technologies in automotive industry, namely, autonomous drive, shared mobility, connected vehicle (V2V and V2X), smart interfaces, etc., are thriving with the help of Big Data Analytics thus making it an important topic to discuss. The following sections discuss significance of Big Data for the automotive OEMs and its role in the development of emerging technologies in the automotive industry.

Automotive Industry and Big Data

The automotive industry has been experiencing a massive change and is still coping with the effects of the fourth industrialization revolution. Among others, one of the greatest challenges is the burst of information that a company has to yield to stay ahead of the market in technology, products, and consumer requirements.

Technology has brought the cars to life. Cars now communicate and interact with humans just like any other robot. Based on the connected devices and the sensory data generated, our modern cars are turning into data factories. When all this data is combined, it creates an immense value for all the players in the ecosystem.

However, when the information exceeds beyond the certain limit, then humans and machines tend to become careless and slow. That is one of the reasons why we often tend to forget traffic rules on the street. But what if the information could be fed to the driver in bits and pieces, when it is needed at the right time to enable them to make the best decisions? Still we are talking about a petabytes of data that is coming from numerous sources, and it will be even more complex to decide when and what information to process and deliver.

Some studies (Deloitte 2014) show to surprise that when the customer is making the first purchase of a car, brand image and price are the least considered factors. Among the top factors that influence a customer are usability and technology. However, for a second purchase, usually

technology becomes the most important factor. According to another study (IBM Institute of Business Value 2014), technology is going to be the most important external force that will impact the industry in the next decade.

Considering the size and the extent of the automotive industry, it would be months of hard labor to analyze and visualize such huge amount of data before coming to a conclusion (IBM Institute of Business Value 2014). However, first it is necessary to understand where this data is coming from and to understand its relationship.

Data Generation and the Need of Big Data in Automotive Industry

Although the term Big Data has attracted huge attention in the automotive world, behind this big word, there is a simple story. The above example is one simple demonstration of Big Data Analytics in the automotive industry. The Industry leaders, engineers, consulting agencies, and analysts have always been relying on the huge amount of data and information to clinch to the leading position in the market. In the past, this data however has been scattered at different locations.

Development Phase Data

In general, OEMs (and dealers) make immense efforts to collect actual field data to understand their customer better. Once a new vehicle has been developed, a single test drive can incur several terabytes of measurement data, and the amount of data during the development phase often exceeds the petabyte range (Bloem et al. 2014).

Consumer Phase Data

With the advancement in the Internet of things and the rise of shared economy, more and more devices are getting connected to cars. Traditionally these devices would be biometric wearables, home appliances, and audio-visual equipment. Introducing connectivity to automotive has opened new horizons for the services in the car like GPS navigation, e-mail, and live music streaming to mention a few.

The services sector around the car has evolved into a much complex structure with many new business models

- (i) **Infotainment system:** The car of today and the future will turn into a massive infotainment industry. Online streaming, news, weather, direct mobile payments, insurances, and reservations services are few services to mention and are already a billion-dollar industry. According to some conservative estimates, an average car will produce a few terabytes of data by 2020 (McKinsey and Company 2016). This data has enabled the service providers in understanding the trend, behavior, and priorities to the extent of an individual customer.
- (ii) **Mobility service providers:** Over the past few years, e-hailing services, vehicle sharing, and automated remote parking are some of the businesses that have experienced a rapid growth with the success of shared economy. Various companies are now defining location-based services based on the huge amounts of incoming data from the car for customer safety, resource optimization, better vehicle allocation, and customer management.
- (iii) **Insurance service providers:** For a long period of time, insurance providers have been relying on the aggregated data such as the driver age, gender, brand, model, etc., to set their insurance package for car and/or driver. However *usage-based insurance* is one of the new innovations in the insurance industry. Insurance companies can now monitor the mileage and driving behavior through the onboard diagnostics (OBD) in the car. User-based insurance is one of the top five innovations related to the connected car (SAS 2015).
- (iv) **Aftersales service:** In the past the OEMs have been traditionally relying on the reactive reliability statistics to improve the reliability of the vehicle and reduce the downtime. But with the advent of the Big Data technologies, this data has become much more valuable and enabled car companies to switch to predictive analysis.

As cars are becoming more and more intelligent, failures can now be predicted through data analysis for incoming data from the car sensors and radars (Pickhard 2016).

How Big Data Is Transforming Automotive Industry

Usually accidents gets unavoidable when there are millions of over speeding drivers, faulty parts in the car, kids running into the street, or an unintentional glimpse at the phone beep. There are number of other such reasons when the driver's attention is taken away, and it may cause a hazard. In such situations, the first thing an accident-affected person would want is alerting the medical aid. The next important thing could be to inform the approaching vehicles about the incident so that they may avoid any disruption. This would have also been a critical information for the navigation system on the ambulance to take the shortest route and reach in time to save the lives at the location. At times this road information is also important for other departments, like the road and traffic management departments that design the roads and manage the traffic, to ensure smooth traffic and public safety. This data would also be of immense utility for the automaker who could have identified or predicted the problem with the part, before the incident happened.

Most of this information is of importance for the city planners. This can enable them to create a whole ecosystem by networking all these building blocks of our transportation system into a standard traffic protocol and create solutions. The overall characteristics of these solutions can be classified with three words: revenue generation, cost reduction, or safety and security enhancement. However this incoming information may be too overwhelming for the few policy-makers and thus would require uncountable man hours to sort out the logic for making a common policy that might fit for all in our transportation ecosystem.

Often these solutions are drivers for the breakthrough technology that may eventually become the trend for the future automotive industry. Some of these trends are discussed below in light of implication with the Big Data; however this development is also reliant on the other associate

technologies, called enablers, that will be discussed along the way for each case.

(a) **Development phase:** Data can be a vital resource to refine or even redefine how our future vehicles are designed. By mining data from the repair shops, data from the embedded sensors in the car, and many other sources, the engineers now understand that they can reduce the engineering cycles, optimize energy usage, and reduce development costs. This is enabling car companies to roll out new models that are reliable, sustainable, and innovative. Through data analysis, OEMs are learning the trends about the customers from various regions and preparing cars that are customized for the specific region, e.g., Chinese customers may prefer an SUV when choosing a normal passenger car. The information regarding the customer to such extent would not have been possible without the Big Data. The engineers on the other hand can now also process the data and optimize the production plan to ensure the availability of the different models within the deadlines. The OEMs can also collect the data from the car to improve the downtime of the vehicle (McKinsey and Company 2016).

(b) **Market and customer:** In the past the OEMs have been traditionally relying on the reactive reliability statistics to improve the aftersales of the car. However, these days OEMs can define an overall strategy in advance by performing the proactive diagnostics. The customer who may have decided to change a faulty part at a later time due to the wait time can now be prevented from any further traffic hazards. On the other hand, OEMs can improve life expectancy of a vehicle by providing superior parts based on the weather and terrain requirements of different regions. Based on this data, OEMs can redesign their marketing strategies according to the regions. A customer in the hot desert will have very different requirements compared to a person in the frozen mountains, and the vehicle would have very different requirements for the engine oil, fuel, or other parts. Through the customer data and feedback, it can also re-

flect the vehicle performance in different terrains and what could be the future improvements in the R&D phase. Although these benefits have been theoretically proven, but yet there is a long way to go before the infrastructure is in place.

(c) **Insurance and security:** A single car may produce huge data each day, and valuable clues regarding the performance and health of the vehicle are hidden in the data generated from the car. As for the scenario defined above, there could be major challenge for the insurance companies to correctly identify the responsibility and damage estimation. As for now the user-based insurance has proved to be a feasible solution. However, real time speed and location data generated from the car, for instance, can help determine the cause and location of the accident. Big Data analysis has significantly lowered the payments that the customers had to make to insurance companies in the past.

The data collected from the accident scene can be carefully analyzed to find reasonable innovations that could be made to ensure safety of the future user. Enhanced car safety features can save many lives that would otherwise go wasted. Through the data analysis, now companies offer strong laminated windshields that would not shatter in the case of an accident, and the modernized airbags will inflate just before the impact to prevent the driver from any head injury.

(d) **Autonomous drive:** Autonomous driving is the headline of every news article, and its value is much known. As for now the driver assistive systems, collision prevention, and lane keeping are some of the features that define our so-called autonomous vehicles. But in the future, Big Data analysis will play a vital role in making the vehicles smarter. Huge amounts of traffic and roadside assistance data was fed to the car to enable it to successfully maneuver through the densely populated cities. The arrival of fully autonomous vehicles will not only reshape the mobility but also the way we humans see the car.

The interior of the car may require to be fully redefined based on the human activities. We have already seen some of the concepts presented at the auto shows by different automakers (Al Najada and Mahgoub 2016). As the data generated in the car will no longer be just about the engine speed or location, so there may be need to redefine the data clusters (Al Najada and Mahgoub 2016).

(e) ***Connected cars and Internet of things (IoT):***

IHS Automotive forecasts that there will be 152 million actively connected cars on global roads by 2020, and it will be a 40 billion-dollar industry. This makes connected cars much more interesting for the OEMs and startups. 5G technologies, with 10 GB download speed and near-zero latency, will bring in the true connected vehicle; however 4G-edge is serving the purpose at the moment. This means that in the future, the car will be able to share the data at in real time. The incoming data can be analyzed to enable many use cases. The in-car entertainment features are already in the car for some time now. The new streaming services will be offering online games, movies, and more based on the behavior of the user to bring a customized content to the user. Syncing this information with home devices will continue to provide the customer with the same experience from the car till home. Through navigation analytics, a car will be able to actuate the connected devices at the home or in office and route the way by analyzing the most updated weather and traffic conditions, keeping in view the previous preferences of the driver. Thus, Big Data Analytics will be increasingly important part of the car once it can fully integrate IoT and realize V2X communication.

Traditional Ways to Store and Process Data in Automotive Industry

If we tend to think about the data vehicles produced, then we realize it's a very complex ecosystem. Data from cars, service providers, weather reports, and environment all need to be processed and stored simultaneously. Traditionally the automotive companies spend hundreds of man-hours

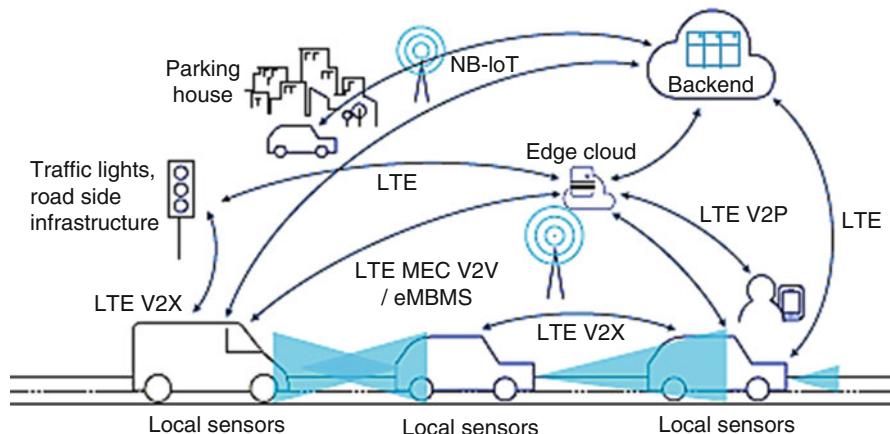

and then collect data to large servers placed at various centralized locations. These data storage techniques may work fine for the small scale ecosystems. However in future ahead with complex ecosystem of autonomous driving, requiring global monetization of car data in real time, such techniques might fail to serve. It is only then that a car manufactured in China will be able to operate fully autonomously in the USA or other parts of the world. What's needed be understood is that technology is actually removing the boundaries among different territories for the automotive.

Although the relationship of data clusters is well defined to realize the autonomous drive and for the connected cars in the future, the challenge still remains; but how do you store the data in order to retrieve and process it in the shortest viable time? Since autonomous cars require data processing in almost real time, effective Big Data processing algorithms (as in Daniel et al. (2017)) can be one of the possible solutions; however, the car industry will be looking up to even more effective means such as combination of edge and cloud computing (Liu et al. 2017) as shown in Fig. 1.

At times the sensors on board are sufficient to detect and handle certain road situations, but yet they are unable to make the car respond to the bigger ecosystem. Upcoming hazards, weather conditions, traffic jams, roadside assistance, etc., are yet to be realized through a connected network. This information is crucial and must be provided spontaneously to enable the driver to make a better decision on the road (Sherif et al. 2017). This concept proposes certain information like the humans on road and a traffic hazard directly to the edge clouds that can then provide this information to the car directly with a negligible lag. Automotive will require this and other similar concepts to not always rely on the Internet speed for better faster data processing and transfer.

Future Opportunities and Challenges for Big Data in Automotive Industry

In a complex work environment of a car, it is essential for in-vehicle measurement to be complete and time synchronization of measurement

Big Data in Automotive Industry, Fig. 1 V2X communication (Nokia 2017)

signals from different sources. The sensors and stereo cameras on the future car, for instance, will stream in large amounts of raw data during the journey. However, this incoming data must be processed in real time (Amini et al. 2017). Although, this sounds too ambitious to shorten the testing days and measurement campaigns, but it is realistic. With modern Big Data Analytics techniques, the calibration of the automotive could be done in virtual environments, and this would save hours of man time. To enhance the electronic and performance capabilities of cars, Big Data Analytics will be the most logical solution.

Another research (SAS 2015) estimated that investments in Big Data will account over \$2.8 billion in 2017 and will grow at 12% over the next 3 years. It surely has been one of the biggest enablers of the technological revolution in the automotive industry and has successfully helped to create many disruptive business models and determine new fields of innovation and research. Applying the advanced data analytics across the manufacturing value chain has generated exponential value. Well-defined sets of data have been utilized to perform analytics like the customer behavior analytics, market mix analytics, supply chain optimization analytics, and predictive quality analytics. Executives now do better process risk analytics and set new and better KPIs based on customer data accumulated globally. It enables them to make better strategies for the companies and bring stronger and more competitive products

to the market, with better technological features, through deep understanding of the global market. Big Data has enabled the globalization yet keeping the element of personalization in future cars.

Although Big Data has created several business opportunities, along come certain challenges. Technically speaking Big Data still relies on two things: proper data storage and the computational power. While using the mobility services, customers entrust mobility platforms with a considerable amount of data including their personal information and financial details, which are saved on the respective enterprise servers. For the customer it is always of utmost concern how this data is treated by these enterprises. This issue will be even more complex once the autonomous vehicles arrive and people will be riding robot taxies. Autonomous cars will be sharing numerous data content with the servers, which, if not sufficiently secured or hacked, can cause significant damage to the customer and company integrity (Sherif et al. 2017). Thus, data flowing in require proper storage and protection. The location of data storage also has direct relation to the computational power. Computation power can be evaluated from two aspects: computational speed and accuracy. Connection speed, algorithm, and data processing are among the many factors that may affect the computational speed; however, the location of data storage is also an equally important factor. Taking the data from one

location to another is often a reason of having lag between the data retrieval and processing. Can 5G completely satisfy the requirement, or should the systems be supplemented with edge cloud computing? The bigger question would be that how to prepare the automotive companies to design their automotive data management systems in a way that supplements fast and effective Big Data Analytics.

Furthermore, it is yet to be seen how Big Data evolves along with the fast-changing technological landscape. Artificial intelligence (AI) has dramatically changed the human perception about the machines and is becoming a core of future cars. Thus, it should be determined how to unite these two technologies. A bigger question would be when our autonomous car receives data through Big Data Analytics; can AI enable that car to make the right decision between colliding a tree or a child? The industry however will continue to have faith in Big Data to experiment, discover, and innovate the future opportunities.

Overview

Network monitoring applications (e.g., anomaly detection and traffic classification) are among the first sources of *big data*. With the advent of algorithms and frameworks able to handle datasets of unprecedented scales, researchers and practitioners have the opportunity to face network monitoring problems with novel data-driven approaches. This section summarizes the state of the art on the use of big data approaches for network monitoring. It describes why network monitoring is a big data problem and how the big data approaches are assisting on network monitoring tasks. Open research directions are then highlighted.

Network Monitoring: Goals and Challenges

Monitoring and managing the Internet is more fundamental than ever, since the critical services that rely on the Internet to operate are growing day by day. Monitoring helps administrators to guarantee that the network is working as expected as well as to plan its evolution, raising alerts in case of attacks or anomalies, and assisting on the prediction of traffic loads based on historical data.

Network measurements are key for these tasks. Measurements are collected from network links, forwarding equipment and end nodes in real time by exporting either information extracted directly from the traffic (i.e., passive measurements) or from probing packets injected in the network (i.e., active measurements). A variety of methods and algorithms have been proposed to extract higher-level knowledge from the measurements, from ad hoc heuristics that maintain basic statistics describing the status of the network to advanced machine learning methodologies that detect anomalies and inform operators about problems automatically.

However, collecting and analyzing network measurements is by no means a simple task. The sheer traffic volumes, the large number of legitimate services running on the network, the widespread presence of vulnerabilities and ma-

licious traffic, and the variety of traffic sources are just some examples of the challenges to monitor the Internet. Critical monitoring applications, such as anomaly detection and traffic classification, require efficient mechanisms that allow the processing of millions of events per second – events that otherwise would be of little value if analyzed in isolation.

These challenges match well with what is nowadays used to define *big data* – i.e., data that is intrinsically large (volume) and heterogeneous (variety) that needs to be analyzed in real time (velocity) and generates knowledge crucial for those managing, operating, and planning the network (value).

Are researchers and practitioners leveraging big data approaches for network monitoring problems? What are the open challenges to fully exploit the big data potentials when monitoring the network? This section explores these questions providing a brief overview on why network monitoring can be characterized as a big data problem and how big data approaches are assisting network monitoring. Open research directions are then highlighted.

Network Monitoring: A Big Data Problem

The list of traffic monitoring applications that could be characterized as a big data problem and thus profit from big data approaches is vast. Traffic classification and anomaly detection for cybersecurity are used in the following to illustrate why network monitoring is a big data problem.

Traffic Classification

Valenti et al. (2013) define traffic classification as the problem of recognizing services generating streams of packets. Traffic classification is an essential step for many network applications, such as to perform per-service traffic engineering, traffic accounting, etc. Callado et al. (2009) and Nguyen and Armitage (2008) have categorized the several methodologies for traffic classification, grouping them according to the core classification strategy:

- (i) *Packet inspection methods* search for predefined fingerprints that characterize services (e.g., protocol messages) in packet contents. These algorithms are recognized to be generally fast and precise, but their importance has been drastically reduced by the increasing deployment of encrypted protocols;
- (ii) *Machine learning methods* automatically search for typical traffic characteristics of services. Supervised learning algorithms are usually preferred, in which features of the traffic, e.g., packet sizes and inter-arrival times, are used as input to train classification models describing the traffic. Neural networks, decision trees, and support vector machines are some examples of suitable learning algorithms. These methods are appealing since they can find complex patterns describing the services with minimal human intervention. However, they require large training datasets to build up good-quality models. Moreover, it is hard to achieve general classification models. In other words, the models that classify traffic in one network may not be able to classify traffic from other networks. Data from different networks is usually needed to build up generic models.
- (iii) *Behavioral methods* identify services based on the behavior of network nodes – e.g., servers that are typically reached by clients and the order in which servers are contacted. Also in this case, machine learning algorithms can help to discover patterns, e.g., learning rules that describe the behavior of nodes and outputting the most likely services running on the nodes. Behavioral methods require little metadata, thus working well with encrypted services. However, as before, they require large datasets for learning the hosts' behaviors, as well as training data from different networks, in particular if coupled with machine learning algorithms.

Anomaly Detection

Bhuyan et al. (2013) and García-Teodoro et al. (2009) describe diverse techniques for anomaly

detection that are often employed in cyber-security tasks. For example, anomaly detection is used in network security contexts to detect traffic related to security flaws, virus, or malware, so to trigger actions to protect users and the network.

Anomaly detection for cyber-security builds on the assumption that malicious activities change the behavior of the network traffic, which is determined by interactions with legitimate services. Anomaly detection methods rely on models that summarize the “normal” network behavior from measurements, i.e., building a baseline. Traffic classification algorithms can be leveraged for learning the behavior of legitimate services, e.g., by building behavioral models that are able to identify popular services. Live traffic is then monitored and alerts are triggered when the network behavior differs from the baseline models according to predefined metrics.

Anomaly detection methods are attractive since they allow the early detection of unknown threats, e.g., zero-day exploits. These methods however may not detect stealth attacks, which are not sufficiently large to disturb the traffic. Moreover, the large number of Internet services represents a challenge for anomaly detection, since unknown services (that are possibly legitimate) might be considered anomalies as well. In other words, anomaly detection may suffer from false positives, i.e., false alerts triggered because of unknown services or by transient changes in legitimate services.

Big Data Challenges on Network Monitoring

Network monitoring applications face all challenges of typical big data applications.

Taking *velocity* as a first example: Traffic classification and anomaly detection are often performed in high-speed networks, e.g., backbone links at Internet service providers (ISPs). The systems need to cope with tens or even hundreds of gigabits of traffic per second since thousands of users are aggregated in such links. Many scalable network monitoring approaches have been proposed to overcome this challenge. Flow monitoring is one prominent example.

Instead of letting complex algorithms handle raw traffic directly, a specialized equipment that implements basic preprocessing steps in hardware is deployed. This equipment is usually called a *flow exporter*. The flow exporter builds summaries of the traffic according to the *flows* seen active in the network. Flow exporters have been shown to scale well, processing more than 40 Gbps of network traffic with commodity servers (Trevisan et al. 2017). Analysis applications then operate on such flow-level summaries. For instance, machine learning algorithms have been shown to deliver promising results with flow-level measurements, despite the coarse granularity of the measurements – see Sperotto et al. (2010) for details.

Hofstede et al. (2014), however, show that even flow-based approaches are starting to be challenged by the ever-increasing network speeds. Table 1 illustrates the speed in which flow exporters would send out data from a vantage point when observing 50 Gbps of raw traffic on average. The table includes volumes estimated for different flow export technologies – i.e., Cisco’s NetFlow v5 and NetFlow v9 as well as IPFIX, which is the IETF standard protocol to export flow-level information from the network. The data rate leaving the flow exporter is remarkably smaller than the raw traffic stream. Nevertheless, applications processing only the flow summaries (e.g., for anomaly detection) would still have to handle more than 70 Mbps if IPFIX is chosen to export data. More than that, these numbers refer to a single vantage point, and there could be hundreds of vantage points in a midsized network. Whereas sampling is often used to reduce exported volumes (see numbers

for the 1:10 sampling rate), it reduces the *value* of the data, making it harder to run some monitoring applications.

The *volume* of measurements is another clear example on why network monitoring faces big data challenges. The availability of historical data is a strong asset for some monitoring applications, e.g., security applications that perform forensics can rely on historical data to detect whether users have been impacted by previously unknown attacks. Table 1 suggests that the archival of network measurements requires large storage capacity even if highly efficient formats such as compressed flow summaries are selected. Figure 1 quantifies this requirement by depicting the storage space needed to archive compressed flow measurements from vantage points monitoring around 30,000 end users. Note that these vantage points are relatively small, observing only few Gbps of traffic on peak periods. The figure shows that the space occupied by the measurements grows almost linearly with time as expected. After 4 years, the archival consumes almost 30 TB.

Around three billion flows have been reported by flow exporters in each month depicted in the figure. This shows how challenging is to extract *value* from network measurements. Consider an anomaly detection system that triggers an event every time a set of flows is considered suspicious. The system would likely bother network administrators with the false alerts even if only a single false alert would be generated every tens of millions flows.

Big Data in Computer Network Monitoring, Table 1

Estimated stream of packets and bytes leaving a flow exporter that observes 50 Gbps on average – source (Hofstede et al. 2014)

Sampling	Protocol	Packets/s	Bits/s
1:1	NetFlow v5	4.1 k	52 M
1:1	NetFlow v9	10.2 k	62 M
1:10		4.7 k	27 M
1:1	IPFIX	12.5 k	75 M

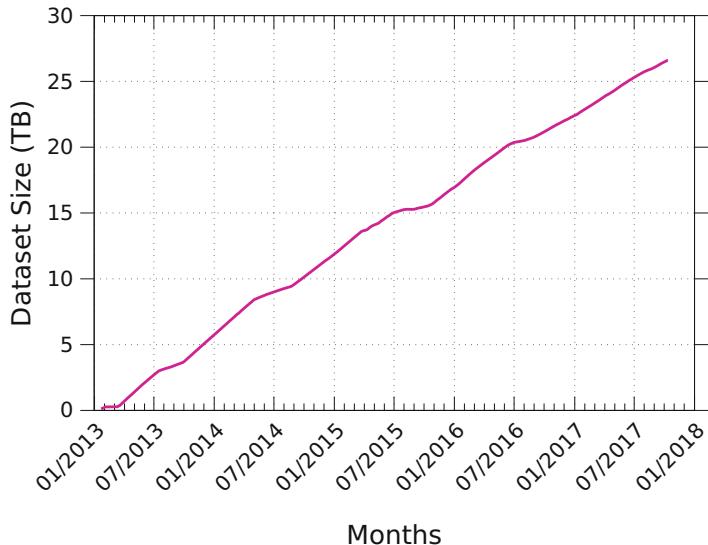

Big Data Technologies in Network Monitoring

Since network monitoring shows the characteristics of a big data problem, a natural question is whether researchers and practitioners are leveraging big data approaches in this context.

There is still a small number of academic works that actually leverage big data for network monitoring. This is somehow surprising considering that big data technologies such as

Big Data in Computer Network Monitoring,

Fig. 1 Storage to archive flow measurements from links aggregating around 30 k end users

MapReduce are rather mature – in fact, MapReduce has been introduced by Dean and Ghemawat (2004). Even considering the well-known weaknesses of some technologies, e.g., MapReduce inefficiencies when dealing with iterative algorithms over large datasets, alternatives do exist, and they are now already well-established too. A prominent example is Spark, proposed by Zaharia et al. (2010) precisely to overcome the weaknesses of MapReduce.

This raises questions on whether these technologies lack characteristics to fulfill the requirements of network monitoring applications. Roughly speaking, early adopters have mostly tried to adapt or to extend existing big data technologies to better fit the network monitoring applications.

To fully understand current efforts, it is convenient to put the ongoing research on big data approaches for network monitoring in the perspective of a knowledge discovery in data (KDD) process. The classical KDD process, attributed to Fayyad et al. (1996), is summarized as a sequence of operations over the data: gathering, selection, preprocessing, transformation, mining, evaluation, interpretation, and visualization. This schema is depicted in Fig. 2. Next works applying big data approaches for network monitoring are discussed according to the covered KDD phases, which are clustered in two groups:

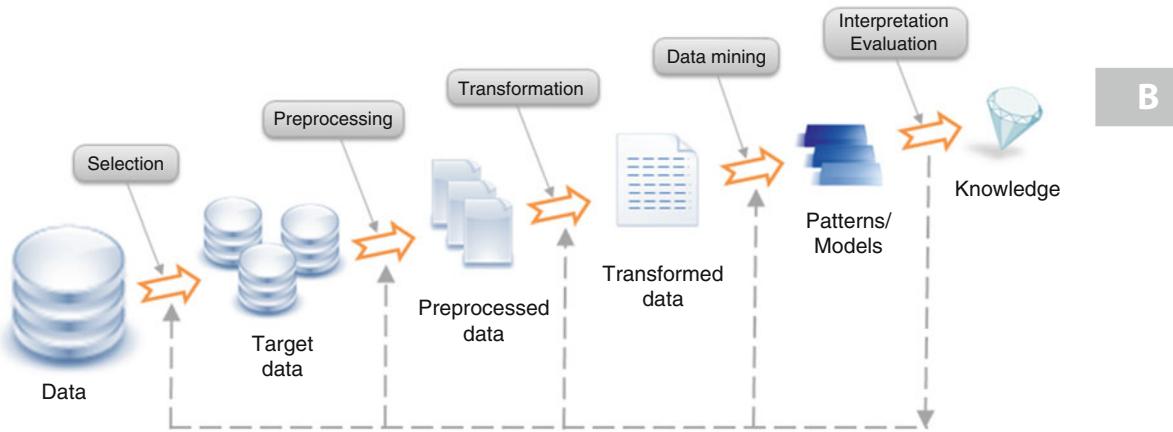

data management (from data gathering until transformation) and analytics (i.e., the remaining operations).

Data Management

Marchal et al. (2014) introduce an intrusion detection system that relies on heterogeneous sources, e.g., NetFlow, DNS logs, and honeypots. Intruders are identified by ad hoc metrics that spot anomalies (possibly malicious) in the data. Queries that are generally common in network monitoring are solved to calculate the metrics, such as for finding records containing a given string and records that pass particular filters – e.g., to count contacted destination IP addresses given a source address.

The authors benchmark different big data technologies concluding that Spark and Shark answer queries faster than alternatives (e.g., Hive). They however highlight challenges to process the measurements: There is a shortage of solutions for ingesting, reading, and consolidating measurements in the distributed file systems supported by the frameworks.

Lee and Lee (2013) have also identified these problems. Network measurements are often captured and transferred in optimized binary formats that cannot be directly and efficiently stored in distributed databases and file systems. The authors focus on how to process raw PCAP and

Big Data in Computer Network Monitoring, Fig. 2 Classical knowledge discovery in data (KDD) process – source (Fayyad et al. 1996)

NetFlow traces in Hadoop. Since HDFS does not know how to split PCAPs and NetFlow formats, the processing of each file in Hadoop-based solutions cannot profit from parallelism and data locality to scale up horizontally. Authors implement new Hadoop APIs to explicitly process PCAP and NetFlow archives, showing that the APIs improve performance.

These APIs are however specific to HDFS, PCAP, and NetFlow and allow only sequential reading of the archives in HDFS. While they certainly alleviate the problem, challenges persist if one would need advanced analytics or functionalities that are not able to interact with the APIs. For instance, when faced with similar problem of ingesting heterogeneous measurements into big data frameworks, Wullink et al. (2016) have created an extra preprocessing step to convert measurements from the original format (i.e., PCAPs in HDFS) into a query-optimized format (i.e., Parquet). This conversion is shown to bring massive improvements in performance, but only preselected fields are loaded into the query-optimized format.

These works make clear that big data frameworks are attractive to process network measurements, thanks to built-in capabilities to handle the usually large volumes of measurements. Nevertheless, they shed lights on how basic steps, like ingesting measurements into the frameworks, are by no means trivial. Those are not the only chal-

lenges. Other challenges immediately become evident when one considers that network monitoring applications often operate not only with batches of historical data (i.e., volume) but also with live measurement streams that need to be evaluated on the fly (i.e., velocity).

Bär et al. (2014) show that solutions targeting batch processing (e.g., Spark) present poor performance for such online analysis, and even stream-oriented alternatives (e.g., Spark Streaming) miss functionalities that are essential for network monitoring applications. The latter is also highlighted by Čermák et al. (2016), who mention the difficulties to recalculate metrics from old data as one of the several weaknesses in such general stream processing engines. Bär et al. (2014) propose DBStream to calculate continuous and rolling analytics from online data streams. DBStream is thus built upon some ideas of big data frameworks but specialized to solve network monitoring problems. DBStream is still a centralized system, relying on a single-node SQL database, thus lacking the horizontal scalability features of a modern big data solution.

Noting a similar gap in stream analytics tools for BGP measurements, Orsini et al. (2016) introduce BGPSstream. They point out that although BGP is a crucial Internet service that manages routing, efficient ways to process large BGP measurements on real time are missing, e.g., to detect anomalies and attacks in the routing service. BG-

PStream provides tools and libraries that connect live BGP data sources to APIs and applications. BGPSStream can be used, for instance, to efficiently ingest online data into stream processing solutions, such as on Spark Streaming.

Analytics

The management of network measurements, i.e., gathering, ingestion etc., is just the starting point of network monitoring applications. Often data analytics methods used by these applications have troubles to handle big data – e.g., some machine learning algorithms do not scale well with large datasets or are hard to parallelize.

Selecting the best algorithms for the specific network monitoring problem is a complex task. For instance, it is commonly accepted that there is no single best learning model for addressing different problems simultaneously. Indeed, even if multiple models could be very well suited for a particular problem, it is very difficult to understand which one performs best in operational network where different data distributions and statistical mixes may emerge. Recently, Vanerio and Casas (2017) have proposed a solution for network security and anomaly detection that is suitable for big data. Their method is based on the use of *super learners*, a class of ensemble learning techniques known to perform asymptotically as well as the best combination of the base learners.

Liu et al. (2014), Fontugne et al. (2014) and Wang et al. (2016) are other examples of authors that have started to implement analytics methods based on MapReduce or Spark to process large collections of measurements (e.g., feature selection). However, works on big data analytics for network monitoring are still incipient, lacking comprehensive approaches that are applicable for more sophisticated cases.

Research Directions

From this short survey, it can be concluded that researchers have identified the potential of big data approaches for network monitoring, but current technologies seem to miss features required

by network monitoring applications. It is also clear that there is work in progress to fill in this gap.

If one considers the KDD process in a big data context, there are several general big data frameworks and technologies that cover the initial stages, e.g., data gathering and preprocessing. The network monitoring community has clearly focused on these initial stages when measurements become big data. The community is on the way to answer questions such as how to ingest measurements in big data frameworks and how to process large streams of live measurements from different sources. However, these efforts are still somehow isolated. Lessons learned need to be incorporated in the frameworks, so to allow easier processing of other sources and the reuse of APIs and libraries for different network monitoring analytics. One recent attempt in that direction is Apache Spot (2017), which proposes an open data model to facilitate the integration of different measurements, providing a common taxonomy for describing security telemetry data and to detect threats.

Since both online stream and offline batch analyses are needed for network monitoring, another research direction is toward the unification of the two programming models. For example, building upon the *dataflow* abstraction (Akidau et al. 2015), Apache Beam (2017) offers one of such unified programming models. It can represent and transform both (i) batch sources and (ii) streaming sources, thus relieving programmers from the burdens of keeping two code bases and increasing portability across execution engines.

As the challenges in the initial phases of the KDD process are tackled, researchers are moving toward subsequent KDD phases, such as by proposing data mining algorithms and visualization techniques suitable for big data. The recent progresses in training deep learning models with big datasets are just some examples of this trend. However, network monitoring applications that profit from these progresses are almost nonexistent.

Casas et al. (2016) are working on Big-DAMA, one of the few initiatives that are

trying to face these challenges comprehensively. Big-DAMA aims at conceiving a new *big data analytics framework* specifically tailored to network monitoring applications. Big-DAMA will include scalable online and offline machine learning and data mining algorithms to analyze extremely fast and/or large network measurements, particularly focusing on stream analysis algorithms and online processing tasks. Big-DAMA aims also at creating new benchmarks that will allow researchers and practitioners to understand which of the many tools and techniques emerged in recent years suit best for network monitoring applications.

Projects such as Apache Spot and Big-DAMA are at their early stages and clearly there is still a long way to go. It seems however a matter of time until the network monitoring community fills in the gaps, fully exploiting the potential of big data approaches to improve network monitoring applications.

Big Data in Cultural Heritage

Vincenzo Moscato

Dipartimento di Ingegneria Elettrica e delle Tecnologie dell'Informazione, University of Naples, Naples, Italy

Definitions

Cultural heritage information management mainly concerns the development of tools and applications for the storage, processing and retrieval of cultural digital contents, coming from distributed and heterogeneous data sources such as digital libraries and archives of cultural foundations, multimedia art collections, web encyclopedias and social media networks, and so on. In addition, if we also consider data from possible sensor networks – deployed in a given cultural environment (e.g., museums, archeological sites, old town centers, etc.) – the information to manage assumes characteristics of volume, velocity, and variety typical of big data. Thus, technologies for big data management can be properly investigated to realize a useful platform for cultural heritage applications.

Overview

In this chapter, we describe the main technological challenges and issues for the management of Big Data related to the Cultural Heritage domain.

Introduction

Nowadays, using information and communication technologies (ICTs) to enhance and promote worldwide cultural heritage (CH) surely represents a very important research issue with a variety of potential applications. In addition, we can observe how this challenge is particularly important in Italy, whose artistic heritage embodies a universal resource of priceless value, attracting every year millions of visitors to monuments, archeological sites, and museums.

Indeed, ICTs have been giving for many years and in different ways a very useful support to CH fruition and preservation (Kabassi 2013).

The initial challenge was to provide several techniques, tools, and systems to assist the annotation and cataloguing of CH objects within digital repositories that in many cases can include a large amount of contents with rich and different metadata.

Successively, other advancements of ICT have made possible to “enrich” the original information (e.g., by means of social media and augmented/virtual reality techniques), in order to improve and facilitate fruition of cultural objects, also using web and mobile applications.

As an example, the mode of fruition, and even the purpose, of CH exhibitions has radically changed in the last decade rapidly moving from an old vision, providing tourists with static information consisting of a large amount of “cultural signs,” to novel personalized services that meet the visitors’ personal tastes by considering their cultural needs and preferences (e.g., by means of the introduction of recommendation facilities Albanese et al. 2013).

More recently, the adoption of *Future Internet* technologies, particularly the paradigm of the *Internet of Things*, has allowed to realize *smart* cultural environments, whose “state” is captured by a set of sensors: from temperature/humidity sensors to social (user) devices.

We can thus imagine a novel scenario where *persons* (citizens, tourists, etc.) and *objects* (artifacts, buildings, rooms, etc.) conveniently equipped with the appropriate devices (smart-

phone, video cameras, temperature/humidity sensors, etc.) can communicate supporting a lot of cultural *context-aware* services (from multimedia storytelling of an artwork when a user is near to the related artifact, to cultural items' monitoring for preservation and security aims) and generating a very large amount of information that has to be properly managed leveraging proper infrastructures (Amato et al. 2012; Colace et al. 2015).

In particular, it is easy to note as the tremendous quantity of digital data within a smart cultural environment shows the well-known *Big Data* features, mainly due to their high change rate, their large volume, and the intrinsic heterogeneity, especially if we try to combine information coming from different cultural repositories and social media networks (Chen and Zhang 2014).

Thus, in the design of smart cultural environments, we have to necessarily contemplate big data technologies (i.e., distributed file systems, NOSQL and in-memory databases, models and engines for distributed processing, data ingestion and analytics, resource management facilities, etc.) and understand how CH information systems can leverage platforms based on such facilities to effectively and efficiently manage all the different kinds of data.

Also current work on infrastructures relevant to digital cultural objects, such as DARIAH and CLARIN, and large-scale aggregators of content, like EUROPEANA and ARIADNE, are now investigating how the use of big data technologies can improve the discussed CH fruition and preservation aspects.

In this entry, we first describe the main characteristics and functionalities required to a general big data platform for CH information management; then we present CHIS (cultural heritage information system), a big data system to query, browse, and analyze cultural digital contents from a set of distributed and heterogeneous digital repositories. In particular, the system prototype has been developed within DATABENC, the high technology district for cultural heritage management of the Campania Region, in Italy (www.databenc.it).

Functionalities and Features of a Big Data Platform for CH Applications

B

We can imagine a *smart cultural heritage environment* (e.g., museums, archeological sites, old town centers, etc.) as grounded on a set of cultural *points of interest* (PoI), which correspond to one or more cultural objects (e.g., specific ruins of an archeological site, sculptures and/or pictures exhibited within a museum, historical buildings, monuments and famous squares in an old town center, and so on) (Schaffers et al. 2011).

Consequently, a very large amount of data can be generated within such environments. In particular, we have to deal with heterogeneous information coming from different data sources:

- annotations provided by CH foundations' archives or digital libraries;
- descriptions from open encyclopedias (e.g., Wikipedia/DBpedia);
- sensor data related to environmental parameters (e.g., humidity and temperature) and captured by proper sensor networks deployed in a given PoI;
- multimedia contents – video, text, image and audio – coming from social media networks (e.g., Picasa, YouTube, and Flickr) and other kinds of digital libraries;
- social data as opinions and comments of users from common online social networks like Facebook, Twitter, etc.;
- any other kind of useful data gathered by means of web services, e.g., about other touristic attractions, or accommodations in the same geographic area, or meteorological information and so on.

In order to meet variety, velocity, and volume of all the described information related to a smart cultural environment, a general purpose CH big data platform has to be characterized by the following functionalities:

- capability to gather information from the distributed and heterogeneous data sources (e.g.,

- sensor networks, social media, digital libraries and archives, multimedia collections, etc.);
- advanced data management techniques and technologies;
 - system resources management;
 - real-time and complex event processing for monitoring and security aims;
 - ability to provide useful and personalized data to users based on their preferences/needs and context and advanced information retrieval services, data analytics, and other utilities, according to the SOA (service-oriented architecture) paradigm.

By means of a set of ad hoc APIs, and exploiting the discussed services, a CH big data platform has to be able to support several applications: mobile guides for cultural environments; web portals to promote the cultural heritage of a given organization, multimedia recommender, and storytelling systems; event recognition for cultural heritage preservation and security; and so on.

Concerning technical features, a big data platform for CH applications has to be built on a layered architecture (see Fig. 1). In the following, we describe the responsibilities of each layer.

The *resource management layer* has to coordinate and optimize the use of the different resources needed for implementing the whole system by means of the Resource Manager component.

The *data source layer* has as main goal to manage the “ingestion” of all the different data coming from the heterogeneous data sources. The data ingestion component can operate in a continuous or asynchronous way, in real-time or batched manner or both depending on the characteristics of the source. In addition, ingested data has to be then represented according to a given format.

The *stream processing layer* has to be used to provide real-time processing and event recognition activities on the data streams using a stream processing engine and a complex event processor (Cugola and Margara 2015; Panigati et al. 2015).

The *data storage and management layer* has to store and manage data of interest in a proper

knowledge base (KB) in compliance with a given data model, eventually exploiting the LD/LOD (linked data/linked open data) paradigm (possible data integration problems for heterogeneous data sources can be addressed by means of schema mapping, record linkage and data fusion techniques).

In addition, specific semantics to be attached to the data can be provided using annotation schemata, including ontologies, vocabularies, taxonomies, etc., related to the cultural heritage domain.

The KB can leverage different data repositories realized by advanced data management technologies (e.g., distributed file systems, NoSQL, in-memory and relational databases) and provides a set of basic APIs to read/write data by an access method manager.

The *data processing layer* has to provide a query engine that can be invoked by user applications.

It has as main task the search of data of interest using information retrieval facilities by means of proper information filters, as an example:

- query by keyword or tags and using specific metadata of the annotation schemata,
- query by example for cultural items with images,
- ontology based and query expansion semantic retrieval,
- etc.

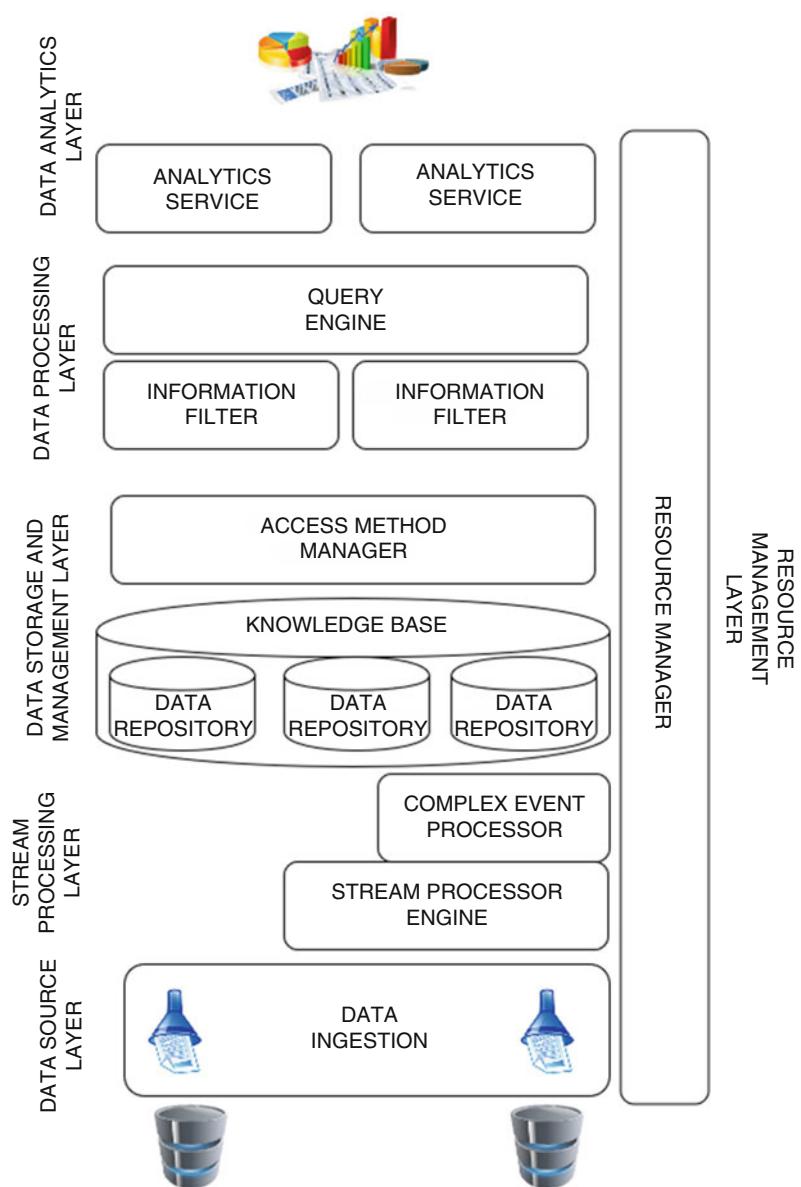

Finally, the *data analytics layer* is based on different analytics services allowing to create personalized “dashboards” for a given cultural environment. In addition, it provides basic data mining, graph analysis, and machine learning algorithms useful to infer new knowledge.

CHIS: A Big Data Platform for CH Applications

CHIS (cultural heritage information systems) (Castiglione et al. 2017) is the name of a big data platform which prototype was realized within

Big Data in Cultural Heritage, Fig. 1

Architecture of a big data platform for CH applications

the DATABENC project to support several CH applications.

It allows to query, browse, and analyze cultural digital contents from a set of distributed and heterogeneous digital repositories, providing several functionalities to guarantee CH preservation and fruition.

It shows all the functionalities and technical features required to a CH big data system. In the following, we describe the main characteristics, also providing some implementation details.

First of all, the CHIS data model is based on the concept of *cultural item*: examples are specific ruins of an archeological site, sculptures and/or pictures exhibited within a museum, historical buildings and famous squares in an old town center, and so on.

In the model, it is possible to describe a cultural item with respect to a variety of annotation schemata, by aggregating different harvesting sets of “metadata,” for example, the archeological view, the architectural perspective,

the archivist vision, the historical background, etc., as in the *Europeana Data Model* (EDM) (A proposal that aims at bridging the gaps between different harvesting standards providing a unique solution to metadata specification (<http://pro.europeana.eu/edm-documentation>)).

Stream processing of data from sensor networks has been realized according to a “publish-subscribe” paradigm; concerning its implementation details, CHIS uses *Apache Kafka* to realize message brokers and the publish-subscribe communication, *Apache Storm* as stream processing engine, and *Apache Zookeeper* as coordinator.

On the other hand, ingestion mechanisms from the other kinds of data sources (digital archives/libraries and social media networks) have been realized using the available APIs or by means of basic wrapping techniques.

All the extracted data are converted in a JSON format according to the described data model. In particular for multimedia contents, the descriptions in terms of metadata are captured and stored within CHIS, while raw data can be opportunely linked and, in other cases, temporarily imported into the system for content-based analysis (Bartolini and Patella 2015).

Data are then stored in the CHIS KB. In particular, the KB leverages a stack of different technologies that are typical of a big data system:

- The data describing basic properties of cultural items (e.g., name, short description, etc.) and basic information on users profiles are stored into a *key-value data store* (i.e., *Redis*).
- The complete description in terms of all the metadata using the different annotation schemata is in turn saved using a *wide-column data store* (i.e., *Cassandra*). A table for each kind of cultural objects is used, having a column for each “metadata family”; column values can be literals or URIs (according to LD paradigm).
- The *document store* technology (i.e., *MongoDB*) is used to deal with JSON messages, complete user profiles, and descriptions of internal resources (multimedia data and textual

documents, etc.) associated with a cultural item.

- All the relationships among cultural items within a cultural environment and interactions with users (behaviors) are managed by means of a *graph database* (i.e., *Titan*).
- The entire cartography related to a cultural environment together with PoIs is managed by a *GIS* (i.e., *PostGIS*);
- Multimedia data management has been realized using the *Windsurf* library (Bartolini and Patella 2015);
- CHIS exploits an *RDF store* (i.e., different *Allegrograph* instances) to memorize particular data views in terms of triples related to a given cultural environment and useful for specific aims, providing a SPARQL endpoint for the applications;
- All system configuration parameters, internal catalogues, and thesauri are stored in a relational database (i.e., *PostgreSQL*)
- All the basic analytics and query facilities are provided by *Spark* based on *HDFS*;
- Semantics of data can be specified by linking values of high-level metadata to some available internal (managed by *Sesame*) or external ontological schemata.

Eventually, several analytics can be performed on the stored data using graph analysis and machine learning library provided by *Spark*. As an example, the analysis of the graph coding interactions among users, multimedia objects, and cultural items can be properly used to support recommendation or influence analysis tasks.

This heterogeneous knowledge base provides basic *Restful* APIs to read/write data and further functionalities for importing/exporting data in the most common diffused web standards. CHIS adopts such heterogeneous technologies in order to meet the specific requirements of the applications dealing with the huge amount of data at stake.

For example, social networking applications typically benefit of graph database technologies because of their focus on data relationships.

In turn, more efficient technologies (key-value or wide-column stores) are required by tourism applications to quickly and easily access the data of interest.

The overall system architecture is made by using multiple virtual machines rent by a cloud provider, each equipped with *Hadoop/YARN* and *Spark* packages, accessing an horizontally scaling dynamic storage space that increases on demand, according to the evolving data memorization needs. It consists in a certain number of slave virtual machines (that can be increased over time in the presence of changing demands) and two additional ones that run as masters: one for controlling HDFS and another for resource management.

The CHIS platform has been then used to support several CH applications, as an example the multimedia guide for the *Paestum archeological site* described in Colace et al. (2015).

Concluding Remarks

This entry focused on the importance of big data technologies to support smart cultural environments. We outlined the main characteristics and functionalities required to a general big data platform for CH information management and described CHIS, i.e., a big data system to query, browse, and analyze cultural digital contents from a set of distributed and heterogeneous digital repositories, thus providing several functionalities to guarantee CH preservation and fruition.

[Big Data in cellular networks](#)

Definitions

The term **Big Data in mobile networks** refers to datasets generated by and collected from mobile cellular networks. Such datasets consist in both the actual user data transported by the network (e.g., voice or data traffic) and metadata and control messages supporting network management.

Overview

A mobile or cellular network is a telecommunication system characterized by a radio last mile and the capability of managing the mobility of end terminals in a seamless fashion (i.e., without interrupting the communication). Such a network is geographically distributed over area units called cells (from which the name *cellular* originates), each served by one or more radio transceivers called *base stations*.

Mobile networks are nowadays the most popular mean for accessing both the traditional public switched telephone network (PSTN) and the public Internet. According to a projection by GSMA, the trade association of mobile operators, 70% of people worldwide will be mobile subscribers by the end of 2017 (Iji 2017). Considering the high penetration of cellular devices, data practitioners look at mobile technologies as an unprecedented information source. Indeed, every terminal produces a large amount of meta-information that can be exploited not only for network optimization and troubleshooting tasks but also for less technical-oriented use cases, such as the study of aggregated human behaviors and trends.

The data volume transferred over an operational network, and the associated metadata such as billing records, deeply varies depending on the network size (number of customers, links, geographical distribution, etc.) and monitored interfaces and can reach rates of several tens of terabytes per day. The analysis of such massive amount of data requires specific system specifications in terms of scalability for storage and processing and ability to deal with historical and real-time data analytics, depending on the

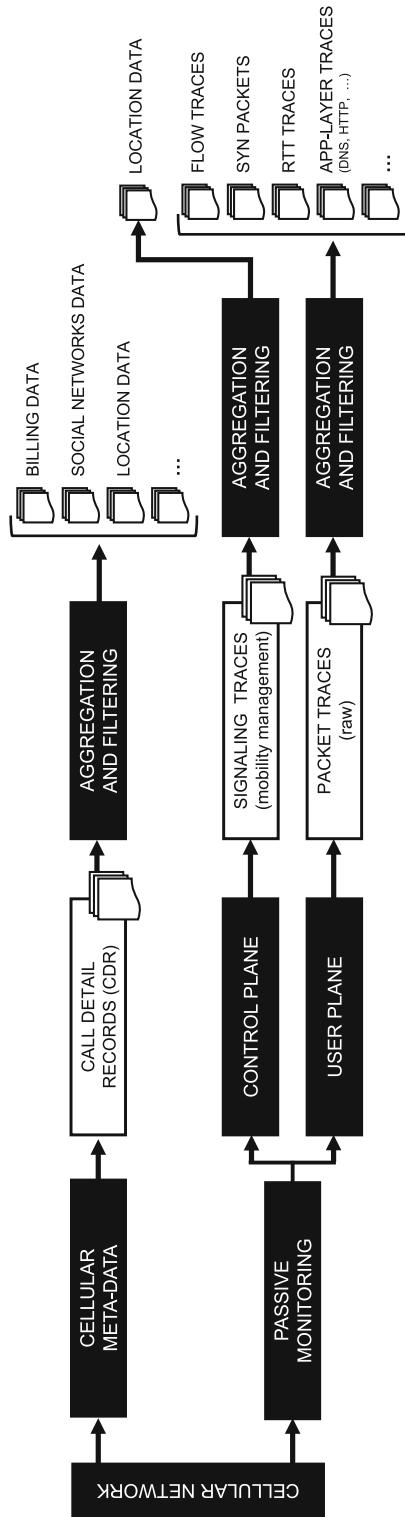

application field. Luckily, the progress in the field of Big Data analytics has facilitated the design and deployment of platforms for supporting Network Traffic Monitoring and Analysis (NTMA) applications in cellular context that meet these requirements. In particular, distributed frameworks based on the MapReduce paradigm have been recently started to be adopted in the field of NTMA, cfr. (Fontugne et al. 2014). Specifically, network monitoring approaches based on Apache Hadoop have been proposed in Lee and Lee (2012), while Liu et al. (2014) focus on rolling traffic analysis.

Cellular Data Types

Operational mobile networks generate an enormous amount of data, both on the **user plane** (e.g., user traffic transferred through the packet-switched domain or voice traffic through the circuit switched) and on the **control plane** (e.g., operators' billing data, signaling for terminals' mobility management and paging), as shown in He et al. (2016). In general, one can distinguish between two macro-groups of cellular data: **billing records** (also called CDR, inherently control data) and **passive traces** (which encompass both user and control data). Figure 1 shows a summary of the cellular data types.

Call Detail Record (CDR)

Call detail record (CDR) is the most extensively explored cellular data type. CDRs are metadata generated for supporting the billing of mobile subscribers. They consist in summary tickets of telephone transactions, including the type of activity (voice call, SMS, 2G/3G/4G data connection), the user(s) involved (the *caller* and the *callee*), a time stamp, technical details such as routing information, and the identifier of the cell offering connectivity to the terminal. The latter is especially interesting as it allows to localize the associated action in the boundaries of the cell's coverage area. In other words, CDRs carry details about subscribers' positions when they perform actions, aside from the details needed by the operator for charging them.

Big Data in Mobile Networks, Fig. 1 Summary of data types produced (or carried) by cellular networks. Billing metadata such as call detail records (CDRs) can be exploited for generating users' location data, social network information (from users' interactions), etc. Passively monitored traffic flowing in selected links allows the extraction of signaling messages of the cellular mobility management (which, in turn, provide fine-grained location and mobility data) and integral or partial user frames (packet traces) that can be further parsed to produce aggregated flow traces or filtered to application-specific traces

CDRs might not be as rich as other cellular data (e.g., signaling data including handover information), but they have been a popular study subject since the 2000s, in particular as a mean to observe human mobility and social networks at scale. The reason behind this interest should be sought in their rather high availability, as network operators are collecting these logs for billing which makes them a ready-made data source. They, in fact, do not require specialized infrastructure for the acquisition. Indeed, there is a fairly rich literature on the their exploitation for a plethora of applications, ranging from road traffic congestion detection and public transport optimization to demographic studies. Despite the initial interest, the research community gradually abandoned this data source as it has become clear that the location details conveyed by CDRs were biased by the users' activity degree. Specifically, the position of a user is observable in conjunction with an activity, which translates in the impossibility of locating a user with fine temporal granularity.

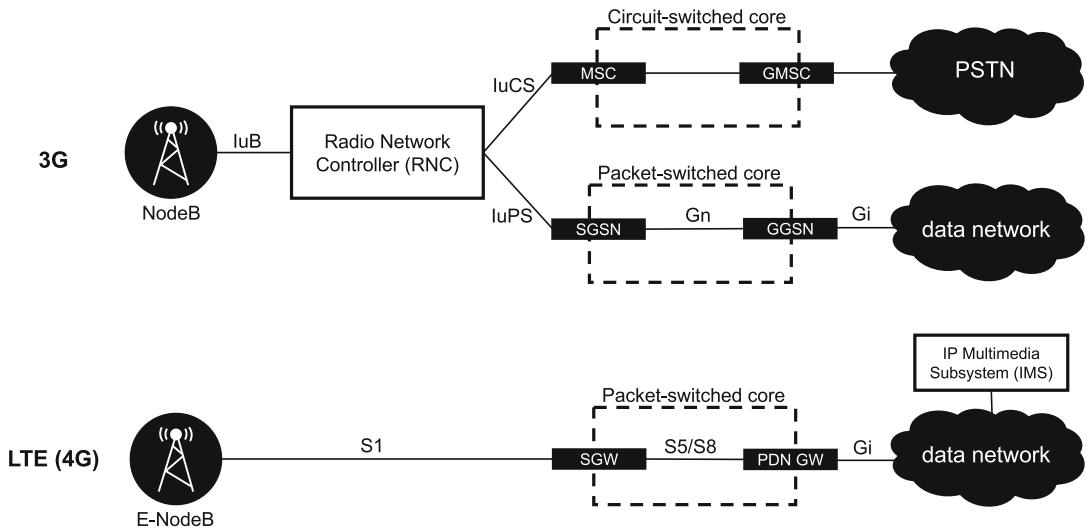

More recent studies (Fiadino et al. 2017), however, argue that the spreading of flat rates for voice and data traffic encourages users to generate more actions. In particular, competitive data plans are nowadays characterized by very high data volume limits, letting customers keep their terminals *always connected*. As a side effect, the quality of mobility data provided by CDRs improved as the average number of tickets per user has increased. A resurgence of research work tackling the study of CDRs is expected to happen in the next years. Indeed, the research community is already targeting some open issues, such as the lack of CDR standardization across operators and more accurate positioning within the cells' coverage areas (Ricciato et al. 2017).

Passive Monitoring

Passive traces are network logs collected through built-in logging capabilities of network elements (e.g., routers) or by wiretapping links through specialized acquisition hardware, such as data acquisition and generation (DAG) cards.

Nowadays, high-performance DAG cards are commercially available and are largely employed by cellular network operators in order to monitor their infrastructures at different vantage points (VPs). Passive measurements allow to gain network statistics at a large scale, potentially from millions of connected devices, hence with a high degree of statistical significance. This data type is intrinsically more powerful than CDRs: passive traces are exact copy of the traffic passing through a VP and open the possibility to fully reconstruct the activity of a mobile terminal through the study of both user traffic and control information. Needless to say, this poses serious challenges, in particular for what concern customers' privacy and the potential disclosure of business sensitive information. These issues have heavily limited the access to this kind of data to third parties and the research community.

The employment of passively collected traces for the purpose of network monitoring and management dates back to the 2000s: a first formalization of the techniques for passively monitoring mobile networks can be found in Ricciato (2006), where the author focuses on 3G networks and list common operator-oriented uses of the passively sniffed data. Despite the evolution of cellular networks (e.g., the passage from 3G to 4G standards), the main concept of passive monitoring has not changed much. Figure 2 illustrates a simplified cellular network architecture and highlights the links that can be wiretapped in order to collect passive traces. The cellular infrastructure is composed of two main building blocks: a radio access network (RAN), which manages the radio last mile, and a core network (CN). Fourth-generation networks (such as LTE) are characterized by less elements at the RAN, where the base stations (evolved NodeBs) are connected in a fully meshed fashion. The CN of 2G (GSM/EDGE) and 3G (UMTS/HSPA) networks is formed by the circuit-switched (CS) and the packet-switched (PS) domains, responsible for the traditional voice traffic and packet data traffic, respectively. In contrast, 4G networks are purely packet switched, as all type of traffic is carried over IP, including

Big Data in Mobile Networks, Fig. 2 A simplified representation of the 3G and 4G cellular network architecture. 3G networks are characterized by the presence of two cores (the packet switched, handling data connections, and

the circuit switched, handling traditional voice traffic). 4G networks have less network elements on the access network side and have just a packet-switched core, optimized for data connections

traditional voice calls which are managed by an IP multimedia subsystem (IMS).

In order to be reachable, mobile terminals notify the CN whenever they change location in the network topology (in other words, to which base stations they are attached to). Therefore, monitoring S1 (in LTE) or IuB/IuCS/IuPS interfaces (in 3G) would allow the collection of mobility information through the observation of network signaling (control) messages (i.e., **signaling traces**). Similarly to CDR datasets, an application for this type of traces is the study of human mobility, as specific signaling messages (such as *handovers*, *location area updates*, *periodic updates*, etc.) allow to reconstruct the trajectory of a terminal in the network topology, which, in turn, can be exploited to infer the actual mobility of the mobile customer with a certain degree of accuracy. These data could potentially provide a higher time granularity in the positioning of terminals w.r.t. CDRs, as the terminal's position is not necessarily observable in conjunction with an action (a call, SMS, data connection). The actual time granularity and position accuracy depend on multiple factors: activity state of the terminal (in general, *active* terminals provide their location changes with higher temporal granularity, even

when monitoring at the CN), monitored interfaces (the closer the passive sniffing occurred to the RAN, the higher the chance to get finer-grained positioning in the cellular topology), and use of triangulation (to calculate the position within the cell's coverage area, in case the signal strength is available). The interested reader might refer to Ricciato et al. (2015) for a comprehensive discussion on the passively observed location messages, their time and space granularity, and how they compare with the more popular CDRs.

Monitoring interfaces at the core of the PS domain, such as the Gn/Gi in 3G network and S5/S8/Gi interfaces in LTE, allows the collection of large-scale **packet traces**, i.e., a copy of frames at IP level augmented with metadata such as time stamps, the ID of the link where the wiretapping occurred, and a user (IMSI) and device (IMEI) identifier. The packet traces consist of the full frames (in case the payload is kept) or the header only. Cellular packet traces are extremely informative data, as they provide a complete snapshot of what happened in the network, supporting network management and troubleshooting (e.g., detection of network impairments, data-driven and informed dimensioning of resources, etc.) but also large-scale user

behavior studies (e.g., web surfing profiles, marketing analysis, etc.). For most applications, the header brings enough information, and therefore the payload can be discarded, making privacy and storage management easier. It should be noted that the payload is more and more often encrypted.

Raw packet traces can be further processed to produce more refined datasets. For example, by applying a *stateful* tracking of packets, it is possible to reconstruct **flow traces**, i.e., records summarizing *connections* (sequence of packets) between a source and a destination, aggregating by IPs and ports. Such logs could support, among others, the observation of throughput, latency, round-trip time (RTT), or other performance indicators that can be exploited for service-level agreement (SLA) verification and quality of service (QoS) studies. Another typical post-processing approach is filtering specific packet types (e.g., TCP SYN packets for the study of congestions over links and network security enforcement) or applications (i.e., **application-layer traces**, such as DNS, HTTP).

Uses of Cellular Data

In the last years, cellular network data has been broadly employed in different application areas, not necessarily with technical purposes. Indeed, the progress in the development of Big Data technologies, coupled with the decrease of prices for storage, has unlocked endless possibilities for the exploitation of the massive amount of data carried and produced by mobile networks.

In general, one can distinguish between two classes of use cases, i.e., **network-related** (tech-

nical) and **human-related** (nontechnical). The use cases in the first class aim at achieving *informed* network management and optimization actions, including more specific tasks such as detection of anomalies, troubleshooting, resource dimensioning, and security monitoring. Nontechnical applications focus on the study of human behavior relying on both user and control data exchanged among user equipments, cellular network components, and remote services. Some common human-related uses of cellular data are the study of human mobility (through CDRs or signaling messages), analysis of social networks, and web surfing behavior (through passively monitoring DNS or HTTP traffic at the CN), with applications in the field of marketing and behavioral studies.

The remainder of this section provide a non-exhaustive list of common uses of cellular data found in the scientific literature (also summarized in Table 1).

Technical Areas

The analysis of cellular data, and passive traces in particular, could support technical tasks aimed at achieving data-driven network engineering and optimization. There is an interesting research branch in this direction, targeting self-optimization, self-configuration, and self-healing based on machine learning approaches. One example is Baldo et al. (2014), where authors investigate the advantages of adopting Big Data techniques for **Self Optimized Networks** (SON) for 4G and future 5G networks. A comprehensive survey on the use of Big Data technologies and machine learning techniques in this field was edited by Klaine et al. (2017).

Big Data in Mobile Networks, Table 1 A non-exhaustive list of applications for mobile network data divided into two main categories (technical and nontechnical) plus a hybrid class of uses

Technical areas	Nontechnical areas	Hybrid areas
Anomaly detection	Churn prediction	Quality of Experience (QoE)
Traffic classification	Customer loyalty	
Network optimization	Web surfing	
Study of remote services	Marketing and tariff design	
Performance assessment and QoS	Human mobility	

Cellular passive traces can be also employed for studying the functioning and behavior of **remote Over The Top (OTT) Internet services** (Fiadino et al. 2016). Indeed, the popularity of mobile applications (e.g., video streaming, instant messaging, online social networks, etc.) poses serious challenges to operators as they heavily load the access of cellular networks. Hence, understanding their usage patterns, content location, addressing dynamics, etc. is crucial for better adapting and managing the networks but also to analyze and track the evolution of these popular services.

Congestions and Dimensioning

Nowadays, most of the services have moved over the IP/TCP protocol. The bandwidth-hungry nature of many mobile applications is posing serious challenges for the management and optimization of cellular network elements. In this scenario, monitoring congestions is critical to reveal the presence of under-provisioned resources.

The use of packet traces for the detection of bottlenecks is one of the earliest applications in the field of cellular passive monitoring. Ricciato et al. (2007) rely on the observation of both global traffic statistics, such data rate, as well as TCP-specific indicators, such as the observed retransmission frequency. Jaiswal et al. (2004) target the same goal by adopting a broader set of flow-level metrics, including TCP congestion window and end-to-end round-trip time (RTT) measurements. A more recent work that targets the early detection of bottlenecks can be found in Schiavone et al. (2014).

Traffic Classification

Network traffic classification (TC) is probably one of the most important tasks in the field of network management. Its goal is to allow operators to know what kind of services are been used by customers and how they are impacting the network by studying their passive packet traces. This is particularly relevant in cellular networks, where the resources are in general scarcer and taking informed network management decision is crucial.

The field of TC has been extensively studied: complete surveys can be found in Valenti et al. (2013) and Dainotti et al. (2012). Standard classification approaches rely on deep packet inspection (DPI) techniques, using pattern matching and statistical traffic analysis (Deri et al. 2014; Bujlow et al. 2015). In the last years, the most popular approach for TC is the application of machine learning (ML) techniques (Nguyen and Armitage 2008), including supervised and unsupervised algorithms.

The increasing usage of web-based services has also shifted the attention to the application of TC techniques to passive traces at higher levels of the protocol stack (specifically, HTTP). Two examples are Maier et al. (2009) and Erman et al. (2011), where authors use DPI techniques to analyze the usage of HTTP-based apps, showing that HTTP traffic highly dominates the total downstream traffic volume. In Casas et al. (2013a), authors characterize traffic captured in the core of cellular networks and classify the most popular services running on top of HTTP. Finally, the large-scale adoption of end-to-end encryption over HTTP has motivated the development of novel techniques to classify applications distributed on top of HTTPS traffic (Bermudez et al. 2012), relying on the analysis of DNS requests, which can be derived by filtering and parsing specific passive packet traces.

Anomaly Detection

Anomaly detection (AD) is a discipline aiming at triggering notifications when unexpected events occur. The definition of what is unexpected – i.e., what differs from a normal or predictable behavior – strictly depends on the context. In the case of mobile networks, it might be related to a number of scenarios, for example, degradation of performance, outages, sudden changes in traffic patterns, and even evidences of malicious traffic. All these events can be observed by mining anomalous patterns in passive traces at different level of granularities.

A comprehensive survey on AD for computer networks can be found in Chandola et al. (2009). An important breakthrough in the field of AD in large-scale networks was set by the work of

Lakhina et al. (2005), where authors introduced the application of the principal component analysis (PCA) technique to the detection of network anomalies in traffic matrices. Another powerful statistical approach tailored for cellular networks has been presented in D’Alconzo et al. (2010). The same statistical technique has been expanded and tested in a nationwide mobile network by Fiadino et al. (2014, 2015).

The study presented in Casas et al. (2016a) is particularly interesting: it applies clustering techniques on cellular traces to unveil device-specific anomalies, i.e., potentially harmful traffic patterns caused by well-defined classes of mobile terminals. The peculiarity of this kind of studies consists in the use of certain metadata (device brand, operating system, etc.) that are observable in passive traces collected in mobile networks (in general, monitoring fixed-line networks does not provide such degree of details on the subscribers).

User-Oriented Areas

Mobile network data implicitly bring large-scale information of human behavior. Indeed, operators can mine the satisfaction of users by observing their usage patterns. This type of analysis has clear applications in the fields of marketing, tariff design, and support business decisions in a data-driven fashion. An example is the **prediction of churning users** (i.e., customers lost to competitors): the study presented in Modani et al. (2013) relies on CDRs – and on the social network inferred from them – to extract specific behaviors that lead to termination of contracts.

Another area of user-oriented research is the study of the **quality of experience (QoE)**. The term QoE refers to a hybrid network- and human-related discipline that has the goal of estimating the level of satisfactions of customers when using IP-based services. In other words, practitioners in this field try to map network performance indicators (e.g., throughput, RTT, latency, etc.) with subjective scores assigned by users in controlled environments. Some examples of QoE studies conducted over cellular network data are Casas et al. (2013b, 2016b). In these works, authors study the QoE of popular applications accessed

through mobile devices from the perspective of passive cellular measurements, as well as subjective tests in controlled labs. The performance of multimedia services (VoIP, video streaming, etc.) over cellular networks is affected by a number of factors, depending on the radio access network (signal strength), core network setup (internal routing), and remote provisioning systems. This class of studies helps operators in properly dimensioning network resources not only to meet provisioning requirements from the network perspective but also taking into account the actual perception of quality by final users.

Human Mobility

The exploitation of mobile terminals and cellular networks as source of mobility information is possibly the most popular human-oriented topic in the field of mobile network data analysis. Cellular-based mobility studies have a high number of applications (e.g., city planning, analysis of vehicular traffic, public transportation design, etc.). Recently, cellular location data has been exploited to study the population density (Ricciato et al. 2015) and to infer socioeconomic indicators and study their relationship with mobility patterns (Pappalardo et al. 2016).

Mobility studies through cellular data are based on the assumption that the movements of a terminal in the context of the network topology reflect the actual trajectory of the mobile subscriber carrying the device. Location information can be extracted from CDRs or signaling messages devoted to the mobility management of terminals. Most of the existing literature is based on CDRs (Bar-Gera 2007; González et al. 2008; Song et al. 2010). However, since CDR datasets only log the position of users when an action occurs, their exploitation for the characterization of human mobility has been criticized (Ranjan et al. 2012). In Song et al. (2010), authors highlight some concerns in this direction and also show that users are inactive most of the time. The main limitation lies in the fact that the mobility perceived from the observation of CDRs is highly biased, as it strictly depends on the specific terminals’ action patterns. In other words, users are *visible*

during few punctual instants, which makes most of movements untraceable. Fiadino et al. (2017) claim that the situation is changing and nowadays CDRs are richer than the past, due to the increasing usage of data connections and background applications that has consequently increased the number of records. The now higher frequency of tickets allows a finer-grained tracking of users' positions. Some recent mobility studies, such as Callegari et al. (2017) and Jiang et al. (2017), are, in fact, successfully based on CDRs.

Few studies have explored more sophisticated approaches based on passively captured signaling messages – e.g., handover, location area updates, etc. Caceres et al. (2007). In Fiadino et al. (2012), authors studied the differences between CDRs and signaling data in terms of number of actions per user. Depending on the monitored interfaces, these approaches greatly vary in terms of cost and data quality (Ricciato 2006). Although the analysis of signaling is promising, there is a general lack of studies based on actual operational signaling data (some exceptions are the works by Fiadino et al. (2012) and Janecek et al. (2015), where authors focus on the study of vehicular traffic on highways and detection of congestions), as complex dedicated monitoring infrastructures for the extraction and immense data storage systems are required.

Privacy Concerns

The collection and exploitation of cellular data might raise some concerns. Indeed, given the penetration of mobile devices and the modern usage patterns, cellular networks carry an extremely detailed ensemble of private information. As seen before, by observing cellular metadata or specific network traces, it is possible to reconstruct the mobility of a mobile subscriber and infer the list of visited places, learn the acquaintances and build social networks, and even study the web surfing habits.

Customers' activity is associated to unique identifiers, such as the IMSI (International Mobile Subscriber Identity) and the IMEI (International Mobile Equipment Identity). These IDs

make it possible to link all the collected logs to single users and, in turn, to their identity. To protect customers' privacy, the **anonymization** of such unique identifiers is a common practice adopted by operators before handing privacy-sensitive datasets to internal or third-party practitioners. Indeed, sharing network traces with external entities is critical in some applications, e.g., detection of attacks with federated approaches (Yurcik et al. 2008).

A typical anonymization technique consists in applying nonreversible hashing functions, such as MD5 or SHA-1, with secret salt values to IMSI and IMEI. Being these hash functions cryptographically safe, it is still possible to associate all logs and actions of a single user to an anonymous identifier, with limited risks of *collisions* (differently from other simpler approaches, such as truncation of the last digits of customer identifiers). In addition, their one-way nature prevents reconstructing the original IDs. There is a rather rich literature on advanced anonymization techniques: a recent example can be found in Mivule and Anderson (2015).

It should be noted that all the listed applications for cellular data target macroscopic behaviors, observing users' traces on the large scale. The cases in which a single user needs to be addressed are rare and restricted to specific uses (e.g., detection of malicious users) or following authorized legal warrants. Nevertheless, the industry and the research community are addressing such concerns. For example, Dittler et al. (2016) propose an approach for location management that protects users' location privacy without disrupting the basic functionalities of cellular networks. On the other hand, the increasing adoption of encryption protocols to transport user data (e.g., HTTPS, instant messaging and VoIP with end-to-end encryption, etc.) limits some potentially abusive uses of passive traces.

Big Data in Network Anomaly Detection

Duc C. Le and Nur Zincir-Heywood
Dalhousie University, Halifax, NS, Canada

Synonyms

Network anomaly detection; Network normal traffic/Behavior modeling; Network outlier detection

Definitions

Network anomaly detection refers to the problem of finding anomalous patterns in network activities and behaviors, which deviate from normal network operational patterns. More specifically, in network anomaly detection context, a set of network actions, behaviors, or observations is

pronounced anomalous when it does not conform by some measures to a model of profiled network behaviors, which is mostly based on modelling benign network traffic.

Overview

In today's world, networks are growing fast and becoming more and more diverse, not only connecting people but also things. They account for a large proportion of the processing power, due to the trend of moving more and more of the computing and the data to the cloud systems. There might also come the time when the vast majority of things are controlled in a coordinated way over the network. This phenomenon not only opens many opportunities but also raises many challenges at a much larger scale.

Due to the ever-expanding nature of the network, more and more data and applications are being created, used, and stored. Furthermore, novel threats and operational/configuration problems start to arise. This in return creates the environment for systems such as the network anomaly detection to become one of the most prominent components in the modern networks.

Examples of anomalies on the network

Network anomalies are mostly categorized into two types: performance-related anomalies and security-related anomalies (Thottan and Ji 2003).

- *Anomaly in performance* This type of anomalies represents abrupt changes in network operations. Most of the time, they may be generated by configuration errors or unexpected shifting in the network demand or supply resources. Several examples of such anomalies include server or router failures and transient congestions. A server failure, such as a web server failure, could occur when there is a swift increase in the demand for the site's content to the point that it exceeds the capabilities of the servers. Network congestion at short time scales occurs due to hot spots in the network that may be caused by the

failures of network devices or connections or excessive traffic load at specific regions of the network. In some instances, network anomalies could be the result of errors in the network configuration, such as routing protocol configuration errors causing network instability.

- *Anomaly in network security* This is the main focus of many research works in the literature, where the network anomalous behaviors are caused by security-related problems. Examples are distributed denial-of-service (DDoS) attacks and network anomalies caused by intrusions or insider threats. DDoS attacks are conceivably one of the most noticeable types of anomalies, where the services offered by a network are disrupted. This effectively prevents normal user from accessing the content by overloading the network infrastructures or by disabling a vital service such as domain name server (DNS) lookups. In case of network intrusions, once the malicious entity obtained the control of some parts of a network, those network resources could end up being used for a large scheme DDoS attack or for other illegitimate resource-intensive tasks. On the other hand, similar to insider threats, the attackers could silently exploit the controlled resources to gather valuable information and credentials, such as credit cards and user ID and passwords, or organization's operational information and strategies. This could result in more resilient, hard to disclose types of anomalies, which in many cases may be overlooked by many anomaly detection systems.
- Another type of anomaly that may appear on the network is the shift or drift in the normal network behaviors. This is labelled as anomalous in many cases, because a deviation is seen compared to the modelled behaviors. Based on specific anomaly detection systems, these observations can be seen as informational alerts or just simply false positives.

Generally, in a specific work, only one type of anomaly is considered the main focus, but from network anomaly detection perspective in this chapter, all types are important and critical

to network operations. The correctly identified deviation from normal network behavior may indicate the troubles in the network configuration, unusual high network demands, connection failures, breached security, or attacks on the network. All of this information is crucial for the health of the network.

From the examples above, given the scale of today's networks, network anomaly detection easily becomes one typical example of big data applications (Laney 2001):

- *High volume* The network anomaly detection data can come from a wide range of sources. Network data collected at host level (from servers to personal devices to things) can be traffic log/capture, system data, or application/user data. At the network level, data can be collected from network probes, network traffic capturing devices, or management data (which can be routers, switches, firewalls) in different locations across the network. Given the scale of networks and the connected devices/systems on the Internet today, one can easily imagine the unprecedented amount of data generated by networks that needs to be analyzed each day. A medium-sized Internet service provider or any organization, such as a university, with a thousand users, can easily collect terabytes of data a day for analyzing. Furthermore, anomaly detection requires processing and modelling of network data over a sufficiently long period for detecting peculiar behaviors in new data.
- *Velocity* Network data is generated perpetually at high speed. Especially, the network anomaly detection problem requires the data to be processed quickly to deal with any possible arising problems within a timely manner.
- *Variety* As stated above, network anomaly detection data comes from a wide variety of sources, from numeric data summarizing network activities to structured time sequence data and unstructured data from mixed sources all over the network and systems. Moreover, variety also comes when the context of networks is expanded to include cellular net-

works or to cyber-physical systems such as power grids and transportation networks.

- *Variability* In addition to the increasing velocities and varieties of data, network data is notorious for including both stationary and nonstationary behaviors. The data stream is not only fluctuated by time but also constantly changing based on the applications and services users employ. This can be challenging to model, understand, and manage.
- *Complexity* Network anomaly detection is a complex task, firstly because analyzing network data itself is hard in nature. Network data comes from multiple sources and at different levels of the network protocol stack. This in return makes it difficult to link, match, cleanse, and transform the data across systems. Besides, most of the network traffic is encrypted to some extent, which inhibits direct analysis of the content. Secondly, anomalies usually are rare events that can easily be overlooked in the mountain of network data gathered a day, making the task "looking for a needle in a haystack." Finally, the task of finding network anomalies is also vague, because anomalies are basically not defined on its own but by a deviation from what is modelled to be the normal behavior for a given system/device.

Literature Review in Network Anomaly Detection

Network anomaly detection has a vibrant development history connected to the growth of networks and connected systems. There have been a good number of techniques for network anomaly detection developed by researchers. In this section, a broad classification of network anomaly detection methods based on the use of big data/machine learning applications is adopted for summarizing anomaly detection techniques.

Early research focused on applying predefined rules and patterns or statistical tools for the task (Thottan and Ji 2003; Bhuyan et al. 2014).

- Rule-based and pattern matching approaches mainly relied on expert systems encoded in a set of rules and patterns for matching against incoming network traffic and behaviors. Examples of this category are Snort and Bro, where anomaly detection can be done in rules or scripts to identify excessive amount in specific properties, such as utilization of bandwidth, the number of open transmission control protocol connections, or the number of Internet control message protocol packets, which exceeds a predefined threshold.
- Ontology and logic-based approaches attempt to model network behaviors using expressive logic structures, such as finite state machines and ontologies for encoding knowledge of experts in the domain. In those models, the sequence of alarms and actions obtained from different locations on a given network are modelled by a reasoning model designed by the experts not only for detecting anomalies and known intrusions but also describing and diagnosing the related problems. Notable works in this category are by Ilgun et al. (1995) and Shabtai et al. (2010), which are based on the state machine model and the knowledge-based temporal abstraction, respectively.

The efficiency of the above approaches quintessentially depends on the accuracy of expert knowledge embedded in the defined rules, patterns, and ontologies. Thus, it is possible that the constructed models do not adapt adequately to the evolution in the network and cybersecurity environments, allowing new faults and threats evade detection. Moreover, given a new network, it may be necessary to spend a considerable amount of time to model the needs for specific patterns/rules for building traffic models to match network conditions. As network topologies and traffic conditions are expanding and evolving, the techniques based on traffic inspection and rule/pattern/model matching may not scale gracefully.

Envisioning the scale and variability of networks and their potential growth in the near future, one can easily realize the need for more

efficient and easily adaptable tools for anomaly detection. Thus, machine learning techniques naturally found applications in this field for their ability to automatically learn from the data and extract patterns that can be used for identifying anomalies in a timely manner. Although most of the machine learning applications in cybersecurity generally and intrusion detection specifically are based on supervised learning techniques, in anomaly detection, unsupervised learning is the most applied technique due to the ability of learning without the label information, i.e., a priori knowledge of anomalies, which essentially is the defining characteristic of anomaly detection.

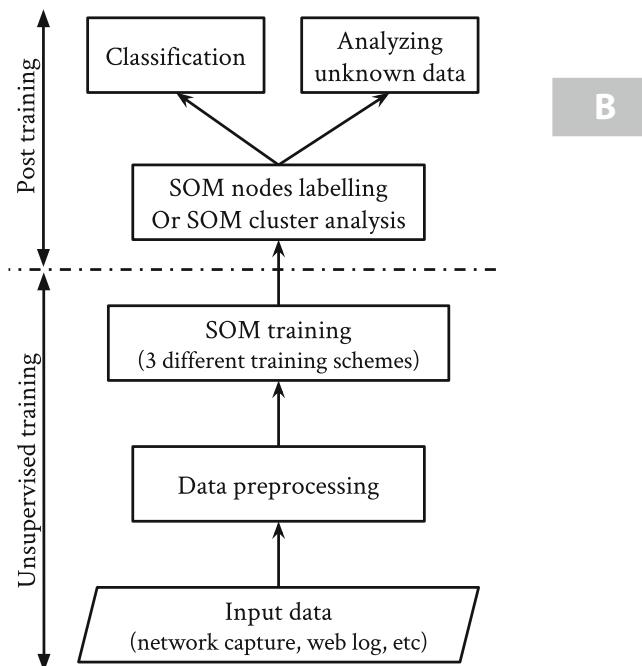

- Unsupervised learning techniques can be used to construct a model generalizing normal network and user behaviors and producing measures which could be used to detect anomalies in network traffic. Examples of different works in this area are by Dainotti et al. (2007, 2009), where temporal correlation, wavelet analysis, and traditional change point detection approaches are applied to produce a network signal model and worm traffic model, and (Sequeira and Zaki 2002) and (Rashid et al. 2016), where user profiles are created from the sequence of user actions in a time window using clustering techniques and hidden Markov model.
- A more direct approach using unsupervised learning for anomaly detection is applying clustering analysis and outlier detection methods. In this approach, clustering algorithms are used to find significant clusters representing majority of normal network/system behaviors. From clustering results, anomalies can be detected automatically as the data instances that do not fit into the constructed clusters of normal data using outlier detection methods. Notable works are Otey et al. (2006), Jiang et al. (2006), Finamore et al. (2011) and Casas et al. (2012).
- Unsupervised learning results can be analyzed by human experts with or without the use of visualization and other supervised learning methods to give more insight. Notable works are Kayacik et al. (2007), Perdisci et al.

(2006) and Leung and Leckie (2005). The self-organizing map (SOM) is a well-known unsupervised learning technique with the ability of not only summarizing the data learned in a topologically preserved way but also presenting the data visually for further inspection (Kayacik et al. 2007; Le et al. 2016; Rajashekhar et al. 2016). Recently, Veeramachaneni et al. (2016) brings the concept of big data closer to anomaly detection, where human experts, multiple outlier detection techniques, and supervised learning are combined to learn from a large amount of data to detect network anomalies and intrusions.

Key Research Findings on Network Anomaly Detection

This section describes a framework based on unsupervised machine learning for network data analysis and is applicable to network anomaly detection (Fig. 1). Following the progress of research described above, one can easily notice one trend in network anomaly detection research. That is to apply machine learning tools with strong pattern recognition and visualization abilities not only to learn from the data and extract results but also to incorporate the domain expert's knowledge and support network administrators. Having a unique combination of unsupervised learning and topology preserving visualization capabilities (e.g., producing hit maps, U-matrix), self-organizing map (Kohonen 2001) is applied in the framework as the underlying technique to support network data analysis in a wide range of conditions.

Fundamentally the framework is based on a *data-driven* approach using unsupervised learning with visualization abilities to learn a wide range of network and system behaviors with minimum prior knowledge. The data is extracted to numerical vectors; examples are network flows from traffic captures or access request characteristics for web log files. Subsequently, the data is preprocessed, for normalization purposes or for dimensionality reduction purposes, before being input to the SOM learning algorithm. Three dif-

Big Data in Network Anomaly Detection, Fig. 1
Proposed framework architecture

ferent schemes based on different training data compositions were tested in the framework: (i) use both known legitimate (normal) and known malicious data for training purposes, as done in the previous supervised learning approaches; (ii) use only legitimate data, as done in the previous anomaly detection methods; and (iii) use only malicious data, as done in some of the previous one-class classifier approaches. The reason behind these training schemes is to not only represent the real-life data acquisition conditions but also to shed light into understanding the performance gains/losses under different types/amounts of labelling information, i.e., ground truth. For example, the data collected by honeypots is usually only considered as being representative of malicious behavior. On the other hand, in idealistic cases of networks where there are no previous attacks, the data collected contains only legitimate traffic. Moreover, even when a threat is discovered in the collected traffic, it is very challenging to fully identify the extent of the threat and label the data collected.

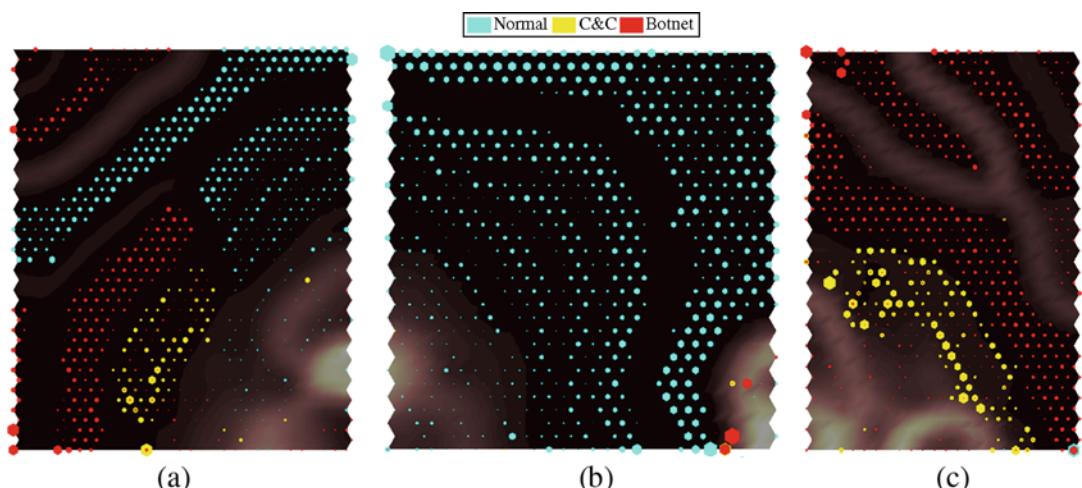

The SOM is trained in an unsupervised manner, with the assumption that learning solely from data, it could learn well-separated clusters to differentiate distinct communication behaviors. Post training, to quantify the system performance, if the ground truth of the training data is available, can be used for labelling the SOM nodes. On the other hand, when label information is not available, cluster analysis based on the trained SOM topology visualization can be used along with expert knowledge and information from other sources to derive meaningful insights from the data. The SOM-based framework then can be used to analyze incoming network data and support network administrators in operation by visualizing the traffic.

Examples of applications The framework can be applied in many network situations with different sources of data and domain knowledge incorporated. Some applications are presented in detail in Le et al. (2016) and Le (2017). In this chapter, a brief description of one example in applying the framework for network flow data analysis in order to detect Virut botnet in a mixed dataset from García et al. (2014) is presented.

Network flows are the summary of connections between hosts, which include descriptive statistics that are calculated from aggregating

Network and Transport layers' header information of the transmitted packets and can be independent from the application layer data. Given that network traffic encryption is very popular in both benign applications for protecting users' privacy and sensitive information, and malicious applications for hiding from the detection systems analyze network packet payload, the detection approach using only netflows exported from packet headers may improve the state of the art in unsupervised learning-based data analysis. Furthermore, the use of network flows can significantly reduce the computational requirement of a network monitoring system by allowing the analysis of each flow as a summary of packets and avoiding deep packet inspection.

Figure 2 presents the results obtained using the three training schemes in the framework. It is clear that the first training scheme, where SOM is formed using both known normal and malicious data, was able to form well-separated regions for the classes and achieve 99.9% detection rate with only 0.6% false-positive rate. Similarly, the second training scheme, which is the most suitable for network anomaly detection applications where only normal data is used to form the SOM, achieved promising results at 80.9% detection rate and 6% false-positive rate. Figure 2b shows that SOM trained using scheme (ii) was able to

Big Data in Network Anomaly Detection, Fig. 2 SOM visualization of test data in the Virut dataset based on the three training schemes. (a) scheme (i) (b) scheme (ii) (c) scheme (iii)

identify the malicious data by mapping them to an unpopular region, which is distanced from the training data. On the other hand, scheme (iii) SOM was able to differentiate only 3.4% of the normal data from the malicious data used for training (Fig. 2c). The visualization capabilities supported by the framework, as shown in Fig. 2, could give network administrators options to quickly analyze network data, even without ground truth by accessing the regions formed by the SOM. In-depth analysis and details of applications of the framework in other use cases, such as web attack and novel botnet detection, can be found in Le (2017).

Challenges in Applying Big Data in Network Anomaly Detection

Although machine learning has been extensively applied in the task of anomaly detection, there are certain challenges that need to be overcome for a successful realization of research results in production network environments. First and foremost, there are challenges which come from the nature of the anomaly detection task that all the approaches, including machine learning-based approaches, must address. Some of them are already summarized in Sommer and Paxson (2010).

- The problems related to the data:
 - Network data is diverse and abundant, yet obtaining high-quality data for designing and evaluating anomaly detection systems typically involves considerable difficulties. Many companies and organizations are prevented from sharing data by agreements protecting users' identities and privacy. Even when the data is shared, most of it comes without any form of ground truth for training and evaluating anomaly detection systems with confidence.
 - Secondly, network anomaly detection data is highly skewed; most of the time, only a small unidentified portion of data is anomalous. One example is insider threats,

where the attackers can perform malicious actions over a long duration, sometimes months (or longer) to evade monitoring systems. Hence detection systems and network operations team could fail to recognize the small changes as the sign of anomalies.

- Network data can be encrypted and/or anonymized, which may inhibit many detection systems that monitor network traffic.
- In many cases, the developers may face the dilemma of impurity in training data. This can seriously affect the efficiency of anomaly detection systems, as a model inadvertently built with abnormal data would encode that as a normal behavior, which makes it incapable to detect future anomalies of the type.
- The very nature of anomaly detection may itself pose a problem to developers in defining an anomaly and in distinguishing it from normal network behaviors. Similarly, machine learning techniques may have trouble identifying the novel behaviors that are dissimilar from learned patterns for anomaly detection tasks. This is unlike other applications of machine learning, such as classification and recommendation systems, where the main focus is in finding similarity.
- There are significant challenges in generalizing anomaly detection methods to become independent of the environment. Different network environments usually have different requirements and conditions for defining normal and anomaly behaviors. Moreover, in each network the concepts of anomaly and normal profiles are continuously shifting or drifting. Therefore, it is necessary to study dynamic, adaptive, and self-evolving anomaly detection systems to overcome limitations of the traditional static models.
- Ideally, an anomaly detection method should pursue highest anomaly detection rates while avoiding a high rate of false alarms. However, in designing a novel anomaly detection method, one always has to take into account a trade-off between the two measures.

Considering the dominance of normal data and the scale of networks, even a small false-positive rate may result in a catastrophic amount of false alarms that need attention from human experts – network operations team. Lessons have been learned that the detection systems with low precision would be impractical for production network environments. This requires the anomaly detection system not only to have the ability to detect abnormal network behaviors but also to correlate and to learn from the alarms in order to provide meaningful feedback to/from human experts to improve.

To apply big data successfully in the anomaly detection problem, not only the aforementioned challenges but also the greater scope and scale of challenges need to be addressed and overcome. These include but are not limited to the following aspects of network-based systems:

- Runtime limitation presents an important challenge for a network anomaly detection system, especially when big data is applied to deal with larger networks. Reducing computational complexity in preprocessing, training, and deployment of such systems is a priority.
- Data for network anomaly detection systems is presented at multiple levels of granularity and formats. The data can be acquired at host or network level, from end devices, network devices, security devices, or servers, in different formats and structures. In small networks, the data can be processed manually by experts; however, when it comes to big data applications, the problem of data acquisition, data representation, and preprocessing must be addressed systematically in order to provide high-quality data for training big data algorithms efficiently. Similarly, developing appropriate and fast feature selection methods is crucial not only to ensure efficiency of anomaly detection systems but also to provide compact representation of the data with sufficient information.

- The very nature of network is streaming. In small networks, gradual drifting and shifting of behaviors and concepts in data can be addressed by retraining learned data models periodically. However, in big data applications, the prevalent phenomenon needs to be addressed adequately from a system design perspective. This requires dynamic and adaptive learning algorithms and self-evolving architectures that are capable of working on high-speed data streams. Furthermore, such systems need to have capabilities for revising/updating themselves in a timely manner according to the ever-changing dynamics of the network environment without sacrificing from their detection performances.
- In big data environments, there is a significant challenge in converting anomaly warnings to meaningful alerts and producing patterns for future prediction, considering the tremendous amount of data that a warning system must process a day. This will require big data systems that are able to cooperate with human experts and continuously learn from human input to evolve itself to adapt to the new normal and malicious behaviors on the network.

Conclusion

Network anomaly detection has become more and more prevalent and crucial to monitor and secure networks. Given the scale and dynamics of a network, developing practical big data applications for the task is an open field of research. Due to the very nature of network data and learning algorithms, many traditional approaches for network analytics and anomaly detection are not scalable. Moreover, novel and task-specific challenges need to be addressed earnestly in order to successfully introduce new big data applications to the field.

Future directions for research In light of the challenges discussed above, we aim to help to strengthen the future research on big data applications for anomaly detection systems by a concrete set of recommendations:

- Drift and shift in network data streams can be addressed using active online learning algorithms (Khanchi et al. 2017).
- Dynamic anomaly detection systems should be capable of learning from multiple sources such as the offline data sources, streaming data sources, expert knowledge, and feedbacks. It has been shown in Le et al. (2016) that learning algorithms with visualization capabilities not only achieve the goals of anomaly detection via clustering and outlier detection techniques but also provide a handy tool for network managers to acquire insights of the different network behaviors. This also enables the involvement of network experts in designing and developing machine learning-based systems.
- The utility of network flows as metadata has been shown to increase the learning efficiency and overcome the opaqueness of the data under certain conditions (Haddadi and Zincir-Heywood 2016). This implies that novel data representation and summarization techniques could help to speed up the implementation and evolution of anomaly detection systems.

Big Data in Smart Cities

Zaheer Khan¹ and Jan Peters-Anders²
¹University of the West of England, Bristol, UK
²Austrian Institute of Technology, Vienna, Austria

Synonyms

Smart cities or future cities; Smart City Big Data or large-scale urban data and/or city data

Definitions

A smart city is a city which invests in Information and Communication Technology (ICT) enhanced governance and participatory processes to develop appropriate public service, transporta-

tion, and energy infrastructures that can ensure sustainable socioeconomic development, healthy environment, enhanced quality-of-life, and intelligent management of environment and natural resources. From a technology perspective, smart cities are focused on capturing, processing, and making effective use of heterogeneous, temporal, and ever increasing large-scale or big urban data.

Overview

City governance is a complex phenomenon and requires new combinations of top-down and bottom-up ICT-enabled governance methodologies to efficiently manage cities. Cities are a major source of urban, socioeconomic, and environmental data, which provide basis for developing and testing Smart City solutions. The notion of Smart Cities has gained a lot of momentum in the past decade. City administrators have realized the potential for ICT to collect and process city data and generate new intelligence concerning the functioning of a city that aims to secure effectiveness and efficiency in city planning, decision-making, and governance. Without urban data and use of ICT, this intelligence either cannot be generated or requires considerable resources, e.g., financial, human, etc.

Recent publications in smart cities domain emphasize better use of urban data by developing innovative domain specific applications which can provide new information or knowledge (Khan et al. 2012, 2014a, 2015; Garzon et al. 2014; Soomro et al. 2016). This new knowledge can be used by city administrations, citizens, and private sector organizations to effectively and efficiently manage their daily activities and/or business processes, as well as the decision-making processes that underpin the governance of the city. The city data is generated from various thematic domains (e.g., transport, land-use, energy, economic, climate, etc.); however, there is little debate on the holistic view of cross-thematic city data which requires Big Data management approaches and high performance computing

paradigms like cloud computing (Khan et al. 2015).

In this entry, we provide a holistic view of Smart City Big Data by reviewing different Smart City projects and applications (UrbanAPI, DECUMANUS, Smarticipate), describing cross-thematic domain Big Data and data management challenges cities face and for which they require appropriate solutions. We also list various datasets available in cities and share lessons learned from the above-mentioned projects.

Smart Cities Big Data: A Holistic View

Smart Cities are tightly coupled with data and information which can be used for knowledge generation to take decisions aiming to resolve societal challenges concerning the quality of life of citizens, economic development, and more generally sustainable city planning. In this section, we try to answer the question: Is Smart City data really Big Data? In this respect, we try to present different facets of Smart Cities data aligned with the main “V” characteristics of the Big Data paradigm, i.e., *variety*, *volume*, and *velocity*. To our knowledge there are several research publications on individual Smart City applications, but a holistic view of the variety of data available in cities is not evident in the current literature.

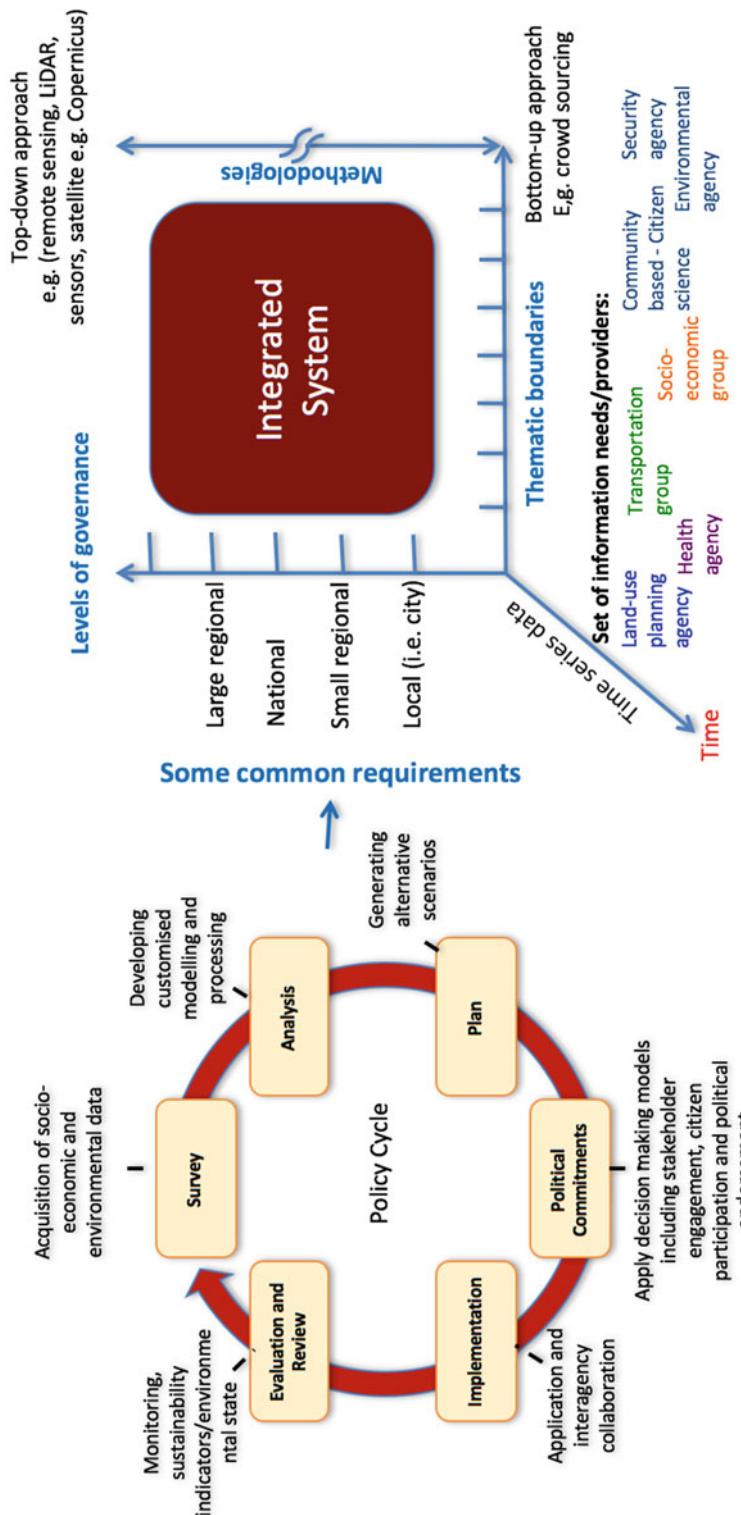

City data includes socioeconomic, built-environment, and environmental data that can be utilized for data analytics to generate useful information and intelligence. Often this data is collected using conventional methods such as daily local business transactions with city administrations, opinion surveys, traffic counters, LiDAR earth observation, sensors for environment monitoring (e.g., noise, air quality, etc.), and well-being and quality of life data from health agencies. More advanced methods like satellite based earth observation imagery (e.g., land monitoring, energy loss, climate change) are also being used to develop the information and intelligence base for analysis across a range of scales from local to city and city-region. Most of the city data has geo-

coordinates which provide location context. This location context helps to perform investigation and data analysis associated with specific areas in cities. This data is stored in different city repositories often managed by different city departments. Some processed data is partly made accessible through open data initiatives (Open Government Data 2017). Often individual elements of open data cannot provide useful information on their own, but when integrated with data from various other data sources (e.g., basemaps, land-use, etc.), it becomes extremely useful to determine the possible effects and impacts of planning interventions that influence the future development of the sustainable Smart City. In addition to the above data sources, new technological inventions such as Internet of Things (IoTs), smart phones (call data records), social media, etc., are also adding to the huge amount of existing urban data.

Figure 1 shows where Smart Cities can make effective use of the city’s Big Data. Cities want to make effective use of data in planning and policy-making processes to make informed decisions. A typical policy-making process generates multiple information requirements, which involves integration of data from different thematic or sectoral domains; addresses the temporal dimension of data; and ensures that data generated at various governance levels, i.e., from city to national and regional levels, is taken into consideration.

This suggests that though application specific data provides necessary information it is not sufficient to provide the holistic overview essential to the monitoring of a city environment by interconnected socioeconomic and environmental characteristics. For instance, land-use and transportation are highly inter-linked, e.g., urban sprawl results in increasing use of the private cars which generates unhealthy particulates affecting air quality in cities, causing health problems for citizens and negative impacts for social/health services. An integrated analysis of the data generated in the urban environment is essential to fully understand the complexities involved in Smart City Big Data governance and management.

In our previous work (Khan et al. 2012), we presented a generic process for integrated

Big Data in Smart Cities, Fig. 1 Integrated view – an example of drivers and impact assessment (Khan et al. 2012)

information system development and identified several technical requirements related to urban and environmental data management including data acquisition, metadata, discovery and metadata catalog, data quality, data retrieval, data storage, schema mapping and transformations, service interoperability, data fusion and synthesis, etc. With the expected growth of IoTs and sensors; extensive use of social media and smart phones; and use of satellite-based very high-resolution imagery for city planning and decision-making, these requirements are still valid for today's Smart City Big Data management.

We present a holistic view of a variety of Smart City data in Fig. 2, classified into two categories: (i) the “Base Data” and (ii) the “Other Thematic/Application specific data.” Typically, cities possess huge amounts of historical data in their databases or electronic files. This data can be related to buildings, base maps, topography, land cover/use, road networks, underground utility/service distribution network, population, green infrastructure, master plan, etc. We refer

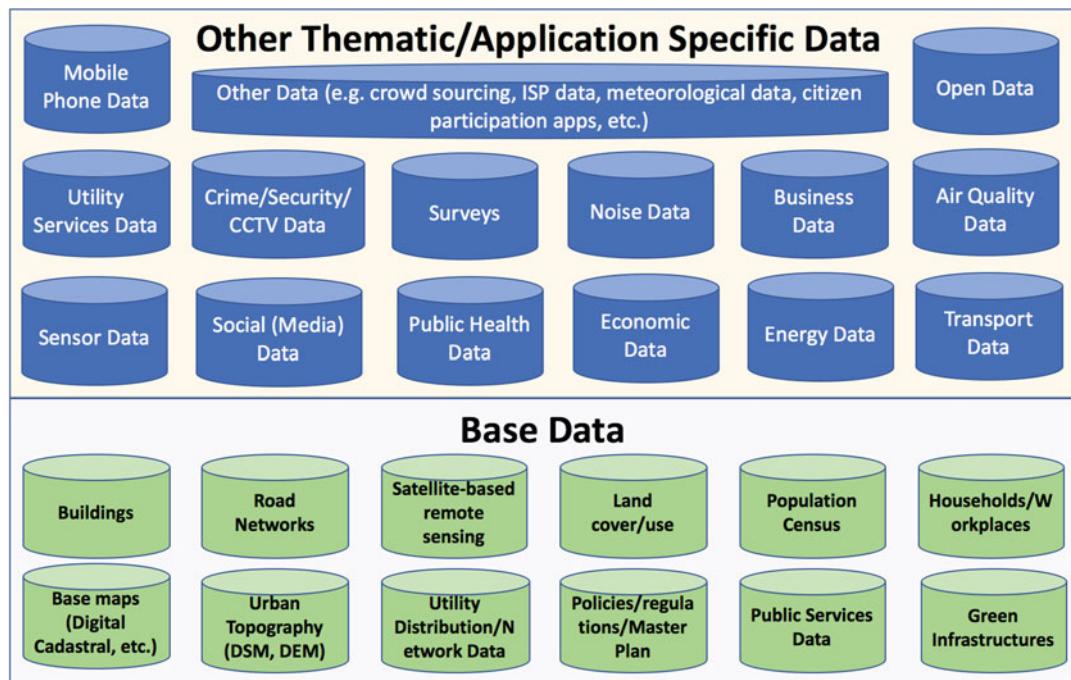

to this data as the base data, which provides the necessary basis for developing Smart City applications. Usually such data is collected by well-tested methods e.g., LiDAR scanning, and hence is trustable (veracity). Such data is usually collected once and updated after many years, e.g., population, road networks, LiDAR based topography. In some cases, a regular update is necessary, e.g., new building constructions. The volume of such data also varies from one city to another. For a medium to large scale city, this data can be from few 100 MBs to 10 s of GBs depending upon preserved historical temporal data (velocity).

The base data may comprise of:

Buildings: 2D/3D building location or structure. This can also be in CityGML format or BIM (Building Information Modeling) compliant data.

Road Networks: include data about major and small road networks, pedestrian or cycle pathways.

Basemaps: provide background maps of a city in different resolutions for orientation purposes.

Big Data in Smart Cities, Fig. 2 Holistic view of smart city big data

Satellite-Based Remote Sensing Data: This can be variety of data collected as high resolution images. This data can be related to light emission, thermal energy loss, and land-monitoring (e.g., land cover changes including green/blue/brown areas).

Land Cover/Use: provides landscape data classified into forests wetlands, impervious surfaces, agriculture, etc. Land cover can be determined by airborne or satellite imagery. In contrast, land-use provides additional information to see land cover changes over time.

Population Census: urban population including density of people (by age and gender) in specific areas.

Households/Workplaces: buildings or places classified as households or workplaces.

Urban Topography: Digital earth images mainly identifying various features. Mostly, it is provided as digital surface model and/or digital elevation model.

Utility Distribution Network Data: Underground sewerage pipes, water distribution pipes, gas/electricity/fiber optic lines, domestic/commercial use of energy, etc.

Policies or Master Plan: Medium to long-term City Master Plan that specifies future urban development.

Green Infrastructure: Tree canopy, parks, front/back gardens, allotments, etc.

Public Services Data: contains information about public services rendered to citizens, e.g., council tax, social housing, social benefits, etc.

The application specific data is more frequently generated (velocity) and belongs to different thematic domains (variety). The temporal dimension of data allows cities to analyze historical changes in the land-use and other applications. For instance, mobile phone data can be in the range of few hundred GBs to TBs per week in unstructured to semistructured format. This data can be used to analyze population distribution and mobility patterns for the daily analysis offering insights concerning the socioeconomic dynamic of the city as a direct input to city planning (Peters-Anders et al. 2017).

As another example, a typical calibrated data reading from a basic sensor can be up to 100

bytes (ceil value) and can be recorded in a CSV or XML file in a semistructured format. As an example, assuming there are 500 sensors deployed in a neighborhood of a city, and each sensor sends data every 10 min, then the total data collected in one hour is: $100 \text{ (approx. bytes)} \times 500 \text{ (sensors)} \times 6 \text{ (for 1 h)} = 300,000$ (about 300 K Bytes). This means total data collected in one day would be: $24 \text{ h} \times 300,000 \text{ bytes} = 7,200,000 \text{ bytes}$ (approximately 7.2 M Bytes), and the total data collected in one year $7.2 \text{ MB (data per day)} \times 365 \text{ (days / year)} = 2.628 \text{ G Bytes}$. It is clear, as there are a variety of other sensors (e.g., infrastructure monitoring sensors, air quality – PM10, NO₂, etc.) in the city environment collecting different thematic data on daily basis, that the daily data collection may reach 100 s of G Bytes to 10 s of T Bytes.

The above example considers only one source of data and there are several other sources like CCTV, energy consumption by households, transport data, social media, etc., which results in the generation of a few 100 s of GBs to 10 s of TBs data on daily basis. The amount of this data will significantly increase with deployment of 1000 s of new sensors, use of smart devices, and billions of Internet of Things (IoTs) in the next few years.

The thematic/application specific data may comprise of:

Mobile Phone Data: call data records (CDR) are generated when a mobile phone user performs any activity on a smart phone, e.g., calling, texting, etc. This data is normally collected by service providers and can be unstructured or semistructured data.

Utility Services Data: energy consumption, fuel (domestic methane gas, vehicle fuel) usage, water consumption, etc. This can be semistructured data.

Sensor Data: variety of sensors including air quality, traffic counters, etc. This can be unstructured data.

Social Media Data: from social media, Twitter, Facebook, etc. This is unstructured data.

CCTV Data: from CCTV footage, transport live feed, etc. This is unstructured data.

Security Data: crime/incidents at different areas represented as semistructured or structured data.

Public Health Data: health records, health surveys, etc. This can be semistructured or structured data.

Economic Data: public financial records as well as overall financial data of city. This can be semistructured to structured data.

Survey Data: survey carried out in different districts about quality of life, public services, etc. This can be unstructured as well as semistructured data.

Business Data: data about local enterprises/businesses, etc. This can be unstructured (e.g., business website) or semistructured data.

Energy Data: data from smart meters, energy grid (demand/supply), etc. This can be semistructured or structured data.

Transport Data: data about public/private transport, traffic counters, traffic cameras, fuel consumption for mobility, etc. This can be unstructured or semistructured data.

Air Quality Data: particulate concentration in the air – PM10, CO, etc. This can be unstructured or semistructured data.

Open Government Data: Data published by the cities for open use by citizens and local businesses. A variety of formats and datasets may be provided and can be unstructured, semistructured, or structured.

In general, the city datasets can be available as unstructured, semistructured, and structured data, and in a variety of formats including PDF, XLS, XML, CSV, SHP, DRG, GeoTIFF, JPEG2000, X3D, GeoJSON, CityGML, etc., or be published online via, e.g., OGC (Open Geospatial Consortium) web-services, like WMS, WMTS, WFS, etc.

Structured data is normally held in a relational data model and stored in databases of different departments or agencies of the city administration. Examples of such data can be land cadastre, population census, public health, energy consumption, vector data, e.g., road networks, etc.

The semistructured data is often stored in file format like, e.g., CSV, XML, JSON, or NoSQL databases. Often application specific high fre-

quency data is stored in the above formats. Such data can be queried by writing specific scripts to generate the required information.

The unstructured data can be social media data (e.g., Twitter), citizens comments on planning applications, audio/video, live traffic feeds (e.g., CCTV), satellite/raster imagery, city master plan or policy documents (e.g., PDF), radar or sonar data (e.g., vehicular, meteorological data), surveys, mobile data, etc. Such data can be in text, audio/video, or image format and hence it is challenging to query such data.

The above discussion highlights the following important aspects:

- (i) Cities generate large amount of data on daily basis which possess all “V” Big Data characteristics
- (ii) Location based (i.e., geo-coordinate related) data is a key element in Smart City Big Data to generate contextual information
- (iii) City data may come in unstructured, semistructured, or structured formats and requires innovative Big Data processing approaches

Applications and Lessons Learned

Here we present key Smart Cities Big Data applications and associated data challenges which need investigation for the development of Smart City information systems.

Applications

The Framework Programme (FP) Seven UrbanAPI project (Khan et al. 2014b) used both base data and thematic/application specific data, which provides a suitable example of the use of unstructured, semistructured, and structured datasets. For example, Peters-Anders et al. (2017) used mobile data (CDR) to gain new insights in the urban environment. It was observed that the mobile data collected by telecom operators may range into few 100 s of GBytes to TBytes on weekly basis. Mostly data is received in customized binary format or in proprietary file formats and millions of records are stored in

sequential (unstructured) order. Processing of such data requires clear understanding of the file formats to extract the required information. It was also observed that the quality and accuracy of the time series data needs to be checked before processing and drawing conclusions on the outcomes. Peters-Anders et al. (2017) explained various base datasets used with the mobile data to generate an interactive visual interface depicting daily population distribution and mobility patterns. The authors highlighted data quality (e.g., difference in temporal and spatial resolution; lack of fine granularity in mobile data; privacy issues), processing issues (e.g., lack of a common data model), and suggested advanced techniques, e.g., a Map-Reduce model or cloud computing, that can be applied to generate required outputs.

In contrast, The FP7 DECUMANUS project (Garzon et al. 2014) provides a suitable example of Big Data application where satellite based very high resolution images are collected, often in 100 s of M Bytes to G Bytes, for the development of Smart City services. For some services, e.g., climate service, data could reach to 100 s of G Bytes to T Bytes. One of the positive aspects of the FP7 DECUMANUS project was that it demonstrated practical use of satellite based earth observation data in city planning (Ludlow et al. 2017). The higher resolution imagery; the capacity to capture more updated images on frequent basis; lower cost; and the potential to complement any gaps by integrating it with in-situ data were the key success factors. However, the data comes in unstructured form and complex algorithms have to be used for digital processing and integration with in-situ data (e.g., base or thematic data). Different DECUMANUS services demonstrated this complexity, e.g., climate change downscaling processing (San José et al. 2015a), health impact (San José et al. 2015b); urban green planning (Marconcini and Metz 2016); and energy efficiency. For instance, San José et al. (2015a) describes the experiments where very high-resolution earth observation images, i.e., covering about 23×20 Kilo meters (km) at European Latitude, were dynamically down-scaled to about 200 and 50 m resolution scales,

which is more suitable to visualize and analyze data at city scale. This downscaling was performed by using the Barcelona Super Computing's high performance computing infrastructure (128 nodes/blades; each blade with 8 GB RAM and two 2.3 GHz processors; Global Parallel File System; Linux OS and Myrinet high bandwidth network to connect nodes) and consumed about 881,664 CPU hours.

As compared to the above applications, the Horizon 2020 smarticipate project makes use of base and thematic datasets to develop citizens participation applications and generate new datasets for public services (Khan et al. 2017a). The smarticipate platform enables cities to create topics of interest, i.e., a specific planning proposal in a neighborhood, and share it with citizens to seek their opinions, suggestions, and alternative proposals with the objective to co-create and/or co-design local neighborhood plans. The topic creation requires datasets from base data (e.g., base maps, layers of information, e.g., road networks, street furniture, etc.) and application/thematic data, e.g., air quality data, soil data, noise, utility infrastructure, etc. For example, Hamburg's tree planting use case requires base maps with street networks, soil data, utility infrastructure, and existing tree data. All this data can be in 2D as well as in 3D to provide visual representation of the area. This means topic creation can make use of structured and semistructured data. Once citizens are invited to participate for a specific topic, they can provide Web2.0 based comments by engaging in a dialogue with other citizens (unstructured data), showing likeness/dis-likeness or creating alternative proposals by adding more data on the platform.

It is expected that a typical topic creation may add 10 s of MBytes to 100 s of MBytes (3D scene) and may seek citizens' participation for a full week (7 days). Let us assume 50 MBytes is used for tree planting topic creation. Now imagine on average each user adds about 1000 bytes of comments to one proposal, and if we assume that about 1000 citizens provide their comments, the total amount of unstructured data generated will be $1000 \times 1000 = 1$ MBytes approximately. This

means one instance of a proposal can generate about 1MBytes of unstructured data, so total data for one instance will become 50 MBytes (topic) + 1 MBytes (comments) = 51 MBytes. If half of the sample group create alternative proposals (with same base/thematic or new data) and attract new comments on the alternative proposals, then the data generated will be: 51 MBytes (data from main topic/proposal) \times 500 (alternative proposals) = 25.5 GBytes. This means, typically, about 25 GBytes data per week is expected. Imagine if there are 10 different topics initiated by the city council in different neighborhoods, then it is expected to generate about 250 GBytes of data per week. This amount may further increase if the topic creation is more complex such as the Forte Trionfale refurbishment scenario (i.e., with buildings and other surrounding infrastructure) for the city of Rome, where over 100 MBytes may be used for topic creation. Over time the amount of data generated by the smarticipate platform will increase significantly and to be effective must utilize Big Data management and processing capabilities by using Edge, Hadoop, Spark and Storm, etc., based approaches.

Challenges as Lessons Learned

Structuring of Data: The structuring of data varies from one city to another, i.e., one city may have a specific dataset in unstructured format, whereas another city may have designed it in well-structured format. For example, most cities have their city master plan in a static format, e.g., image or document. However, cities with more advanced data collection and management resources (e.g., Hamburg in the smarticipate project) have their city master plan defined in an Object Oriented Data Model that provides more flexibility to query the plan and perform monitoring and validation of land-use development.

The spatial data is often represented in a specific spatial reference system. Cities in different countries use different spatial reference systems which may require Smart City applications to accommodate different reference systems for harmonizing and processing the data and providing the information in a uniform representation, e.g., to perform comparative analysis.

Cities collect new data on regular basis and provide temporal time series data that can be used to detect changes, e.g., land-use, built environment or atmosphere, etc. For example, land monitoring data (e.g., LiDAR) can be collected bi-yearly due to data collection costs; likewise, satellite based remote sensing data can be collected more frequently, e.g., bi-monthly; in contrast, mobile data, e.g., Call-Data-Records contain data instances based on any mobile phone activity and can be in seconds, minutes, or hours.

All the above applications indicate that there is no standard approach defined and adopted by the cities to manage the temporal and spatial dimension of city data, which makes it difficult to develop generic processing scripts or applications which can be reused by many cities. This highlights the need to use standard data representation or exchange formats, like CityGML, which can tackle variety of data format heterogeneity by using its so-called Application Domain Extension (ADE) to represent energy, utilities, etc.

Quality of Data: The base data is often stored in a non-normalized schema; have different data formats; and is managed/owned by different departments or agencies. In addition, often there is incomplete or no meta-data available and not all the data comes with geo-coordinates. Data may have different spatial resolution scales and often data is not available in the required spatial scale, e.g., up to few centimeters. All these aspects compromise the quality of the data and require rigorous data harmonization and compatibility efforts and preprocessing to prepare the data for possible use in different thematic applications.

Veracity of Data: The level of accuracy of the base and thematic data may vary from one application to another. Most base data are collected by using reliable data collection methods, e.g., LiDAR, official population census, etc. However, not all the thematic applications relying on the data from citizen science or public participation, down-scaled satellite imagery, etc., provide highly accurate data, and this suggests the need to validate the data source to make it trustworthy, reliable, and usable in other applications or in decision-making processes. For instance, W3C PROV model (2013) is used in citizen participa-

tion applications to validate the source of data and establish trust in it (IES Cities 2013).

Data Access and Availability: A lot of data is managed in different departmental silos. This data is often without standard accessible interfaces or APIs (e.g., OGC's WFS interface), which makes it difficult to discover/search or access from the external world. As a result, cities might have duplicate and often nonmatching data in different departments or agencies.

Data Security and Privacy: Security and privacy related concerns right up the agenda in response to security and privacy related legislations, e.g., the Data Protection Act 1996 or the General Data Protection Regulations (GDPR). While suitable harmonizing and integration and processing approaches are needed for city data, this must not accidentally violate individuals' privacy. This becomes really challenging when multiple data sources are combined for Smart City Big Data processing. Also, Smart City services should provide end-to-end security and privacy by adopting novel security frameworks, e.g., SSServProv Framework (Khan et al. 2017b) or blockchain based authentication and self-verification techniques, e.g., VeidBlock (Abbasi and Khan 2017).

Data Processing and Data Transfer: Many applications are developed by using OGC compliant services. Use of Apache Hadoop and Spark and Storm based platforms permit the processing of historical as well as real-time data (Khan et al. 2014a, 2015; Soomro et al. 2016). Other libraries and tools for geo-processing (e.g., Java based GeoServer on the back-end and JavaScript based mapping libraries like, e.g., OpenLayers, Leaflet, etc., in the front-end) can be utilized to process and present city data to different stakeholders (Khan et al. 2017a). In some cases, micro-services or a typical service oriented environment can be used to design service workflows; data can be accessed and processed by using OGC compliant WFS and WPS interfaces. In most cases, data is fetched from remote repositories, transferred, and stored in central repositories (or on the cloud) to process the data (Khan et al. 2012). In such situations, a transfer of huge amounts of data

takes place which is not sustainable, and hence requires alternative distributed computing models such as fog computing (Perera et al. 2017) and/or edge computing (Ai et al. 2017).

Summary and Future Directions for Research

This entry provides a thorough insight into Smart City Big Data covering "V" characteristics and main categories: basic and thematic data. From the Smart City Big Data perspective, we presented three applications from FP7 UrbanAPI, FP7 DECUMANUS, and H2020 smarticipate projects. We also highlighted various data related challenges cities are facing today including city data possess harmonization, integration, and processing, which require further research to apply distributed or edge computing models.

The applications and challenges provide pointers to future research directions including: (i) designing common data models for data harmonization and application development; (ii) defining and using standard approaches for data representation or exchange, e.g., CityGML; (iii) inventing new edge based models so that processing can be performed close to the data source and unnecessary data transfer can be limited; (iv) providing necessary security and privacy measures to avoid violation of privacy laws; (v) assessing and improving data quality and provenance through new techniques; (vi) introducing intuitive visualization of data for better awareness raising; and (vii) innovative data analytics approaches to generate new information and knowledge to support decision-making in city governance.

Big Data in Social Networks

Antonio Picariello

Università di Napoli Federico II – DIETI,
Napoli, Italy

Synonyms

Big data analytics; Social networking

Definitions

Online social networking is a novel paradigm within the big data analytics framework, where massive amounts of information about heterogeneous social facts and interactions are stored, at a very high variability rate. By considering important problems such as influence diffusion and maximization and community detection, we show the importance of this research field in big data analysis.

Overview

We describe the main research activities in big data social networking, focusing on influence diffusion and maximization and community detection performed on on-line social networks.

Social Networks as Big Data

Nowadays, we can say undoubtedly that social networking is one of the main applications of big data techniques and tools. *Online social networks* (OSN) usually produce a collection of very huge data sets (*volume*) with a great diversity of types (*variety*) and sometimes with a high frequency of variability (*velocity*). In addition, how to manage the *veracity* of such kind of data is still a challenge, and the use of social data may have a great economic and competitive impact (*value*). Consequently, in social networking all the 4 + 1 V that characterize big data are really addressed. The rapid development of the application of big data techniques to social networks (sometimes also called *social networking big data*) is bringing revolutionary changes to our daily lives, producing a novel global business. Just to mention an example about one of the most popular OSNs, in terms of volume, in June 2017, Facebook has 2 billion users per month, with hundred billion friendship edges; Facebook adds 500,000 new users every day and 6 new profiles every second; 72% of all US online adults visit Facebook at least once a month. Worldwide, 38.6% of the online population use Facebook. In terms of ve-

locity, Facebook, respectively, generates about 500 Tbytes of data *daily*: Twitter a little less. And in addition these data (text, images, video, audio) also need to be processed at a high speed. In this framework, social network management and analysis evolve into a big data problem when IT specialists try to predict behavior (predictive analytics) or to suggest decisions for getting advantages of the analysis (prescriptive analysis). Clearly, the novel paradigm of social networking and big data should provide approaches for efficiently adopting effectively big data analytic algorithms. In particular, due to the complexity and diversity of OSNs and the produced data, there are two important aspects that need to be deeply investigated: (a) how to conduct social network analysis considering big data and (b) how to use big data analytics technique with respect to privacy and security issues.

In the next sections, we will first describe into details online social networks and related models, and we will focus on social network analysis describing influence diffusion and maximization and community detection techniques.

Online Social Networks

Currently, most social networks connect people or groups who expose *similar* interests or features. However, such networks could surely connect in the next future other entities, such as software, web services, and data repositories (Tan et al. 2013).

Let us now consider a social network as a group of people connected through social relationships: an online social network service is an online platform where people create social relationships with other people sharing similar interests. Usually the interactions between them are performed through media contents: in this case, we sometimes refer to *social media networks*, usually subdivided into the following categories:

- *Online social networks and multimedia social networks*: these networks are based on user-

generated contents. Hence, it is possible to exploit the relationships established among users, users and contents for different purposes, such as (i) identify the most appropriate content for specific users, (ii) ranking of social network users with respect to a given item, and (iii) identify a subset of user to maximize the influence of specific contents and so on. The following – famous – social networks lie into these categories: Twitter, Facebook, Instagram, Google+, Last.fm, and Flickr.

- *Location-based social networks*: These networks introduce location as a new object. Some examples are Foursquare, Yelp, and TripAdvisor.
- *Social movie rating businesses*: In this category, we can identify the following social networks: Flixster, IMDb, and MovieLens.

Social networking has its beginnings in the work of social scientists in the context of human social networks, mathematicians and physicists in the context of complex network theory, and, most recently, computer scientists in the investigation of information social networks. New challenges and research topics are thus arising, especially concerning marketing applications like recommendation, influence maximization, influence diffusion, viral marketing, word of mouth, etc. and also problems related to security like Lurker detection and malicious user detection (Amato et al. 2016a).

Social Networks Models

Graphs are the most suitable data structure that can reflect and represent social networks: a graph can exactly depict the relationships among different users. How to model an OSN with a graph is dependent on the different kinds of objects forming the network.

Generally speaking, a social network is a directed graph $G = (V, E)$, V being the set of vertices of the network – e.g., users, multimedia objects, tags, and so on – and E the set of edges among vertices, e.g., the social ties.

The different entities that could be considered in an OSN typically are *users*, the set of users

that are the subject of the analysis, every user corresponding to a node of the graph (call this set U); *social relationships*, the set of relationships among two users; we can refer to it as the set of edges E ; *multimedia object*, the media contents generated by users and through which users can interact among them; and *tags*, the keywords associated with a particular user-generated content.

In the last few years, the scientific community focused a particular interest into *multimedia social networks*, i.e., the OSN added with multimedia user-generated content. In this case, we can detect different relationships: *user to user*, this is the most common relationship, where two users are connected to each other (e.g., friendships, memberships, following, and so on); *similarity*, this kind of relationships exists between two multimedia objects and refers to the similarity of these contents; it is based on the analysis of high-level and low-level features; and *user to multimedia*, this represents the actions that a particular user can make on a particular content.

In order to handle in a compact way the different kinds of data contained in a OSN, a powerful data structure that is emerging is the hypergraph (Amato et al. 2016b). A hypergraph is the generalization of the concept of graph, in which edges are not referred only to two vertices, but to an undefined number of vertices. Formally, a hypergraph is defined as $H = (X, E)$, X being a set of vertices and E a set of non-empty subsets of X , called hyperedges or edges. Therefore, E is a subset of $2^X \setminus \{\emptyset\}$, where 2^X is, as usually, the power set of X .

Social Network Analysis

When applied on an OSN, the big data analytics techniques may provide what is sometimes called “the wisdom of the crowds” (i.e., the collective opinion of a group of individuals rather than that of a single expert), thus revealing sentiments, detecting typical patterns, providing recommendations, and influencing people or groups of people. Social networks analysis, or SNA, is one of the key points of the modern sociology, especially for the study of society and social relationship between people. Nowadays, the growing popularity of OSNs and the data generated by them lay

the foundations for analyzing several sociological phenomena that are used in many fields. SNA involves several techniques like machine learning, text analysis, and media analysis. Analyzing such huge amount of data allows to understand the social tie between nodes. The chance to analyze this huge amount of data is really important for many kinds of application in very different fields. A summary of these applications are *recommendation systems*, which are the products to suggest to users, based on *collaborative filtering* in which the products to suggest are based on the interests of similar users (Amato et al. 2017b); *influence analysis*, the analysis of the most influential users in the network (Amato et al. 2017a) *community detection*, the detection of different communities of similar users in a network; and *advertising systems*, which ads should be promoted to users.

Briefly, SNA may be broadly divided into two categories: (a) *linkage-based and structural analysis*, the analysis of links among nodes of network to understand social relationships, and *content-based analysis*, the analysis is based on contents generated in the OSN.

Influence Diffusion

Influence diffusion analysis describes how information propagates across the users in a network. The main goal of this research field is to create a diffusion model that describes how information could be “diffused.” Different models have been proposed in the literature, which can be classified into two categories: *progressive* and *nonprogressive* models. The nonprogressive models make the assumption that nodes’ states can change indefinitely, while in the progressive ones, when a node is active, it cannot switch its status. For both the described categories, it’s possible to classify the proposed models into *stochastic*-, *epidemiologic*-, and *voting*-based models.

The stochastic diffusion models are based on stochastic processes; in this case, considering an OSN modeled as a graph, a node can have only two possible states: *active* and *inactive*, depending on if the node has been influenced by the new information or not. Stochastic diffusion models have two properties related to the *influence spread function*: (a) *monotonicity*, meaning

that if we add more nodes to a *seed set*, we cannot reduce the size of the final set, and (b) *sub-modularity*, meaning that a function has the property of the *diminishing returns*. Note that sub-modularity tells us that the obtained gain adding a node v to the total set T is always lower than – equal – adding that node v to a subset S . In mathematical terms:

$$f(S \cup v) - f(S) \geq f(T \cup v) - f(T) \quad (1)$$

The most used stochastic diffusion models are the *independent cascade model* (IC) and the *linear threshold model* (LT).

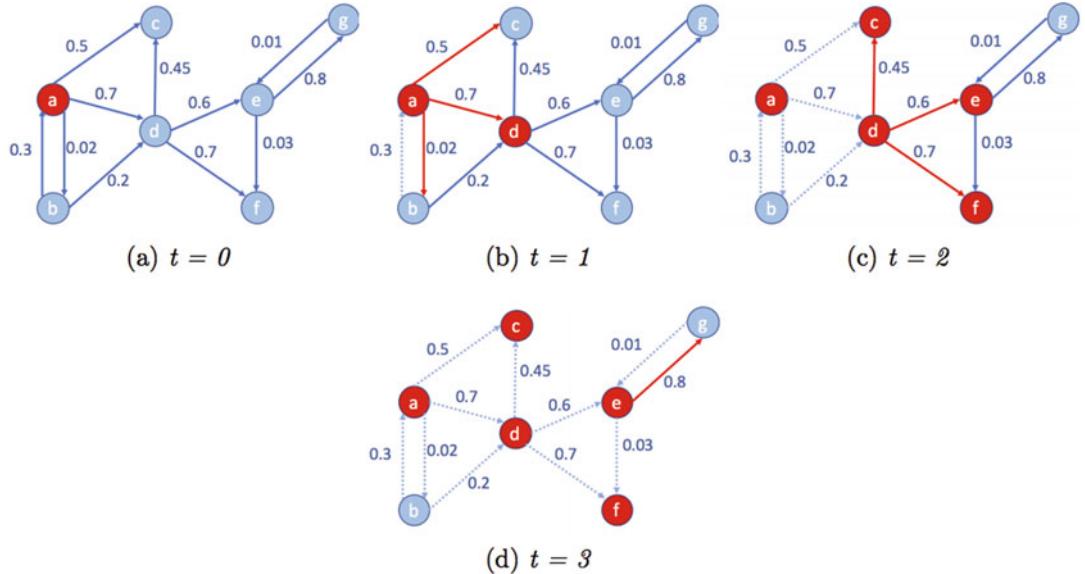

The IC model is described by Kempe et al. 2003a based on the and marketing research Goldenberg et al. 2001. This model is also related to epidemic models (Keeling and Eames 2005).

In this approach, every edge $e_{u,v} \in E$ has a probability $p_{u,v} \in [0, 1]$, and the model works as following:

1. at initial step $t = 0$, an initial seed set S_0 is activated, while the remaining nodes are inactive;
2. each active node u executes an *activation attempt* by performing a *Bernoulli* trial with the probability $p_{u,v}$ to active its neighbors v_i ;
3. if a node v has not been activated, the node u has no others chances to achieve this. If the node v is activated we can add this node to the active sets S_t in the following step $t + 1$. When a node is activated, it can’t turn inactive again;
4. the steps 1–3 are repeated until no new nodes become activated, at time t_n .

This kind of diffusion is very useful to explain the diffusion behavior of information or viruses, like in *contagion*.

Figure 1 shows an example of this diffusion process. At time $t = 0$ only the node a is active Fig. 1a, and it represents the seed set. At step $t = 1$, node a attempts to activate nodes b , c , and d Fig. 1b, and only d is activated; in this case a fails to activate b and c . At this point, the edges used or that have a destination already active, are left out. At step $t = 2$ only d tries to activate its neighbors c , e , and f Fig. 1c. In the

Big Data in Social Networks, Fig. 1 Independent cascade algorithm. (a) $t = 0$. (b) $t = 1$. (c) $t = 2$. (d) $t = 3$

last step, $t = 3$ node e tries to affect g but fails, and the diffusion stops because there are not any outgoing edges to inactive nodes. Fig. 1d. The main problem of this model is that we assume that in each step, a node can be activated only by one of its neighbors, and so the influence of a node depends only on one source.

To overcome the constraints that the influence of a node depends only on one source, scientists considered a novel approach where a node u is activated when it receives influence by more than one neighbor, also known as the LT model, proposed by Kempe et al. 2003b. In this model, every node u has a weight $w(v) \in [0, 1]$ that indicates the threshold to reach to influence the node v . This means that to activate the node v , the sum of the probability $p_{u,v}$ of its active neighbors has to be more than w_v . This corresponds to say that a single node activation depends on multiple sources. Initially, only an initial seed set S_0 is active. The steps of the algorithm are the following:

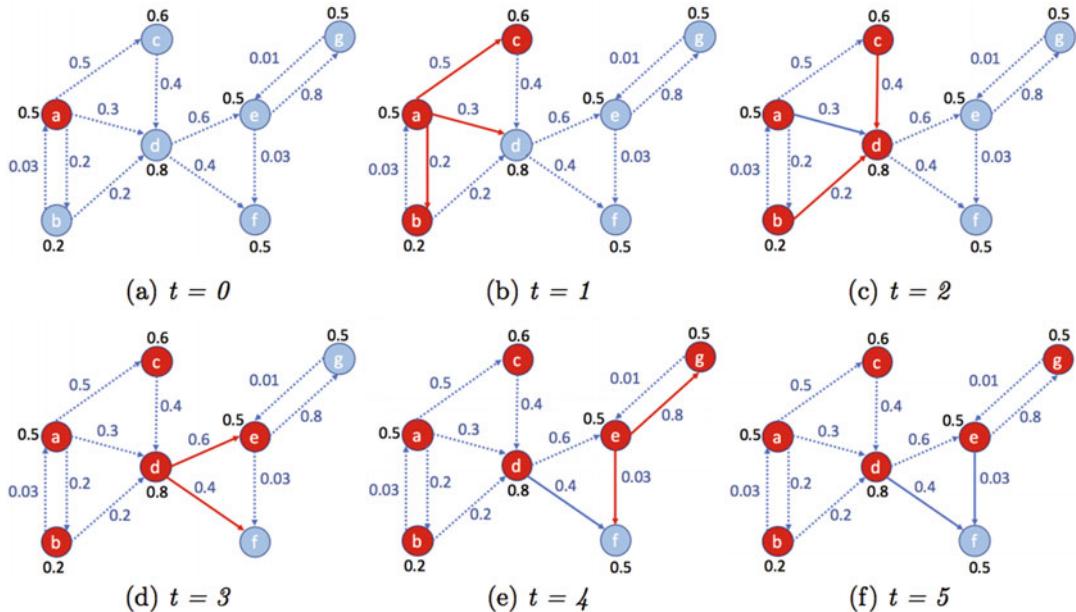

1. at each step t_i every node $u \in S_{t_i}$ attempts to activate its inactive neighbors v_i with a probability $p_{u,v}$, where S_{t_i} indicates the active set at time t_i . The node v becomes active if

the sum of the probabilities is greater than its threshold. If we indicate $N(v)$ as the neighbors nodes of v , it becomes active if:

$$\sum_{v \in N(v) \cap S_{t_i}} p_{u,v} \geq w_v \quad (2)$$

2. if the node v became active, it belongs to the S_{t_i+1} , and it can attempt to influence its neighbors. If it doesn't become active, other new active nodes can contribute to activate it in further steps.

Figure 2 shows an example of LT diffusion process. As in the IC model, when a node becomes active, we mark it with red color; indeed near each node v is shown the threshold w_v . At step $t = 0$, only the node a is active Fig. 2a, it begins to influence its neighbors, but it succeeds only with c and b because their threshold is lower than $p_{a,b}$ and $p_{a,c}$ Fig. 2b. The $p_{a,d}$ is not sufficient to activate d , but it goes on to influence also at step $t = 2$ where, through the influence of c and b , the threshold is reached and node d is activated. The process goes on until there are not nodes become active Fig. 2c.

Big Data in Social Networks, Fig. 2 Linear threshold model. (a) $t = 0$. (b) $t = 1$. (c) $t = 2$. (d) $t = 3$. (e) $t = 4$. (f) $t = 5$

Influence Maximization

The *influence maximization* problem in an OSN requires to find the k nodes having maximum influence. Initially, let us consider a seed set S_0 , formed by all the nodes that can activate a huge number of nodes in the network. Kempe et al. 2003b proved the NP-hardness of this problem. The general approach to this problem is to define a *greedy* algorithm that can get an approximation of the optimal solution.

Kempe demonstrated the following fundamental theorem.

Theorem 1 For a nonnegative, monotone submodular function f , let S be a set of size k obtained by selecting elements one at a time, choosing an element that provides the largest marginal increase in the function value. Let S^* be a set that maximizes the value of f over all k -element sets. Then $f(S) \geq (1 - 1/e) \cdot f(S^*)$; in other words, S provides a $(1 - 1/e)$ -approximation.

There are several approaches to this problem, as in the following categories:

- *Stochastic*: most known approaches are Monte-Carlo based (Kempe et al. 2003a), TIM (Tang et al. 2014, 2015).
- *Biologically inspired*: bio-inspired approaches, mainly based on bee waggle dance model and ant colony model (Sankar et al. 2016).
- *Game theory based*: based on game theory; one of the most important is multi-armed bandit theory (Vaswani et al. 2015);
- *Genetic algorithms*: based on genetic algorithm and so more efficient than greedy approach (Bucur and Iacca 2016);

Community Detection

The modern science of networks has brought significant advances to our understanding of complex systems. One of the most relevant features of graphs representing real systems is community structure, or clustering, i.e., the organization of vertices in clusters, with many edges joining

vertices of the same cluster and comparatively few edges joining vertices of different clusters. Such clusters, or communities, can be considered as fairly independent compartments of a graph. Detecting communities is of great importance in sociology, biology, and computer science, where usually systems are often represented as graphs. This problem is very hard and not yet satisfactorily solved, despite the huge effort of a large interdisciplinary community of scientists working on it over the past few years. In graph theory, community detection is a fundamental task to analyze and understand the structure of complex network. As reported in Wang et al. (2015), “revealing the latent community structure, which is crucial to understanding the features of networks, is an important problem in network and graph analysis.”

During the last decade, many approaches have been proposed to solve this challenging problem in diverse ways. The term “community” has been extensively used in the literature in different contexts and with different connotations.

A first definition is provided by Gulbahce and Lehmann 2008 that define a community as “a densely connected subset of nodes that is only sparsely linked to the remaining network.” Porter et al. (2009) provide a definition based on the fields of sociology and anthropology, in which a community is a “cohesive group of nodes that are connected more densely to each other than to the nodes in other communities.” Moreover, Fortunato 2010 defines communities as “groups of vertices that probably share common properties and/or play similar roles within the graph.” The most commonly used definition is that of Yang et al. (2010): “a community as a group of network nodes, within which the links connecting nodes are dense but between which they are sparse.” Papadopoulos et al. (2012) ultimately define communities as “groups of vertices that are more densely connected to each other than to the rest of the network.”

However, the definition of a community is not clear because it is complex to define the concept of “good” community. Several possible

communities can be computed in a social network $G(V, E)$ whose enumeration is a NP-complete problem. The aim of several community detection algorithms is to optimize a goodness metric that represents the quality of the communities detected from the network.

It is possible to define the two main types of community. A *strong community* is a subgraph in which each vertex has more probability to be connected with the vertices of the same community compared to a node in a different community. A *weak community* is a subgraph in which the average edge probability between each vertex in the same community exceeds the average edge probability between the vertex with the vertices of any other group.

As shown in Chakraborty et al. (2017), usually community detection analysis is composed of two phases: detection of meaningful community structure from a network and, second, evaluation of the appropriateness of the detected community structure. In particular, the second phase raises the importance to define several metrics that are the fundamentals of different community detection definitions. Moreover community detection approaches can be classified in two categories: global, which require the knowledge of entire network, and local algorithms, which expand an initial seed set of nodes into possibly overlapping communities by examining only a small part of the network.

Finally, the algorithms for community detection can be classified as in the following: (a) cohesive subgraph discovery, (b) vertex clustering, (c) community quality optimization, (d) divisive, and (e) model based.

Big Data in the Cloud

S. M. Zobaed and Mohsen Amini Salehi
High Performance Cloud Computing (HPCC)
laboratory, University of Louisiana at Lafayette,
Lafayette, LA, USA

Definitions

Then eventually discuss big data handling challenges, issues, and how big data can be stored, processed, and accessed in the cloud.

Overview

Cloud storage services have emerged to address the increasing demand to store and process huge amount of data, generally alluded as “Big Data” (Wu et al. 2014). Typically, organizations store the huge volume of data to various clouds.

Cloud computing offers organizations the ability to manage big data and process them without the cost and burden of maintaining and upgrading local computing resources. However, efficient utilization of clouds for big data imposes new challenges in several domains. In this chapter, we discuss challenges in big data storage, distribution, security, and real-time processing. It is also explained how clouds can be instrumental for big data generated by Internet of Things (IoT). An overview of popular tools that are available in clouds for big data analytics is depicted. Finally, there is a discussion on future research directions in these areas.

Key Research Findings Big Data in the Cloud

Storage Levels for Big Data in the Cloud

A cloud storage consists of enormous number (order of thousands) of storage server clusters connected by a high-bandwidth network. A storage middleware (e.g., SafeSky (Zhao et al. 2015)) is used to provide distributed file system and to deal with storage allocation throughout the cloud storage.

Generally, cloud providers offer various storage levels with different pricing and latencies. These storage levels can be utilized to store big data in the cloud, depending on the price and latency constraints. Amazon cloud, for instance, provides *object storage*, *file storage*, and *block storage* to address the sheer size, velocity, and formats of big data.

Object storage is cheaper and slower to access, generally used to store large objects with low access rate (e.g., backups and archive data). This type of storage service operates based on Hard Disk Drive (HDD) technology. Amazon simple storage service (<https://aws.amazon.com/s3/>) (S3) is an example of Object storage service (Wu et al. 2010).

File storage service is also offered based on HDD storage technology. However, it provides file system interface, file system access consistency, and file locking. Unlike object storage, file storage capacity is elastic which means growing and shrinking automatically in response to addition and removal of data. Moreover, it works as a concurrently accessible storage for up to thousands of instances. Amazon Elastic File System (<https://aws.amazon.com/efs/>) (EFS) is an example of this type of storage.

Block storage level is offered based on Solid-State Drives (SSD) and provides ultra-low access latency. Big data with frequent access or delay sensitive can be stored in this storage level. Amazon Elastic Block Store (EBS) is an example of Amazon cloud service offered based on block storage. High-performance big data applications (e.g., Sagiroglu and Sinanc 2013) commonly use storage level to minimize their access latency.

Cloud Big Data: Persistence Versus Distribution

Although clouds provide an ideal environment for big data storage, the access delay to them is generally high due to network limitations (Terzo et al. 2013). The delay can be particularly problematic for frequently accessed data (e.g., index of big data search engine). As such, in addition to storage services, other cloud services need to be in place to manage distribution of big data so that the access delay can be reduced. That is, separating the big data storage in the cloud from the distribution.

Content Delivery Network (CDN) is a network of distributed servers aiming to reduce data access delay over the Internet (Pierre and Van Steen 2006). The CDN replicates and caches data within a network of servers dispersed at different geographical locations.

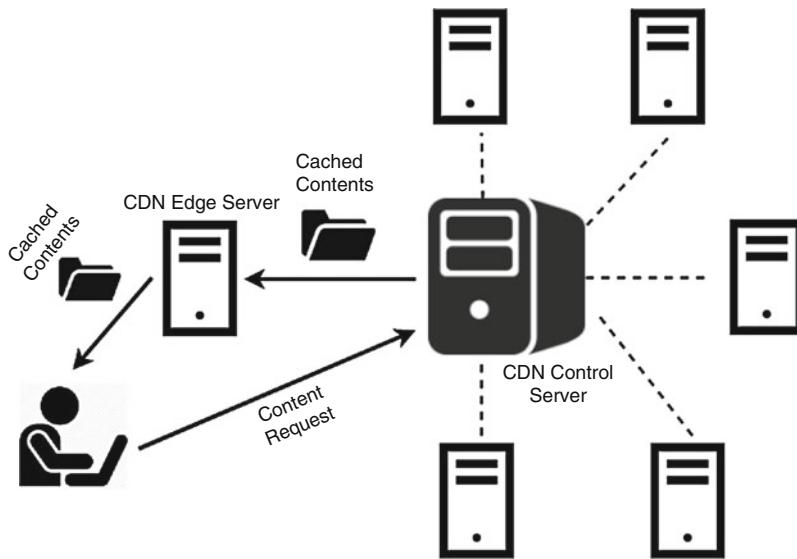

Figure 1 depicts how CDN technology operates. As we can see in this figure, upon receiving a request to access data, CDN control server caches the data in the nearest edge server to deliver it with minimum latency.

Cloud providers offer distribution services through built-in CDN services or by integrating with current CDN providers. For instance, Amazon cloud offers CloudFront (Dignan 2008) CDN service. Akamai, a major CDN provider has been integrated with Microsoft Azure cloud to provide short delay in accessing big data (Sirivara 2016).

Real-Time Big Data Analytics in the Cloud

Cloud big data can be subject to real-time processing in applications that detect patterns or perceive insights from big data. For instance, in S3C (Woodworth et al. 2016) huge index structures need to be accessed to enable a real-time search service. Other instances are big data analytics for sensor data (Hu et al. 2014), financial data (Hu et al. 2014), and streaming data (Li et al. 2016).

The faster organizations can fetch insights from big data, the greater chance in generating revenue, reducing expenditures, and increasing productivity. The main advantage of separating

Big Data in the Cloud, Fig. 1 CDN technology helps to minimize access latency for frequently accessed big data in the cloud

storage from distribution is to help organizations to process big data in real-time.

In most cases, data collected from various sources (e.g., sensor data, organizations' data) are raw and noisy, thus, are not ready for analysis. Jagannathan (2016) propose a method to deal with this challenge.

Security of Big Data in the Cloud

One major challenge in utilizing cloud for big data is security concerns (Dewangan and Verma 2015). The concern for big data owners is essentially not having full control over their data hosted by clouds. The data can be exposed to external or, more importantly, to internal attacks.

A survey carried out by McKinsey in 2016 (Elumalai et al. 2016) showed that security and compliance are the two primary considerations in selecting a cloud provider, even beyond cost benefits. In October 2016, external attackers performed a Distributed Denial of Service (DDoS) attack that made several big data dealing organizations (e.g., Twitter, Spotify, Github) inaccessible. Prism (Greenwald and MacAskill 2013) is an example of an internal attack launched in 2013. In this section, we discuss major security challenges for big data in the cloud and current efforts to address them.

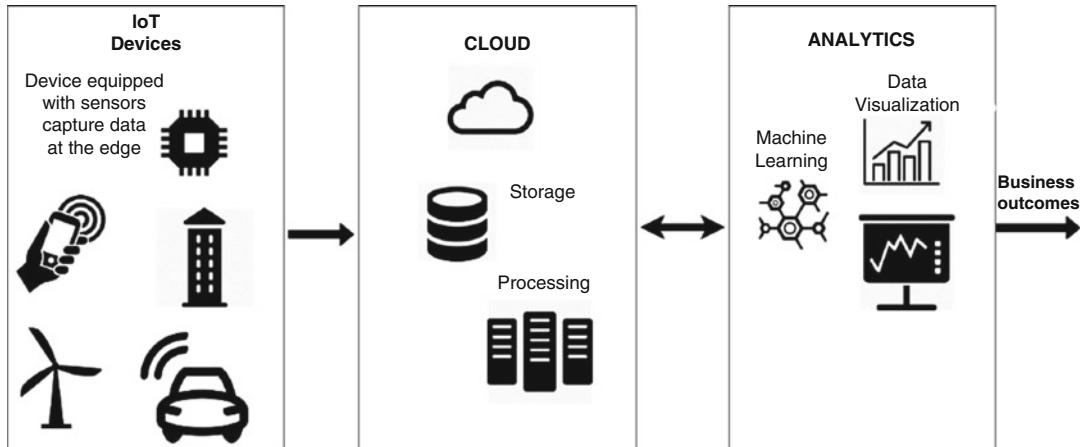

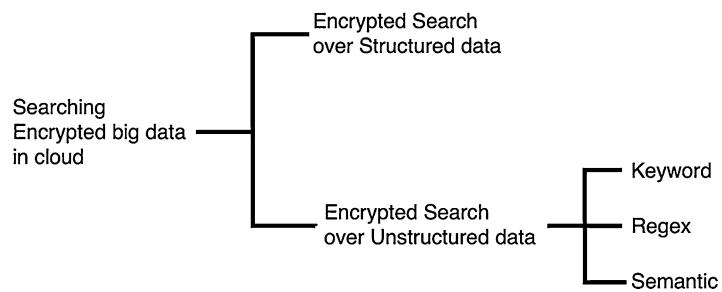

Security of Big Data Against Internal Attackers

In addition to common security measures (e.g., logging or node maintenance against malware), user-side encryption (Salehi et al. 2014; Woodworth et al. 2016) is becoming a popular approach to preserve the privacy of big data hosted in the cloud. That is, the data encryption is done using user's keys and in the user premises; therefore, external attackers cannot see or tamper with the data. However, user-side encryption brings about higher computational complexity and hinders searching big data (Wang et al. 2010).

Several research works have been undertaken recently to initiate different types of search over encrypted data in the cloud. Figure 2 provides a taxonomy of research works on the search over encrypted data in the cloud. In general, proposed search methods are categorized as search over structured and unstructured data. Unstructured searches can be further categorized as keyword search, Regular expression search, and semantic search.

Privacy-Preserving query over encrypted graphstructured data (Cao et al. 2011) is an instance of search over encrypted structured data. REseED (Salehi et al. 2014), SSE (Curtmola et al. 2006), and S3C (Woodworth et al. 2016) are

Big Data in the Cloud,
Fig. 2 Taxonomy of different types of search over encrypted big data

Big Data in the Cloud, Fig. 3 Work-flow of IoT systems dealing with big data in the cloud

tools developed for regular expression (Regex), keyword, and semantic searching, respectively, over unstructured big data in the cloud. Big data integrity in the cloud is another security concern. The challenge is how to verify the data integrity in the cloud storage without downloading and then uploading the data back to cloud. Rapid incoming of new data to the cloud makes verifying data integrity further complicated (Chen and Zhao 2012). Techniques such as continuous integrity monitoring are applied to deal with big data integrity challenge in the cloud (Lebdaoui et al. 2016).

Security Against External Attackers

External attackers are generally considered as potential threats to the cloud that handle big data. If cloud storages face external attacks, users' data will be leaked and controlled by attackers. So, implementing security on the cloud that handles big data is a challenge.

To address the security challenge, researches have been done in that area. For instance, a layered framework (Reddy et al. 2012) is proposed for assuring big data analytics security in the cloud. It consists of securing multiple layers, namely, virtual machine layer, storage layer, cloud data layer, and secured virtual network monitor layer.

IoT Big Data in the Cloud

The Internet of Things (IoT) is a mesh of physical devices embedded with electronics, sensors, and network connectivity to collect and exchange data (Atzori et al. 2010). IoT devices are deployed in different systems, such as smart cities, smart homes, or to monitor environments (e.g., smart grid). Basic work-flow of IoT systems that use cloud services (Dolgov 2017) is depicted in Fig. 3. According to the figure, the IoT devices produce streams of big data that are hosted and analyzed using cloud services. Many of these

systems (e.g., monitoring system) require low latency (real-time) analytics of the collected data.

Big data generated in IoT systems generally suffer from redundant or noisy data which can affect big data analytic tools (Chen et al. 2014).

Knowledge Discovery in Databases (KDD) and data mining technologies offer solutions for analysis of big data generated by IoT systems (Tsai et al. 2014). The big data are converted into useful information using KDD. The output of KDD is further processed using data mining or visualization techniques to extract insights or patterns of the data.

Amazon IOT (<https://aws.amazon.com/iot/>), Dell Statistica (<http://iotworm.com/internet-things-business-data-analytics-tools/>), Amazon Greengrass (<https://aws.amazon.com/greengrass/>) Azure stream analytics are tools that function based on the aforementioned work-flow in clouds to extract insights from IoT big data with low latency.

Fog computing (Bonomi et al. 2012) extends the ability of clouds to edge servers with the goal of minimizing latency and maximizing the efficiency of core clouds. Fog computing can also be used to deal with noisy big data in IoT (Bonomi et al. 2012). For instance, Amazon service enables creation of fog computing that can be pipelined to other Amazon cloud services (e.g., Amazon SimpleDB and EMR) for big data processing.

Cloud-Based Big Data Analytics Tools

Unlike conventional data that are either structured (e.g., XML, XAML, and relational databases) or unstructured, big data can be a mixture of structured, semi-structured, or unstructured data (Wu et al. 2014). It is approximated that around 85% of total data come from organization are unstructured and moreover, almost all the individuals generated data are also unstructured (Pusala et al. 2016).

Such heterogeneous big data cannot be analyzed using traditional database management tools (e.g., relational database management system (RDBMS)). Rather, a set of new cloud-based processing tools have been developed for processing big data (Chen et al. 2014).

NoSQL-NoSQL (generally referred to as “Not Only SQL”) is a framework for databases that provides high-performance processing for big data. In fact, conventional relational database systems have several features (e.g., transactions management and concurrency control) that make them unscalable for big data. In contrast, NoSQL databases are relieved from these extra features and lend themselves well to distributed processing in the clouds. These database systems can generally handle big data processing in real-time or near real-time. In this part, an overview of the NoSQL databases offered by clouds is explained.

- **Hadoop MapReduce** – MapReduce framework was published by google in 2005 (Ditttrich and Quiané-Ruiz 2012). Hadoop is an open source implementation tool based on MapReduce framework developed by Apache (Vavilapalli et al. 2013). Hadoop is a batch data analytics technology that is designed for failure-prone computing environments. The specialty of Hadoop is that developers need to define only the map and reduce functions that operate on big data to achieve data analytics. Hadoop utilizes a special distributed file system, named Hadoop Distributed File System (HDFS), to handle data (e.g., read and write operations). Hadoop achieves fault-tolerance through data replication. Amazon Elastic MapReduce (EMR) (<https://aws.amazon.com/emr/details/hadoop/>) is an example of Hadoop framework (Jourdren et al. 2012) offered as a service by Amazon cloud. Amazon EMR helps to create and handle elastic clusters of Amazon EC2 instances running Hadoop and other applications in the Hadoop system.

- **Key-Value Store** – key-value database system is designed for storing, retrieving, and handling data in mapping format where data are considered as a value and a key is used as an identifier of a particular data as because keys and values are resided pairwise in the database system. Amazon DynamoDB (<https://aws.amazon.com/dynamodb/>), GoogleBigTable (<https://cloud.google.com/bigtable/>), and HBase (<https://hbase.apache.org/>) are examples of cloud-based key-value store databases to handle big data.

• **Document Store** – These database systems are similar to key-value store databases. However, keys are mapped to documents, instead of values. Pairs of keys and documents (e.g., in JASON or XML formats) are used to build data model over big data in the cloud. This type of database systems are used to store semi-structured data as documents, usually in JSON, XML, or XAML formats. Amazon cloud offers Amazon SimpleDB (<https://aws.amazon.com/simpledb/>) as a document store database service that creates and manages multiple distributed replicas of data automatically to enable high availability and data durability. Data owner can change data model on the fly, and data are automatically indexed later on.

• **Graph Databases** – These database systems are used for processing data that have graph nature. For instance, users' connections in a social network can be modeled using a graph database (Shimpi and Chaudhari 2012). In this case, users are considered as nodes and connections between users are represented as edges in the graph. The graph can be processed to predict links between nodes. That is, possible connections between users. Giraph (<http://giraph.apache.org/>), Neo4j (<https://zeroturnaround.com/rebellabs/examples-where-graph-databases-shine-neo4j-edition/>), and FlockDB (https://blog.twitter.com/engineering/en_us/a/2010/introducing-flockdb.html) are examples of cloud-based graph database services. Facebook (<https://www.facebook.com>), a large social networking site, is currently using Giraph database system to store and analyze their users' connections.

In Memory Analytics – These are techniques that process big data in the main memory (RAM) with reduced latency (Dittrich and Quiané-Ruiz 2012). For instance, Amazon provides Elastic-Cache (<https://aws.amazon.com/elasticcache/>) service to improve web applications' performance which at previous generally relied on slower disk-based databases. Beside that there are also tools for performing **in memory analytics** on the big data in cloud such as Apache Spark, SAP, and Microstrategy (Sultan 2015).

Different big data analytic tools introduced in this section are appropriate for different types of datasets and applications. There is no single perfect solution for all types of big data analytics in the cloud.

Future Directions for Research

Cloud-based big data analytics has progressed significantly over the past few years. The progression has led to emergence of new research areas that need further investigations from industry and academia. In this section, an overview of these potential areas is provided.

Different businesses use various cloud providers to handle their big data. However, current big data analytics tools are limited to a single cloud provider. Solutions are required to bridge big data stored in different clouds. Such solutions should be able to provide real-time processing of big data across multiple clouds. In addition, such solutions should consider security constraints of big data reside in different clouds.

The distribution of access to data is not uniform in all big datasets. For instance, social network pages and video stream repositories (Li et al. 2016 and Darwich et al. 2017) have long-tail access patterns. That is, only few portions of big data are accessed frequently, while the rest of the datasets are rarely accessed. Solutions are required to optimally place big data in different cloud storage types, with respect to access rate to the data. Such solutions can minimize the incurred cost of using cloud and access latency to the data.

Security of big data in cloud is still a major concern for many businesses (Woodworth et al. 2016). Although there are tools that enable processing (e.g., search) of user-side encrypted big data in cloud, further research is required to expand processing of such data without revealing them to the cloud. Making use of homomorphic encryption (Naehrig et al. 2011) is still in its infancy. It can be leveraged to enable more sophisticated (e.g., mathematical) data processing without decrypting data in the cloud.

Conclusion

The size of digital data is rapidly growing to the extent that storage and processing have become challenging. Cloud services have emerged to address these challenges. Nowadays, cloud providers offer collection of services that can address different big data demands. In particular, they provide levels of storage with different prices and access latencies. They also provide big data distribution based on CDN techniques to reduce access latency further. For big data analytics, clouds offer several services, including NoSQL databases and in memory big data analytics.

Although clouds have been instrumental in enabling big data analytics, security and privacy of data are still major impediments for many businesses to embrace clouds.

B

Definitions

The major theme of this topic is building indexes, which are auxiliary data structures, on top of big datasets to speed up its retrieval and querying. The topic covers a wide range of index types along with a comparison of their structures and capabilities.

Overview

Big data infrastructures such as Hadoop are increasingly supporting applications that manage structured or semi-structured data. In many applications including scientific applications, weblog analysis, click streams, transaction logs, and airline analytics, at least partial knowledge about the data structure is known. For example, some attributes (columns in the data) may have known data types and possible domain of values, while other attributes may have little information known about them. This knowledge, even if it is partial, can enable optimization techniques that otherwise would not be possible.

Query optimization is a core mechanism in data management systems. It enables executing users' queries efficiently without the users having to know how their queries will execute. A query optimizer figures out the best query plan to execute, in which order the query operators will run, where the data should be located and how will it move during the processing, and which segments of a query can execute in parallel versus running in sequence. Query optimization in big data is highly important, especially because (1) the datasets to be processed are getting very large, (2) the analytical queries are increasing in complexity and may take hours to execute if not carefully optimized, and (3) the pay-as-you-go

cost models for cloud computing add additional urgency for optimized processing.

A typical query in big data applications may touch files in the order of 100s of GBs or TBs of size. These queries are typically very expensive as they consume significant resources and require long periods of time to execute. For example, in transaction log applications, e.g., transaction history of customer purchases, one query might be interested in retrieving all transactions from the last 2 months that exceed a certain amount of dollar money. Such query may need to scan billions of records and go over TBs of data.

Indexing techniques are well-known techniques in database systems, especially relational databases (Chamberlin et al. 1974; Maier 1983; Stonebraker et al. 1990), to optimize query processing. Examples of the standard indexing techniques are the B+-tree (Bayer and McCreight 1972), R-Tree (Guttman 1984), and Hash-based indexes (Moro et al. 2009) along with their variations. However, transforming these techniques and structures to big data infrastructures is not straightforward due to the unique characteristics of both the data itself and the underlying infrastructure processing the data. At the data level, the data is no longer assumed to be stored in relational tables. Instead, the data is received and stored in the forms of big batches of flat files. In addition, the data size exceeds what relational database systems can typically handle.

On the other hand, at the infrastructure level, the processing model no longer follows the relational model of query execution, which relies on connecting a set of query operators together to form a query tree. Instead, the MapReduce computing paradigm is entirely different as it relies on two rigid phases of *map* and *reduce* (Dean and Ghemawat 2008). Moreover, the access pattern of the data from the file system is also different. In relational databases, the data records are read in the form of disk pages (a.k.a disk blocks), which are very small in size (typically between 8 to 128 KBs) and usually hold few data records (10s or at most 100s of records). And thus, it is assumed that the database systems can support record-level access. In contrast, in the Hadoop file system (HDFS), a single data block ranges

between 64 MBs to 1 GB, and usually holds many records. Therefore, the record-level access no longer holds. Even the feasible operations over the data are different from those supported in relational databases. For example, record updates and deletes are not allowed in the MapReduce infrastructure. All of these unique characteristics of big data fundamentally affect the design of the appropriate indexing and preprocessing techniques.

Plain Hadoop is found to be orders of magnitude slower than distributed database management systems when evaluating queries on structured data (Stonebraker et al. 2010; Abadi 2010). One of the main observed reasons for this slow performance is the lack of indexing in the Hadoop infrastructure. As a result, significant research efforts have been dedicated to designing indexing techniques suitable for the Hadoop infrastructure. These techniques have ranged from record-level indexing (Dittrich et al. 2010, 2012; Jiang et al. 2010; Richter et al. 2012) to split-level indexing (Eltabakh et al. 2013; Gankidi et al. 2014), from user-defined indexes (Dittrich et al. 2010; Jiang et al. 2010; Gankidi et al. 2014) to system-generated and adaptive indexes (Richter et al. 2012; Dittrich et al. 2012; Eltabakh et al. 2013), and from single-dimension indexes (Dittrich et al. 2010, 2012; Jiang et al. 2010; Richter et al. 2012; Eltabakh et al. 2013) to multidimensional indexes (Liu et al. 2014; Eldawy and Mokbel 2015; Lu et al. 2014).

Table 1 provides a comparison among several of the Hadoop-based indexing techniques with respect to different criteria. Record-level granularity techniques aim for skipping irrelevant records within each data split, but eventually they may touch all splits. In contrast, the split-level granularity techniques aim for skipping entire irrelevant splits. SpatialHadoop system provides both split-level global indexing and record-level local indexing, and thus it can skip irrelevant data at both granularities.

Some techniques index only one attribute at a time (Dimensionality = 1), while others allow indexing multidimensional data (Dimensionality = m). Techniques like HadoopDB and Polybase Index inherit the multidimensional capabilities

Big Data Indexing, Table 1 Comparison of hadoop-based indexed techniques

Technique	Granularity	Dimensionality	DB-Hybrid	Definition	Index Location
Hadoop++ (Dittrich et al. 2010)	Record	1	No	Admin	HDFS
HAIL (Dittrich et al. 2012)	Record	1	No	Admin	HDFS
LIAH (Richter et al. 2012)	Record	1	No	System	HDFS
E3 (Eltabakh et al. 2013)	Split	1 & 2	No	System	DB
SpatialHadoop (Eldawy and Mokbel 2015)	Record/Split	m	No	Admin	HDFS
ScalaGist (Lu et al. 2014)	Record	m	No	Admin	HDFS
HadoopDB (Abouzeid et al. 2009)	Record	m	Yes	Admin	DB
Polybase Index (Gankidi et al. 2014)	Split	m	Yes	Admin	DB

from the underlying DBMS. E3 technique enables indexing pairs of values (from two attributes) but only for a limited subset of the possible values. Most techniques operate only on the HDFS data (DB-Hybrid = N), while HadoopDB and Polybase Index have a database system integrated with HDFS to form a hybrid system.

In most of the proposed techniques, the system's admin decides on which attributes to be indexed. The only exceptions are the LIAH index, which is an adaptive index that automatically detects the changes of the workload and accordingly creates (or deletes) indexes, and the E3 index, which automatically indexes all attributes in possibly different ways depending on the data types and the workload. Finally, the index structure is either stored in HDFS along with its data as in Hadoop++, HAIL, LIAH, SpatialHadoop, and ScalaGist, in a database system along with its data as in HadoopDB, or in a database system while the data resides in HDFS as in E3 and Polybase Index. The following sections cover few of these techniques in more details.

Target Queries: Indexing techniques target optimizing queries that involve selection predicates, which is the common theme for all techniques listed in Table 1. Yet, they may differ on how queries are expressed and the mechanism by which the selection predicates are identified. For example, Hadoop++, HAIL, and LIAH allow expressing the query in Java while passing the selection predicates as arguments within the map-reduce job configuration. As a result, a customized input format will receive these predicates (if any) and perform the desired filtering during execution. In contrast, E3 framework is built on

top of the Jaql high-level query language (Beyer et al. 2011), and thus queries are expressed, compiled, and optimized using Jaql engine (Beyer et al. 2011). An example query is as follows:

```
read( hdfs("docs.json") )
-> transform {
author: $.meta.author,
products: $.meta.product,
Total: $.meta.Qty * $.meta.
    Price}
-> filter $.products == "XYZ";
```

Jaql has the feature of applying *selection-push-down* during query compilation whenever possible. As a result, in the given query the filter operator will be pushed before the transform operator, with the appropriate rewriting. The E3 framework can then detect this filtering operation directly after the read operation of the base file and thus can push the selection predicate into its customized input format to apply the filtering as early as possible.

HadoopDB provides a front-end for expressing SQL queries on top of its data, which is called SMS. SMS is an extension to Hive. In HadoopDB queries are expressed in an identical way to standard SQL as in the following example:

```
SELECT pageURL, pageRank
  FROM Rankings
 WHERE pageRank > 10;
```

SpatialHadoop is designed for spatial queries, and thus it provides a high-level language and constructs for expressing these queries and operating on spatial objects, e.g., points and

rectangles. For example, a query can be expressed as follows:

```
Objects = LOAD "points" AS
(id:int, Location:POINT);
Result = FILTER Objects BY
Overlaps (Location,
Rectangle(x1, y1, x2, y2));
```

ScalaGist enables building Gist indexes, e.g., B+-tree and R-tree, over HDFS data. A single query in ScalaGist can make use of multiple indexes at the same time. For example, given a table T with schema $\{x, \dots, (a1, a2)\}$, where x is a one-dimensional column and $(a1, a2)$ is a two-dimensional column, the following query can use both a B+-tree index (on x) and an R-tree index (on $(a1, a2)$) during its evaluation:

```
SELECT *
FROM T
WHERE x ≤ 100
    AND 10 ≤ a1 ≤ 20
    AND 30 ≤ a2 ≤ 60;
```

Finally, the Polybase system enables expressing queries using standard SQL over HDFS data that are defined as external tables. First, users need to define the external table as in the following example:

```
Create External Table
hdfsLineItem
(l_orderkey BIGINT Not Null,
l_partkey BIGINT Not Null,
...)
With (Location = '/tpch1gb/
lineitem.tbl',
Data_Source = VLDB_HDP_Cluster,
File_Format = Text_Delimited);
```

And then, a query on the external table can be expressed as follows:

```
SELECT *
FROM hdfsLineItem
WHERE l_orderkey = 1;
```

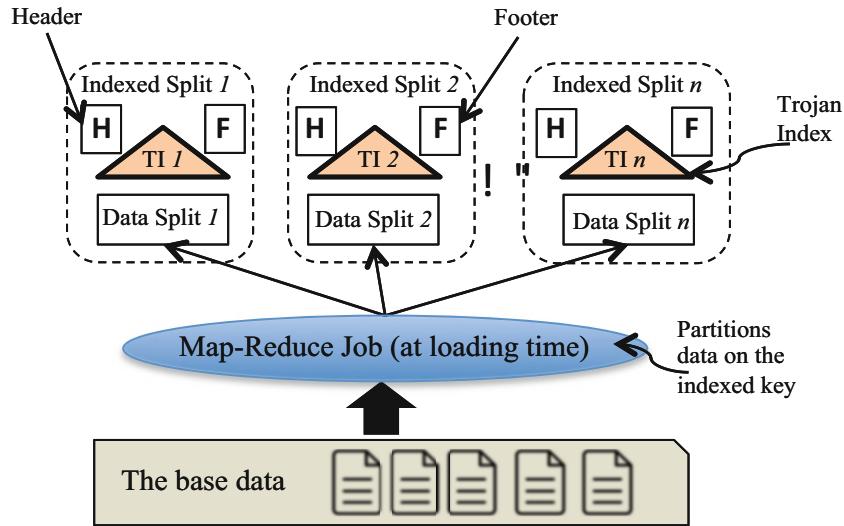

Record-Level Nonadaptive Indexing

Hadoop++ (Dittrich et al. 2010) is an indexing technique built on top of the Hadoop infrastructure. Unlike other techniques that require extensive changes to Hadoop's execution model to offer run-time optimizations, e.g., HadoopDB (Abouzeid et al. 2009; Abouzied et al. 2010), Hadoop++ relies on augmenting the indexing structures to the data in a way that does not affect the execution mechanism of Hadoop. All processing on the indexes, e.g., creating the indexes, augmenting them to the data, and their access, are all performed through pluggable user-defined functions (UDFs) that are already available within the Hadoop framework.

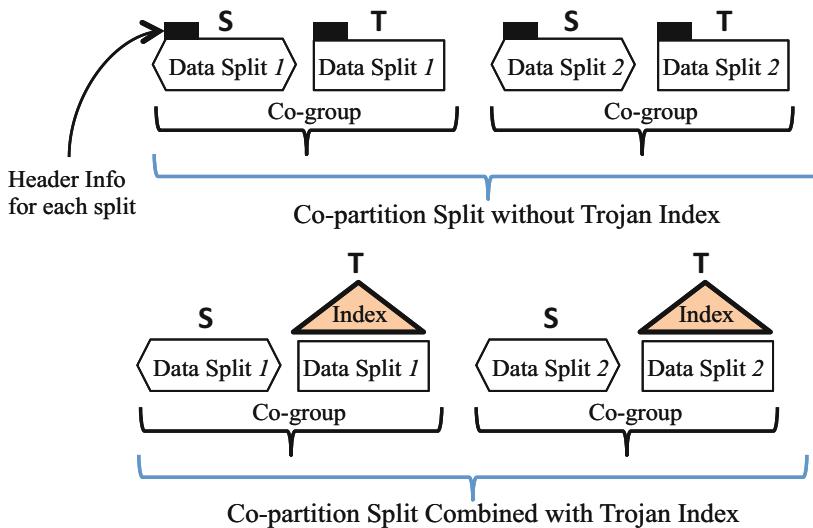

The basic idea of the Hadoop++ index, which is referred to as *a trojan index*, is illustrated in Fig. 1a. At the loading time, the base data is partitioned using a map-reduce job. This job partitions the data based on the attribute to be indexed, i.e., if attribute X is to be indexed, then depending on the X 's value in each record, the record will be assigned to a specific split Id. This assignment is performed by the mapper function. On the other hand, the reducer function receives all the records belonging to a specific split and creates the trojan index corresponding to that split.

The index is then augmented to the data split to form a bigger split, referred to as *an indexed split* as depicted in the figure. Each indexed split will also have a *split header (H)*, and a *split footer (F)*, which together hold the metadata information about each indexed split, e.g., the split size, the number of records, the smallest and largest indexed values within this split, etc. In general, Hadoop++ can be configured to create several trojan indexes for the same data on different attributes. However, only one index can be the primary index according to which the data records are sorted within each split. This primary index is referred to as the *clustered index*, while the other additional indexes are *non-clustered indexes*.

At query time, given a query involving a selection predicate on one of the indexed attributes, the processing works as follows. First, a custom InputFormat function would read each indexed split

(a) Hadoop++ Trojan Index

(b) Hadoop++ Trojan Join

Big Data Indexing, Fig. 1 Hadoop++ Trojan Index and Trojan Join

(instead of the data splits) and consult the trojan index for that split w.r.t the selection predicate. If there are multiple indexes, then the appropriate index is selected based on the selection predicate. If none of the records satisfies the query predicate, then the entire split is skipped, and the map function terminates without actually checking any record within this split. Otherwise, the

trojan index will point to the data records within the split that satisfies the query. If the trojan index is clustered, then this means that the data records within the given block are ordered according to the indexed attribute, and thus the retrieval of the records will be faster and requires less I/Os.

It is worth highlighting that trojan indexes are categorized as *local* indexes meaning that a local

index is created for each data split in contrast to building a single global index for the entire dataset. Local indexes have their advantages and disadvantages. For example, one of the advantages is that the entire dataset does not need to be sorted, which is important because global sorting is prohibitively expensive in big data. However, one disadvantage is that each indexed split has to be touched at query time. This implies that a mapper function has to be scheduled and initiated by Hadoop for each split even if many of these splits are irrelevant to the query.

Hadoop++ framework also provides a mechanism, called *Trojan Join*, to speed up the join operation between two datasets, say S and T (refer to Fig. 1b). The basic idea is to partition both datasets (at the same time) on the join key. This partitioning can be performed at the loading time as a preprocessing step. The actual join does not take place during this partitioning phase. Instead, only the corresponding data partitions from both datasets are grouped together in bigger splits, referred to as *Co-Partition Splits*.

At query time, when S and T need to be joined, the join operation can take place as a map-only job, where each mapper will be assigned one complete co-partition split. As such, each mapper can join the corresponding partitions included in its split. Therefore, the join operation becomes significantly less expensive since the shuffling/sorting and reduce phases have been eliminated (compared to the traditional map-reduce join operation in Hadoop). As highlighted in Fig. 1b, the individual splits from S or T within a single co-group may have a trojan index built on them.

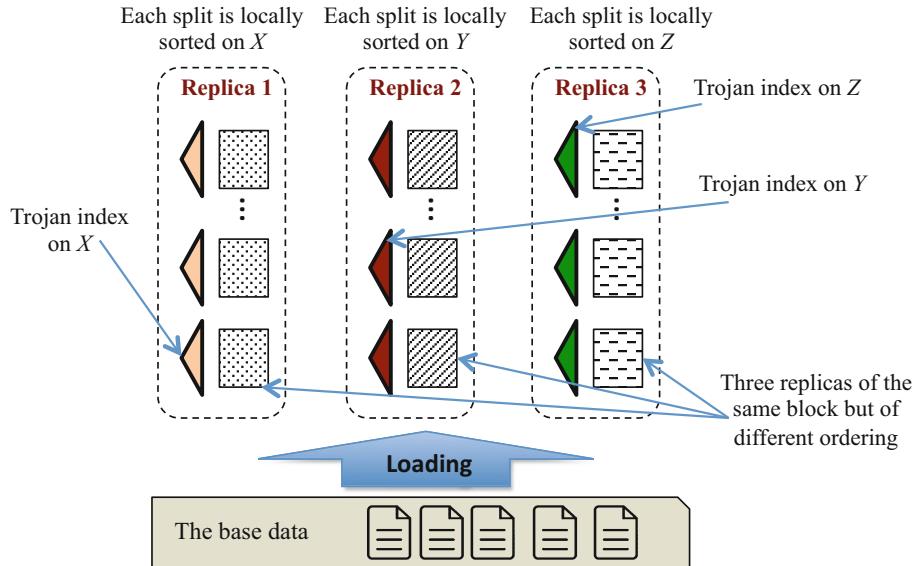

Hadoop++ framework is suitable for static indexing and joining. That is, at the time of loading the data into Hadoop, the system needs to know whether or not indexes need to be created (and on which attributes) and also whether or not co-partitioning between specific datasets needs to be performed. After loading the data, no additional indexes or co-partitioning can be created unless the entire dataset is reprocessed from scratch. Similarly, if new batches of files arrive and need to be appended to an existing indexed dataset, then the entire dataset needs to be reloaded (and

the entire indexes to be re-created) in order to accommodate for the new batches.

Record-Level Adaptive Indexing

The work proposed in Dittrich et al. (2012), Richter et al. (2012) overcomes some of the limitations of other previous indexing techniques, e.g., Dittrich et al. (2010) and Jiang et al. (2010). The key limitations include the following: First, *high creation overhead for indexes*. Usually building the indexes requires a preprocessing step, and this step can be expensive since it has to go over the entire dataset. Previous evaluations have shown that this overhead is usually redeemed from few queries, i.e., the execution of few queries using the index will redeem the cost paid upfront to create the index. Although that is true, reducing the creation overhead is always a desirable thing. The second limitation is the question of *which attributes to index?* In general, if the query workload is changing, then different indexes may need to be created (or deleted) over time. The work in Dittrich et al. (2012) and Richter et al. (2012) addresses these two limitations.

HAIL (Hadoop Aggressive Indexing Library) (Dittrich et al. 2012) makes use of the fact that Hadoop, by default, creates three replicas of each data block – this default behavior can be altered by the end users to either increase or decrease the number of replicas. In plain Hadoop, these replicas are exact mirror of each other. However, HAIL proposes to reorganize the data in each replica in a different way, e.g., each of the three replicas of the same data block can be sorted on a different attribute. As a result, a single file can have multiple clustered indexes at the same time. For example, as illustrated in Fig. 2, the 1st replica can have each of its splits sorted on attribute X , the 2nd replica sorted on attribute Y , and the 3rd replica sorted on attribute Z . These sorting orders are local within each split. Given this ordering, a clustered trojan index as proposed in Dittrich et al. (2010) can be built on each replica independently.

Big Data Indexing, Fig. 2 HAIL Indexing Framework

HAIL also proposes a *replica-aware scheduling policy*. In plain Hadoop, since all replicas are the same, the task scheduling decision does not differentiate between the replicas. In contrast in HAIL the task scheduler needs to take the query predicates into account while selecting the target replica to work on. For example, referring to Fig. 2, given a query involving a selection predicate on attribute Y , then HAIL scheduler will try to assign the map tasks to the splits of the 2nd replica. Otherwise, a full scan operation has to be performed on either of the other replicas because their indexes cannot help in evaluating the given predicate.

LIAH (Lazy Indexing and Adaptivity in Hadoop) indexing framework (Richter et al. 2012) further extends the idea of HAIL by adaptively selecting the columns to be indexed under changing workloads and also lazily building these indexes as more queries execute in the system. LIAH can incrementally build a given index starting from indexing few splits and incrementally indexing more splits as more queries are executed until the entire index is built. This strategy is based on the idea of *piggybacking* the index creation task over other user's queries to reduce the overheads involved in the index creation.

Referring to Fig. 2, in LIAH it is possible that the system starts without any indexes on the base data. And then, by automatically observing the query workload, the system decides that attributes X and Y are good candidates for indexing, e.g., many queries have selection predicates on either of these two attributes. LIAH puts a strategy to incrementally make the splits of the 1st replica sorted based on X , and for each split where its data becomes sorted, its corresponding trojan index is built. LIAH framework keeps track of which blocks have been indexed and which blocks need to be indexed (which will be done progressively and piggybacked over future users' jobs). As more user jobs are submitted to the system and the data blocks are read anyway, additional blocks can be indexed. In this way, the overheads involved in the index creation are distributed over many user queries.

Split-Level Indexing

Most of the previous indexing techniques proposed over the Hadoop infrastructure try to mimic the indexes in traditional databases in that they are record-level indexes. That is, their objective is to eliminate and skip irrelevant

records from being processed. Although these techniques show some improvements in query execution, they still encounter unnecessary high overhead during execution. For example, imagine the extreme case where a queried value x appears only in very few splits of a given file. In this case, the indexing techniques like Hadoop++ and HAIL would encounter the overheads of starting a map task for each split, reading the split headers, searching the local index associated with the split, and then reading few data records or directly terminating. These overheads are substantial in a map-reduce job and if eliminated can improve the performance.

The *E3* framework proposed in Eltabakh et al. (2013) is based on the aforementioned insight. Its objective is not to build a fine-grained record-level index but instead be more Hadoop-compliant and build a coarse-grained split-level index to eliminate entire splits whenever possible. *E3* proposes a suite of indexing mechanisms that work together to eliminate irrelevant splits to a given query before the execution, and thus map tasks start only for a potentially small subset of splits (See Fig. 3a). *E3* integrates four indexing mechanisms, which are *split-level statistics*, *inverted indexes*, *materialized views*, and *adaptive caching*; each is beneficial under specific cases. The split-level statistics are calculated for each number and date field in the dataset.

Examples of the collected statistics include the *min* and *max* values of each field in each split, and if this min-max range is very sparse, then the authors have proposed a domain segmentation algorithm to divide this range into possibly many but tighter ranges to avoid false positives (a false positive is when the index indicates that a value may exist in the dataset while it is actually not present). The inverted index is built on top of the string fields in the dataset, i.e., each string value is added to the index, and it points to all splits including this values. By combining these two types of indexes for a given query involving a selection predicate, *E3* can identify which splits are relevant to the query, and only for those splits a set of mappers will be triggered.

The other two mechanisms, i.e., materialized views and adaptive caching, are used in the cases

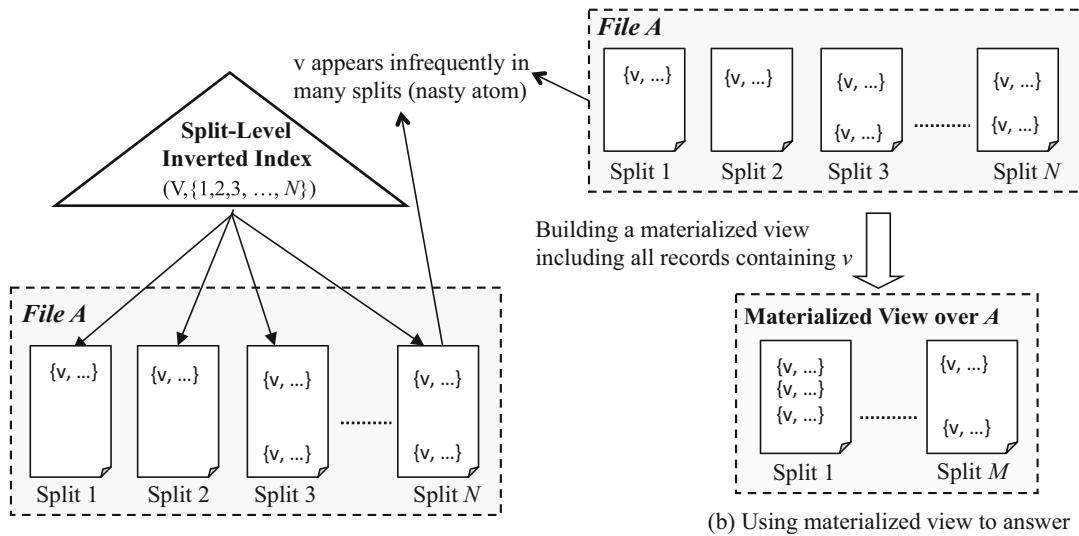

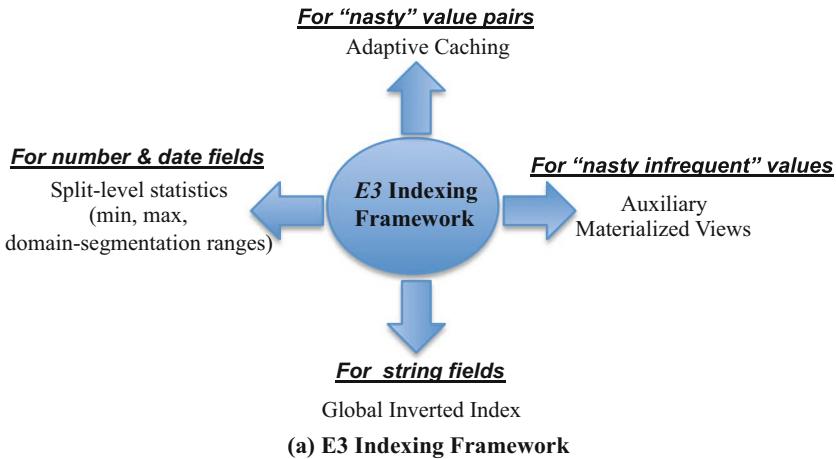

where indexes are mostly useless. One example provided in Eltabakh et al. (2013) is highlighted in Fig. 3b. This example highlights what is called “*nasty values*,” which are values that are infrequent over the entire dataset but scattered over most of the data splits, e.g., each split has one or few records of this value. In this case, the inverted index will point to all splits and becomes almost useless.

E3 framework handles these nasty values by coping their records into an auxiliary materialized view. For example, the base file *A* in Fig. 3b will now have an addition materialized view file stored in HDFS that contains a copy of all records having the nasty value v . Identifying the nasty values and deciding on which ones have a higher priority to handle have been proven to be an NP-hard problem, and the authors have proposed an approximate greedy algorithm to solve it (Eltabakh et al. 2013).

The adaptive caching mechanism in *E3* is used to optimize conjunctive predicates, e.g., ($A = x$ and $B = y$), under the cases where each of x and y individually is frequent, but their combination in one record is very infrequent. In other words, none of x or y is nasty value, but their combination is a *nasty pair*. In this case, neither the indexes nor the materialized views are useful. Since it is prohibitively expensive to enumerate all pairs and identify the nasty ones, the *E3* framework handles these nasty pairs by dynamically observing the query execution and identifying on the fly the nasty pairs. For example, for the conjunctive predicates ($A = x$ and $B = y$), *E3* consults the indexes to select a subset of splits to read. And then, it will observe the number of mappers that actually produced matching records. If the number of mappers is very small compared to the triggered ones, then *E3* identifies (x, y) to be a nasty pair. Consequently, (x, y) will be cached along with pointers to its relevant splits.

Hadoop-RDBMS Hybrid Indexing

There has been a long debate on whether or not Hadoop and database system can coexist

(b) **E3 Inverted Indexes vs. Materialized Views****Big Data Indexing, Fig. 3** E3 indexing framework (Eltabakh et al. 2013)

together in a single working environment and whether or not this strategy is beneficial. There are several successful projects that built such integration (Abouzeid et al. 2009; Gankidi et al. 2014; Floratou et al. 2014a,b; Balmin et al. 2013; Katsipoulakis et al. 2015; Tian et al. 2016).

HadoopDB is one of the early projects that brings the optimizations of relational database systems to Hadoop (Abouzeid et al. 2009). HadoopDB proposes major changes to Hadoop's

infrastructure by replacing the HDFS storage layer by a database management layer. That is, the Data Node and Task Tracker on each slave node in the Hadoop's cluster will be running an instance of a database system. This database instance replaces the HDFS layer, and thus the data on each slave node are stored and managed by the database engine.

HadoopDB will push as much of work as possible to the database engine, and as a result

all indexing capabilities and query optimizations of database systems automatically become accessible. However, the drawback of HadoopDB is that the management of dynamic scheduling and fault tolerance becomes more complicated. In addition, the integration of structured and unstructured data in the same workflow becomes tricky to perform.

Polybase (Gankidi et al. 2014) is another system that enables the integration of Hadoop and database engines. In Polybase, the HDFS datasets are defined within the database system as *external tables*. And then, users' queries can span both the data stored in the DBMS and the data stored in HDFS's external tables. At execution time, part of the query can be translated to map-reduce jobs while another part is SQL-based.

The data flow between the two systems in Polybase takes place through custom Input-Formats and Database Connectors. However, without efficient access plans to the data in the external tables, these tables can easily become a bottleneck, and the entire execution plan slows down. The work in Gankidi et al. (2014) proposes an indexing technique, called *Polybase Split-Indexing*, that creates B+-tree indexes on the HDFS datasets. These indexes reside within the database system. These indexes can be leveraged in different ways. For selection queries, they can be used as early split-level filters to identify the relevant splits in HDFS. For join queries, they can be used for performing a semi-join within the database system before retrieving HDFS's data. Moreover, they can be used as caches of *hot* HDFS data within the database system, and if a query touches only the attributes within the index, then the entire processing can be performed inside the database.

Conclusion

This entry covers various types of big data indexing techniques to speed up and enhance the data's retrieval and querying. These techniques range from record-level to split-level, nonadaptive to adaptive, and non-hybrid to hybrid. They also cover a wide range of data types includ-

ing relational-like data, spatial data, and semi-structured JSON data. The presented techniques are the backbones for numerous applications that run at scale over big data. And with the increasing complexity of these applications in terms of the size of the collected or generated data, the heterogeneity in the data types, and the growing complexity of the applied analytics and querying, the indexing techniques will play an even more important role in bringing the processing performance into the realm of feasibility.

Definitions

Big Sensing Data Streams, CIA triad, Security, Threats.

Overview

This chapter provides security classification of Big Sensing Data Streams in IoT infrastructure, which focused end-to-end data communications from IoT devices to Cloud. Security classification is made based on CIA triad. Individual component of CIA triad is defined by highlighting Big Data Streams security properties. Subsequently, security properties and descriptions are explained individually. Finally, potential threats are highlighted and classified based on CIA.

Introduction

The IoT is enabled by the latest developments in RFID, smart sensors, communication technologies, and Internet protocols. The basic premise is

to have smart sensors collaborate directly without human involvement to deliver a new class of applications (Granjal et al. 2015; Puthal et al. 2016a, b). As security will be a fundamental enabling factor of most IoT applications, mechanisms must also be designed to protect communications enabled by such technologies (Sharma et al. 2017). Granjal et al. (2015) reviewed the first article on IoT communication security. Other surveys do exist that, rather than analyzing the technologies currently being designed to enable Internet communications with sensing and actuating devices, focus on the identification of security requirements and on the discussion of approaches to the design of new security mechanisms (Medaglia and Serbanati 2010; Puthal et al. 2017a; El-Sayed et al. 2017) or, on the other end, discuss the legal aspects surrounding the impact of the IoT on the security and privacy of its users (Puthal et al. 2016a, 2017b; Weber 2010).

Applications dealing with large data sets obtained via simulation or actual real-time sensor networks/social network are increasing in abundance (Puthal et al. 2015a, 2017b, Fox et al. 2004). The data obtained from real-time sources may contain certain discrepancies which arise from the dynamic nature of the source. Furthermore, certain computations may not require all the data, and hence this data must be filtered before it can be processed (Puthal et al. 2015a, 2016b, 2017c). By installing adaptive filters that can be controlled in real time, we can filter out only the relevant parts of the data, thereby improving the overall computation speed.

Nehme et al. (2009) proposed a system StreamShield system designed to address the problem of security and privacy in the data stream. They have clearly highlighted the need of two types of security in data stream, i.e., (1) the “data security punctuations” (dsps), describing the data-side security policies, and (2) the “query security punctuations” (qsps) in their paper. The advantages of such stream-centric security model include flexibility, dynamicity, and speed of enforcement. Stream processor can adapt to not only data-related but also to security-related selectivity, which helps reduce the waste

of resources, when few subjects have access to streaming data (Puthal et al. 2015b, 2017d).

- Security verification is very important in data stream in order to avoid the unwanted and corrupted data.
- Another important problem needs to address to perform the security verification in near real time.
- Security verification should not degrade the performance of stream processing engine, i.e., speed of security verification should be much more efficient than stream processing engine.

There are several applications that exist where IoT devices work as source of data stream (Puthal et al. 2017d, e). Here we list out several applications such as real-time health monitoring applications (health care), industrial monitoring, geo-social networking, home automation, war front monitoring, smart city monitoring, SCADA, event detection, disaster management, and emergency management.

From above all applications, we found data that needs to be protected from malicious attacks to maintain originality of data before it reaches at data processing center (Puthal et al. 2016b, 2017c, d; Chen et al. 2015). As the data sources are sensor nodes, it is always important to propose lightweight security solutions for data stream (Chen et al. 2015).

The rest of the paper is organized as follows: section “[Security Properties](#)” gives the security classification and properties, section “[CIA Triad](#)” highlights the CIA triad properties of big data streams, subsequently section “[Classification](#)” classifies the security issues based on CIA properties, and finally this paper concluded in section “[Conclusion](#)”.

Security Properties

The goal of security services in big data stream is to protect the information and resources from malicious attacks and misbehavior (Puthal et al. 2016a). The security requirements in big data stream include:

- **Availability:** which ensures that the data stream is accessible to authenticated user and specific applications according to the predefined features.
- **Authorization:** which ensures that only authorized user can be involved in data analysis and modification.
- **Authentication:** which ensures that the data are from the legitimate sources by providing end-to-end security services. Data should not be from any malicious sources.
- **Confidentiality:** which ensures that a given message cannot be understood by anyone other than the desired recipients.
- **Integrity:** which ensures that a message sent from sources till the data center (cloud) is not modified by malicious intermediate.
- **Nonrepudiation:** which denotes that the source cannot deny sending a message it has previously sent.
- **Freshness:** which implies that the data is recent and ensures that no adversary can replay old messages.

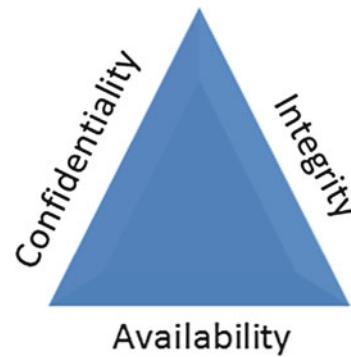

Moreover, forward and backward secrecy should also be considered, when we get the data from net set of sources.

- **Forward secrecy:** a source device should not be able to read any future messages after it leaves the network.
- **Backward secrecy:** a joining source device should not be able to read any previously transmitted message.

By considering above security requirements, we divided the security issues, threats, and solutions of IoT-generated big data stream based on CIA (confidentiality, integrity, and availability) triad. The following sections give the details about this.

CIA Triad

Confidentiality, integrity, and availability, also known as the **CIA triad**, is a model designed to guide policies for information security within

Big Data Stream Security Classification for IoT Applications, Fig. 1 CIA triad of data security either data in transit or in halt

big data stream. The **CIA triad** is shown in Fig. 1. The model is also sometimes referred to as the AIC triad (availability, integrity, and confidentiality) to avoid confusion with the Central Intelligence Agency. The elements of the triad are considered the three most crucial components of security.

Confidentiality – secrecy of the data either in transit or in halt of data. Our data stream deals with data in transit. **Def:** Confidentiality is a set of rules or a promise that limits access or places restrictions on certain types of information in data stream.

Partial confidentiality of the data is when there is considerable informational disclosure on some situation [84]. **Weak confidentiality** is in the case where some parts of the original data blocks can be reconstructed explicitly from fewer than m pieces (Bella and Paulson 1998). Information dispersal algorithms (IDAs) have weak confidentiality, and an eavesdropper can reconstruct some segments of the original file F explicitly from fewer than m pieces in the case of weak confidentiality.

Measures of the impact on confidentiality of a successful exploit of the vulnerability on the target system:

- Partial: There is considerable informational disclosure.
- Complete: A total compromise of critical system information.

Integrity – modifies the data (modify or misuse of the data) to maintain internal consistency and external consistency. **Def:** Integrity, in terms of big data stream, is the assurance that information can only be accessed or modified by those authorized users or applications. Measures taken to ensure integrity include controlling the physical environment of networked terminals and servers, restricting access to data, and maintaining rigorous authentication practices. Authentication process is the part of integrity process.

Authentication: This measures whether or not an attacker needs to be authenticated in big data stream in order to exploit the vulnerability. Authentication is required to access and exploit the vulnerability.

Measures of the impact on integrity of a successful exploit of the vulnerability on the target system:

- Partial: Considerable breach in integrity
- Complete: A total compromise of system integrity

Availability – means data must be available in the system by using controls (administrative controls, technical controls (security, firewalls, encryptions), physical controls (mass layer, i.e., access control, safety of the data)). **Def:** Data availability is a term in big data stream to ensure that data continues to be available at a required level of performance in situations ranging from normal through disastrous. In general, data availability is achieved through providing access to authenticated user and/or applications. It also works same as works at the data center for ensuring data availability (access control).

Measures of the impact on availability of a successful exploit of the vulnerability on the target system:

- Partial: Considerable lag in or interruptions in resource availability
- Complete: Total shutdown of the affected resource

Confidentiality of Big Data Streams

Confidentiality is the ability to cover messages from a passive attacker so that information in big data streams remains confidential. This is one of the most important issues for several applications such as health care, military, etc. Confidentiality must be maintained throughout the entire lifetime of the data, from source smart IoT device to long-term archiving in a cloud data center (Puthal et al. 2017b). Confidentiality is typically achieved via data encryption. This is a kind of passive attack, where unauthorized attackers monitor and listen to the communication medium. The attacks against data privacy are always passive in nature.

Integrity of Big Data Streams

Data integrity of big data streams can be defined as the overall complete consistency of the data. This can be indicated by any malicious activity, while data is transmitted between the IoT devices or between IoT and cloud data center. This can also be defined as the man-in-the-middle attack. Data integrity is generally enforced during the system setup by applying standard security rules. Data integrity can be maintained through applying validation or error checking. Message authentication code (MAC) concept is broadly applied for the data integrity in IoT infrastructure.

Availability of Big Data Streams

Data availability in big data streams is to control the access to the end users or specific applications. This subsection classifies the different access controls with data stream properties. There are two questions required for the access control process, i.e., who and what?

Classification

Table 1 presents the possible threats and attacks of IoT-generated big data stream, and the classification is based on CIA (confidentiality, integrity, and availability) triad from previous discussion. As we have classified the complete security threats and solutions over big data stream in CIA triad in previous sections, here in Table 1, we give the pictorial classifications. As seen from

Big Data Stream Security Classification for IoT Applications, Table 1 Possible threats of IoT-generated big data stream in CIA triad representation

Confidentiality	Integrity	Availability
<ul style="list-style-type: none"> Access authorization Attack against privacy Monitoring and eavesdropping Traffic analysis Camouflage adversaries 	<ul style="list-style-type: none"> Spoofed, altered, or replayed data stream information Time synchronization Selective forwarding Eavesdropping (passive attacks) Dropping data packet attacks Desynchronization Sinkhole Selfish behavior on data forwarding Sybil Wormholes Acknowledgment spoofing Hello flood attacks 	<ul style="list-style-type: none"> Mandatory access control system Role-based access control Attribute-based access control Risk-based access control View-based access control Activity-based access control Encryption-based access control Proximity-based access control Privilege state-based access control Risk-based access control Discretionary access control Information flow control model

Table 1, security threats in big data stream always fall in any properties of CIA triad.

Conclusion

The IoT infrastructure may be already visible in current deployments where networks of smart sensing devices are being interconnected with the wireless medium, and IP-based standard technologies will be fundamental in providing a common and well-accepted ground for the development and deployment of new IoT applications. According to the 4Vs' features of big data, current data stream tends to the new term as big data stream where sources are the IoT smart sensing devices. Considering that security may be an enabling factor of many of IoT applications, mechanisms to secure data stream using data in flow for the IoT will be fundamental. With such aspects in mind, in this survey we perform a basic classification of security protocols.

Next-generation sequencing

Definitions

DNA sequencing is a modern technique for the precise determination of the order of nucleotides within a DNA molecule. Using this technique a huge amount of raw data is generated in life sciences.

Overview

Genome analyses play an important role in different applications in the life sciences ranging from animal breeding to personalized medicine. The technological advancements in DNA sequencing lead to vast amounts of genome data being produced and processed on a daily basis. This chapter provides an overview of the big data challenges in the area of DNA sequencing and discusses several data management solutions.

Next-generation sequencing (NGS) technologies make it possible for life scientists to produce huge amounts of DNA sequence data in a short period of time (Stephens et al. 2015). Using these technologies, in recent years thousands of genomes and short DNA sequence reads for humans, plants, animals, and microbes have been collected and explored, which enables us to develop a deeper understanding and gain new insights into the molecular mechanisms of different diseases including many types of cancer, allergies, or other disorders.

There is no doubt that NGS technologies bring considerable advantages in productivity or significant reduction in cost and time. The complexity and sheer amount of the resulting biological datasets are, however, more intricate than expected making their analysis and handling a real challenge.

Pedersen and Bongo (2016) state that off-the-shelf big data management systems might not be appropriate for an efficient and effective management of biological data: “Biological data differs in that it has more dimensions and noise, it is heterogeneous both with regards to biological content and data formats, and the statistical analysis methods are often more complex.” This

generally also applies to the specific case of DNA sequencing data. In particular, DNA data are often processed in a data analysis pipeline (like the META-pipe Pedersen and Bongo 2016) where not only the raw data but also several additional contextual metadata and provenance data are generated and have to be maintained. The raw data produced during DNA sequencing are image data generated by the sequencing hardware. Further DNA processing steps comprise:

Primary analysis: producing short DNA sequences (called reads) out of the raw data and assigning quality scores to them

Secondary analysis: assembling several short reads guided by a reference DNA sequence – this process is called read mapping – as well as analyzing the reads with respect to the reference sequence by, for example, identifying single nucleotide variants or deletions

Tertiary analysis: processing the genome data to achieve advanced analyses by integrating several data sources (like multiple DNA samples, metadata, annotations, etc.)

Big Data Challenges

Current life sciences are more and more data driven. In practice, this means that data are recorded and generated in an essentially automatic way. A large portion of life science data is taken up by DNA sequences that are, for example, used to identify the genetic basis of a disease in the medical sciences or of (wanted or unwanted) traits of cultivated plants or animals which are supposed to be used in breeding programs. It is obvious that such large bodies of data can no longer be stored and analyzed in the traditional way but can only be harnessed by advanced data management and analysis systems.

For the years around the millennium, the growth rate of computing power kept pace with the growth rate of data output of sequencing facilities, such that then data analysis was feasible even with ordinary PCs. This remarkable parallelism has ended in 2008 with the emergence of a new sequencing technology – next-generation sequencing. While computing power is predicted to follow Moore's law, that is,

roughly doubling every 24 months, the years after the advent of NGS witnessed a decline of sequencing cost that could only be measured in orders of magnitudes as can be seen in the so-called Carlson curves (Carlson 2003).

The challenges that arise by this gap between accumulation of data on the one hand and the capacities to store, analyze, and interpret them in a meaningful way are asking for new and creative, perhaps also radical ways to deal with data. We can distinguish two related, but distinct, aspects of this problem: (1) data storage and accessibility and (2) data analysis in acceptable times.

Key Research Findings

Several ways to address the big data challenges when processing genome sequencing data have been proposed in the last decade. We briefly survey several streams of research in the following subsections.

From Data Storage to Data Disposal

Thus far, the generally acknowledged, albeit in most cases, tacit agreement in the life sciences was to keep all raw data for the purpose of reproducibility or also for secondary analyses. This attitude has begun to erode in DNA sequencing projects. First, it should be clearly defined what raw data are in sequencing projects. In its most primitive form, the sequence raw data are image files which are processed in several steps to yield short sequence reads which in turn are assembled to transcripts, genes, or genomes. It has become a generally adopted practice to consider the short sequence reads, together with quality scores, as raw data which can be archived in the Sequence Read Archive (<https://www.ncbi.nlm.nih.gov/sra>). Probably unknowingly data scientists and analysts have adopted the plant breeders' wisdom: "Breeding is the art of throwing away" (Becker 2011) transforming it into "Managing data is the art of throwing away".

Sophisticated Algorithms for Data Analysis

A PubMed search has revealed a strong increase in scientific articles dealing with ultrafast algorithms suggesting that this is the response to the emergence of big data (Fig. 1). The speed of data processing in DNA sequence analysis can be increased by a combination of several factors, like storing sequence data in data structures that permit rapid access (e.g., hash tables or suffix arrays) and the development of lightweight algorithms that confine themselves to steps that are absolutely necessary. For instance, the quantification of gene expression based upon transcriptome data could be accelerated by an order of magnitude thanks to the so-called quasi-alignments. In short, it is determined via a quasi-alignment if a short sequence read and a given gene sequence match without the explicit calculation of a nucleotide-by-nucleotide alignment extending over the full length of the short read sequence. This is simply not needed for the purpose of expression quantification (Patro et al. 2017).

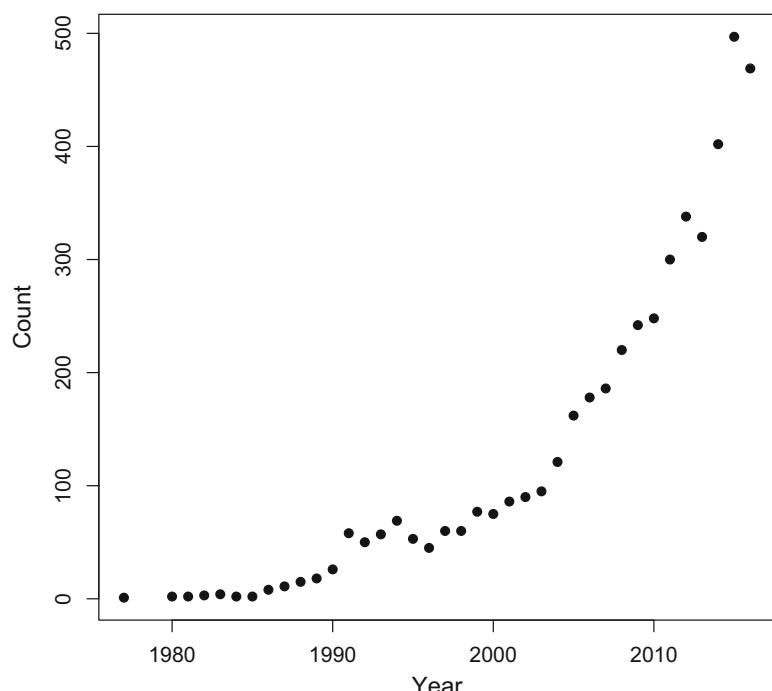

DNA-Specific Compression

Due to its string nature, specialized encodings of genomic data can significantly reduce the storage consumption – either with or without loss of accuracy. In particular, the mappings of several short DNA reads to a longer reference genome string offer benefits in terms of compressed data representation. Various lossless and lossy compression methods were devised and implemented to boil down the disk requirements. Accepting limited data losses, a compression by two orders of magnitude has turned out to be feasible (Popitsch and von Haeseler 2012). An even higher compression could be reached by the so-called delta encoding (Christley et al. 2008).

Such kinds of compression have been incorporated into standardized file formats for genome representation. The Sequence Alignment/Map (SAM) format stores the start position of a short read with respect to the reference genome, the read's actual sequence, and a CIGAR string denoting the differences between the short read sequence and the reference

Big Data Technologies for DNA Sequencing,

Fig. 1 Articles on ultrafast
algorithms in PubMed

genome, thus representing a significant reduction in disk space requirement. The lossy CRAM file format applies a heavyweight compression scheme and thus reduces the storage consumption even more (Bonfield and Mahoney 2013).

Departing from the idea of processing data stored in flat files, integrating genome-specific compression into a database system which holds data in the main memory was developed in Dorok et al. (2017). In this so-called base-centric encoding, each base is stored in a separate row of a database table such that database-specific operations can be used to analyze the genome sequence. This technique requires that the entire genome dataset fits into the main memory.

Parallel Processing and Modern Hardware Support

The accurate and fast detection of genomic variants like DNA insertions/deletions or single nucleotide polymorphisms (SNPs) based on NGS data plays an essential role in clinical researches. For this aim, several analysis pipelines combining short read aligners (e.g., BWA-MEM, Bowtie2, SOAP3, and Novoalign (<http://novocraft.com/>)) with variant callers (e.g., the Genome Analysis Toolkit HaplotypeCaller (GATK-HC), Samtools mpileup, and Torrent Variant Caller (v4.0 Life Technologies)) have been developed. However, the analysis of the raw sequence data is computationally intensive and requires significant memory consumption. In order to deal with this problem, most aligners and variant callers have been implemented in multi-threaded mode (e.g., BWA-MEM, Bowtie2, and Novoalign) or using GPU-based software (SOAP3) to ensure a feasible computation time. For details like memory usage or multithreading of the different approaches, see the review by Mielczarek and Szyda (2016); also see the references therein for details about the different tools mentioned above.

Thus, parallelization of analysis tasks is as important as the sequencing process itself and promises a huge potential for DNA processing. Several frameworks aimed at parallelization for specific applications. The MapReduce paradigm has hence received a lot of attraction. Martínez

et al. (2015) describe a distributed framework for read mapping based on the Message Passing Interface (MPI) in a cluster of nodes. They discuss the issues of splitting and distributing the inputs as well as merging the results. Already in the year 2010, an overview by Taylor (2010) surveyed applications of the Hadoop framework; more recently, other approaches based on the MapReduce framework have been developed (Chung et al. 2014). Other distributed processing systems like Spark have also received attention for applications in genome sequencing and processing (Mushtaq et al. 2017).

To benefit from advances of modern hardware technology, some DNA analysis processes have been ported to run on graphical processing units (GPUs) (Salavert Torres et al. 2012). However, these approaches incur an overhead for preprocessing the data and require highly specialized algorithms in order to take advantage of the GPU platforms.

Integration of Heterogeneous Data

Considering the growth rate of DNA sequencing data, Stephens et al. have demonstrated in their study (Stephens et al. 2015) that the sequencing technologies are one of the most important generators of big data. However, these massive datasets are often neither well structured nor organized in any consistent manner which makes their direct usage difficult. Consequently, the researchers have, first of all, to deal with the handling of big data to perform any analysis or comparison studies between different genomes. Thus, an effort for these big data challenges in life sciences is needed today to store the data in hierarchical systems in more efficient ways that make them available at different levels of analysis.

Management of biological data often requires the connection and integration of different data sources for a combined analysis. By default, biomedical text formats use identifiers (e.g., for genes or genomic variants), and different text files can only be combined by ID-based linking: data combination heavily relies on string equality matching over these IDs. To exacerbate the situation, these IDs are often hidden in larger strings such that these IDs have to be extracted first

before the data can be joined. A conjecture shared by many researchers in the field is that, on the high level of data management, explicitly linking data items in a graph structure by navigational access will enable more efficient data combination than join operations over string IDs. Hence, graph databases are deemed to be most suitable for such a data integration layer (Have and Jensen 2013) because different data sources can be combined by a link (edge) in the data graph.

One prototypical framework that integrates genome data sources and other biological datasets in a common graph-based framework is the BioGraphDB presented by Fiannaca et al. (2016) who use the OrientDB multi-model database to interconnect several text-based external data sources. The BioGraphDB system is able to process queries in the Gremlin graph query language. Textual input data is processed in this framework as follows (Fiannaca et al. 2016): “As general rule, each biological entity and its properties have been mapped respectively into a vertex and its attributes, and each relationship between two biological entities has been mapped into an edge. If a relationship has some properties, they are also saved as edge attributes. Vertices and edges are grouped into classes, according to the nature of the entities.”

Examples of Application

The raw sequencing reads are often stored in public genome repositories like:

- National Center for Biotechnology Information (<https://www.ncbi.nlm.nih.gov>),
- ENCODE (<https://www.encodeproject.org/>)
- Genome 10K Project (<https://genome10k.soe.ucsc.edu>)
- TCGA (<https://cancergenome.nih.gov>)
- Human Microbiome Project (<https://hmpdacc.org/>)

in order to make these large bodies of research data easily accessible. We survey some of these repositories with a focus on bioinformatic applications.

Bioinformatics for Sequencing Data

Bioinformatic skills play an essential role in the exploitation of the full potential of NGS data. Until now, different bioinformatic tools and algorithms have been published for the storage and computational analysis of DNA sequences. Such applications are important for the detection as well as the understanding of relevant biological processes. Currently, in the OMICtools directory (<https://omictools.com/>) for NGS data analysis, there are 47 categories with 9089 applications which are developed, for example, for data processing, quality control, genomic research, data visualization, or the identification of robust genomic associations/variants with complex diseases.

In addition to computational analysis of sequencing data, the field of bioinformatics is crucial for storage of large-scale sequencing data in databases as well as repositories. The Sequence Read Archive (SRA) (<https://www.ncbi.nlm.nih.gov/sra>) is one of the most relevant public domain repositories in which raw sequence data generated using next-generation sequencing technologies are stored for free and continuous access to the data is possible. There are further big data projects that are based on databases/repositories collecting sequencing data in life sciences:

The Encyclopedia of DNA elements (ENCODE) stores more than 15 terabytes of raw data and is thus one of the most general databases for basic biology research.

The Genome 10K Project is a collection for storage and analysis of the sequencing data corresponding to 10,000 vertebrate species. Scientists expect more than 1 petabyte by completion.

The Cancer Genome Atlas (TCGA) is an extensive effort to map the key genomic changes in 33 types of cancer. This database contains to date 2.5 petabytes of data collected from more than 11,000 patients.

Human Microbiome Project is a collection of several databases to provide quick and easy access to all publicly available microbiome data. Currently, the database contains over 14 terabytes of publicly available data in total.

Future Directions for Research

DNA sequencing is one of the major producers of big data. Novel sequencing technology will even increase the amount of DNA sequencing data produced. The introduction of mobile sequencing devices like nanopore-based technologies (Loman and Watson 2015) will turn DNA sequencing into an everyday diagnosis and monitoring tool. Though initially the available devices suffered from high error rates, ongoing technological advances will lead to an improved data quality (Jain et al. 2015).

It might be worthwhile to closely inspect genome data processing pipelines in order to identify bottlenecks. Martínez et al. (2015) report on the use of high-performance profiling that revealed idling hardware resources. By improving the task scheduling, a better runtime could be achieved. This kind of low-level performance optimization is one field of future research to improve performance of DNA processing.

Extrapolating the current drop in sequencing cost, the most radical option could be the so-called streaming algorithms for sequence analysis. With streaming algorithms, DNA sequences are analyzed in real time and are not stored at all, as shown in Cao et al. (2016).

Big Data Visualization Tools

Nikos Bikakis
 ATHENA Research Center, Athens, Greece

Synonyms

Exploratory data analysis; Information visualization; Interactive visualization; Visual analytics; Visual exploration

Definitions

Data visualization is the presentation of data in a pictorial or graphical format, and a *data visualization tool* is the software that generates this presentation. Data visualization provides users with intuitive means to interactively explore and analyze data, enabling them to effectively identify interesting patterns, infer correlations and causalities, and supports sensemaking activities.

Overview

Exploring, visualizing, and analyzing data is a core task for data scientists and analysts in numerous applications. *Data visualization* (Throughout the article, terms *visualization* and *visual exploration*, as well as terms *tool* and *system* are used interchangeably.) (Ward et al. 2015) provides intuitive ways for the users to interactively explore and analyze data, enabling them to effectively identify interesting patterns, infer correlations and causalities, and support sensemaking activities.

The Big Data era has realized the availability of a great amount of *massive* datasets that are *dynamic*, *noisy*, and *heterogeneous* in nature.

The level of difficulty in transforming a data-curious user into someone who can access and analyze that data is even more burdensome now for a great number of users with little or no support and expertise on the data processing part. Data visualization has become a major research challenge involving several issues related to data storage, querying, indexing, visual presentation, interaction, and personalization (Bikakis and Sellis 2016; Shneiderman 2008; Godfrey et al. 2016; Idreos et al. 2015).

Given the above, modern visualization and exploration systems should effectively and efficiently handle the following aspects.

- *Real-time interaction.* Efficient and scalable techniques should support the interaction with billion object datasets while maintaining the system response in the range of a few milliseconds.
- *On-the-fly processing.* Support of on-the-fly visualizations over large and dynamic sets of volatile raw (i.e., not preprocessed) data is required.
- *Visual scalability.* Provision of effective data abstraction mechanisms is necessary for addressing problems related to visual information overloading (aka overplotting).
- *User assistance and personalization.* Encouraging user comprehension and offering customization capabilities to different user-defined exploration scenarios and preferences according to the analysis needs are important features.

The literature on visualization is extensive, covering a large range of fields and many decades. Data visualization is discussed in a great number of recent introductory-level textbooks, such as Ward et al. (2015) and Keim et al. (2010). Further, surveys of Big Data visualization systems can be found at Shneiderman (2008), Godfrey et al. (2016), Bikakis and Sellis (2016), and Idreos et al. (2015). Finally, there is a great deal of information regarding visualization tools available in the Web. We mention dataviz.tools (<http://dataviz.tools>) and [datavizcatalogue](http://datavizcatalogue.com) ([www.datavizcatalogue.com](http://datavizcatalogue.com)).

datavizcatalogue.com) which are catalogs containing a large number of visualization tools, libraries, and resources.

Visualization in Big Data Era

This section discusses the basic concepts related to Big Data visualization. First, the limitations of traditional visualization systems are outlined. Then, the basic characteristics of data visualization in the context of Big Data era are presented. Finally, the major prerequisites and challenges that should be addressed by modern exploration and visualization systems are discussed.

Traditional systems. Most *traditional exploration and visualization systems* cannot handle the size of many contemporary datasets. They restrict themselves to dealing with *small* dataset sizes, which can be easily handled and analyzed with conventional data management and visual explorations techniques. Further, they operate in an *offline* way, limited to accessing *preprocessed* sets of *static* data.

Current setting. On the other hand, nowadays, the *Big Data era* has made available large numbers of *very big* datasets that are often *dynamic* and characterized by high *variety* and *volatility*. For example, in several cases (e.g., scientific databases), new data constantly arrive (e.g., on a daily/hourly basis); in other cases, data sources offer query or API endpoints for online access and updating. Further, nowadays, an increasingly large number of *diverse users* (i.e., users with different preferences or skills) explore and analyze data in a plethora of *different scenarios*.

Modern systems. *Modern systems* should be able to efficiently handle *big dynamic* datasets, operating on machines with limited computational and memory resources (e.g., laptops). The dynamic nature of nowadays data (e.g., stream data) hinders the application of a preprocessing phase, such as traditional database loading and indexing. Hence, systems should provide *on-the-fly processing* over large sets of raw data.

Further, in conjunction with performance issues, modern systems have to address challenges related to *visual presentation*. Visualizing a large number of data objects is a challenging task; modern systems have to “*squeeze a billion records into a million pixels*” (Shneiderman 2008). Even in small datasets, offering a dataset *overview* may be extremely difficult; in both cases, *information overloading* (aka *overplotting*) is a common issue. Consequently, a basic requirement of modern systems is to effectively support *data abstraction* over enormous numbers of data objects.

Apart from the aforementioned requirements, modern systems must also satisfy the diversity of *preferences* and *requirements* posed by different *users* and *tasks*. Modern systems should provide the user with the ability to customize the exploration experience based on her preferences and the individual requirements of each examined task. Additionally, systems should automatically adjust their parameters by taking into account the *environment setting* and *available resources* (e.g., screen resolution/size, available memory).

Systems and Techniques

This section presents how state-of-the-art approaches from data management and mining, information visualization, and human-computer interaction communities attempt to handle the challenges that arise in the Big Data era.

Data reduction. In order to handle and visualize large datasets, modern systems have to deal with information overloading issues. Offering *visual scalability* is crucial in Big Data visualization. Systems should provide efficient and effective abstraction and summarization mechanisms. In this direction, a large number of systems use *approximation techniques* (aka *data reduction techniques*), in which abstract sets of data are computed. Considering the existing approaches, most of them are based on (1) *sampling* and *filtering* (Fisher et al. 2012; Park et al. 2016; Agarwal et al. 2013; Im et al. 2014; Battle et al. 2013; Bikakis et al. 2016) and/or (2) *aggregation* (e.g., binning, clustering) (Elmqvist and Fekete

2010; Bikakis et al. 2017; Jugel et al. 2016; Liu et al. 2013).

Hierarchical exploration. Approximation techniques are often defined in a hierarchical manner (Elmqvist and Fekete 2010; Bikakis et al. 2017), allowing users to explore data in different levels of detail (e.g., hierarchical aggregation).

Hierarchical approaches (sometimes also referred as *multilevel*) allow the visual exploration of very large datasets in multiple levels, offering both an overview, as well as an intuitive and effective way for finding specific parts within a dataset. Particularly, in hierarchical approaches, the user first obtains an *overview* of the dataset before proceeding to data exploration operations (e.g., roll-up, drill-down, zoom, filtering) and finally retrieving *details* about the data. Therefore, hierarchical approaches directly support the visual information seeking mantra “*overview first, zoom and filter, then details on demand.*” Hierarchical approaches can also effectively address the problem of information overloading as they adopt approximation techniques.

Hierarchical techniques have been extensively used in large *graphs visualization*, where the graph is recursively decomposed into smaller subgraphs that form a hierarchy of abstraction layers. In most cases, the hierarchy is constructed by exploiting *clustering* and *partitioning* methods (Rodrigues et al. 2013; Auber 2004; Tominski et al. 2009).

Progressive results. Data exploration requires real-time system’s response. However, computing *complete results* over large (unprocessed) datasets may be extremely costly and in several cases *unnecessary*. Modern systems should *progressively return partial* and preferably *representative* results, as soon as possible.

Progressiveness can significantly improve efficiency in *exploration scenarios*, where it is common that users attempt to find something interesting without knowing what exactly they are searching for beforehand. In this case, users perform a sequence of operations (e.g., queries), where the result of each operation determines the formulation of the next operation. In systems where progressiveness is supported, in each operation, after inspecting the already

produced results, the user is able to interrupt the execution and define the next operation, without waiting for the exact result to be computed.

In this context, several systems adopt *progressive techniques*. In these techniques the results/visual elements are computed/constructed incrementally based on user interaction or as time progresses (Stolper et al. 2014; Bikakis et al. 2017). Further, numerous recent systems integrate incremental and approximate techniques. In these cases, approximate results are computed incrementally over progressively larger samples of the data (Fisher et al. 2012; Agarwal et al. 2013; Im et al. 2014).

Incremental and adaptive processing. The dynamic setting established nowadays hinders (efficient) data preprocessing in modern systems. Additionally, it is common in exploration scenarios that only a small fragment of the input data is accessed by the user.

In situ data exploration (Alagiannis et al. 2012; Olma et al. 2017; Bikakis et al. 2017) is a recent trend, which aims at enabling on-the-fly exploration over large and dynamic sets of data, without (pre)processing (e.g., loading, indexing) the whole dataset. In these systems, *incremental* and *adaptive* processing and indexing techniques are used, in which small parts of data are processed incrementally “following” users’ interactions.

Caching and prefetching. Recall that, in exploration scenarios, a sequence of operations is performed and, in most cases, each operation is driven by the previous one. In this setting, *caching* and/or *prefetching* the sets of data that are likely to be accessed by the user in the near future can significantly reduce the response time (Battle et al. 2016; Bikakis et al. 2017). Most of these approaches use prediction techniques which exploit several factors (e.g., user behavior, user profile, use case) in order to determine the upcoming user interactions.

User assistance. The large amount of available information makes it difficult for users to manually explore and analyze data. Modern systems should provide mechanisms that assist the user and reduce the effort needed on their part,

considering the diversity of preferences and requirements posed by different users and tasks.

Recently, several approaches have been developed in the context of *visualization recommendation* (Vartak et al. 2016). These approaches recommend the most suitable visualizations in order to assist users throughout the analysis process. Usually, the recommendations take into account several factors, such as data characteristics, examined task, user preferences and behavior, etc.

Especially considering data characteristics, there are several systems that recommend the most suitable visualization technique (and parameters) based on the type, attributes, distribution, or cardinality of the input data (Key et al. 2012; Ehsan et al. 2016; Mackinlay et al. 2007; Bikakis et al. 2017). In a similar context, some systems assist users by recommending certain visualizations that reveal surprising and/or interesting data (Vartak et al. 2014; Wongsuphasawat et al. 2016). Other approaches provide visualization recommendations based on user behavior and preferences (Mutlu et al. 2016).

Examples of Applications

Visualization techniques are of great importance in a wide range of application areas in the Big Data era. The volume, velocity, heterogeneity, and complexity of available data make it extremely difficult for humans to explore and analyze data. Data visualization enables users to perform a series of analysis tasks that are not always possible with common data analysis techniques (Keim et al. 2010).

Major application domains for data visualization and analytics are *physics* and *astronomy*. Satellites and telescopes collect daily massive and dynamic streams of data. Using traditional analysis techniques, astronomers are able to identify noise, patterns, and similarities. On the other hand, visual analytics can enable astronomers to identify unexpected phenomena and perform several complex operations, which are not feasible by traditional analysis approaches.

Another application domain is *atmospheric sciences* like *meteorology* and *climatology*. In

this domain high volumes of data are collected from sensors and satellites on a daily basis. Storing these data over the years results in massive amounts of data that have to be analyzed. Visual analytics can assist scientists to perform core tasks, such as climate factor correlation analysis, event prediction, etc. Further, in this domain, visualization systems are used in several scenarios in order to capture real-time phenomena, such as hurricanes, fires, floods, and tsunamis.

In the domain of *bioinformatics*, visualization techniques are exploited in numerous tasks. For example, analyzing the large amounts of biological data produced by DNA sequencers is extremely challenging. Visual techniques can help biologist to gain insight and identify interesting “areas of genes” on which to perform their experiments.

In the Big Data era, visualization techniques are extensively used in the *business intelligence* domain. *Finance markets* are one application area, where visual analytics allow to monitor markets, identify trends, and perform predictions. Besides, *market research* is also an application area. Marketing agencies and in-house marketing departments analyze a plethora of diverse sources (e.g., finance data, customer behavior, social media). Visual techniques are exploited to realize task such as identifying trends, finding emerging market opportunities, finding influential users and communities, and optimizing operations (e.g., troubleshooting of products and services), business analysis, and development (e.g., churn rate prediction, marketing optimization).

²Department of Information Systems, ALGORITMI Research Centre, University of Minho, Guimarães, Portugal

Synonyms

Industry 4.0; Smart Industry

Definition of Terms

Big Data Warehouse (BDW). A BDW can be defined as a scalable, highly performant, and flexible storage and processing system, capable of dealing with the ever-increasing volume, variety, and velocity of data, i.e., Big Data, while lowering the costs of traditional Data Warehousing architectures through the use of commodity hardware. Big Data imposes severe difficulties for traditional data storage and processing technologies, and the BDW aims to overcome these challenges and support near real-time descriptive and predictive Big Data Analytics over huge amounts of heterogeneous data (Krishnan 2013; Russom 2016; Costa et al. 2017; Santos et al. 2017).

Smart Industry. A Smart Industry can be seen as an organization chain from any industrial sector (e.g., manufacturing, services) with high digitalization levels, which supports the replication of the physical world into a virtual world, through an environment that is highly connected with the entire chain of stakeholders (e.g., suppliers, customers, partners). The Smart Industry term is directly related with the Industry 4.0 initiative, aiming to change the actual business processes and work paradigm, using several concepts like IoT, cyber-physical systems, social web, Big

Data, or robots, in order to provide intelligence to equipment and products (Kagermann et al. 2013).

B

Overview

Nowadays, we live in a world where the strong connection between people, devices, and sensors tends to produce a vast volume and variety of data, flowing at different velocities (Villars et al. 2011; Dumbill 2013). This concept is commonly defined as Big Data, which can be used to bring intelligence to several contexts, such as healthcare, cities, factories, and retail (Manyika et al. 2011; Chen et al. 2014). In the Industry 4.0 context, (Big) Data Analytics is also identified as one of the key points in this initiative, being frequently mentioned as an important way of bringing value to the organizations. This is a main requirement, due to all the data that is produced and can be used to improve businesses (Kagermann et al. 2013; Hermann et al. 2016).

At this point, the handling of this data needs more attention than the one that practitioners tend to give to traditional data. Consequently, the concept of BDW emerged as a topic of interest within Big Data systems, bringing new relevant characteristics to traditional Data Warehouses (DWs), some of which can be highlighted as (Costa and Santos 2017a):

- Flexible storage
- High scalability at low costs through the use of commodity hardware
- High performance
- Low-latency data ingestion
- Mixed and complex analytical workloads (e.g., data mining/machine learning, intensive geospatial analytics, simulations)

In an effort to guide the implementation of Big Data Warehouses (BDWs), this entry presents a flexible architecture, infrastructure, and data model that have been developed and constantly validated using performance benchmarks and examples of application in different contexts. Consequently, besides aiming to foster future

research and help practitioners to build BDWs, this entry also focuses on the relevance and value of BDWs for Smart Industries, such as the analysis of customer complaints or the identification of patterns between defective parts and production data, decreasing the time needed to fulfill complaints.

Key Research Findings

In order to design and implement a BDW, practitioners should focus on three main aspects: the architecture of the system, the technologies to use, and the data modeling technique. This section presents the foundations, i.e., models and methods (Hevner et al. 2004), to approach these same issues.

The Big Data Warehousing approach presented in this entry takes into consideration general and scarce scientific contributions regarding Big Data systems, integrating and extending them with the appropriate contributions considering the specific characteristics of BDWs previously enumerated. First, the architectural components are as aligned as possible with the Big Data Reference Architecture from the National Institute of Standards and Technology (NIST), which presents the general components of a Big Data system (NBD-PWG 2015). Second, the approach presented in this entry follows several guidelines of the Lambda Architecture (Marz and Warren 2015), motivating practitioners to store the data with the highest level of detail, storing it as a set of immutable events (if possible), and clearly dividing the workflows as batch and streaming workflows. Finally, contributions such as the Big Data Processing Flow (Krishnan 2013) and the Data Highway Concept (Kimball and Ross 2013) are also relevant in this approach, as can be seen in the following subsections.

Architecture

Logical components help practitioners in the design of a BDW. Figure 1 illustrates the BDW architecture, highlighting the several logical components and data flows.

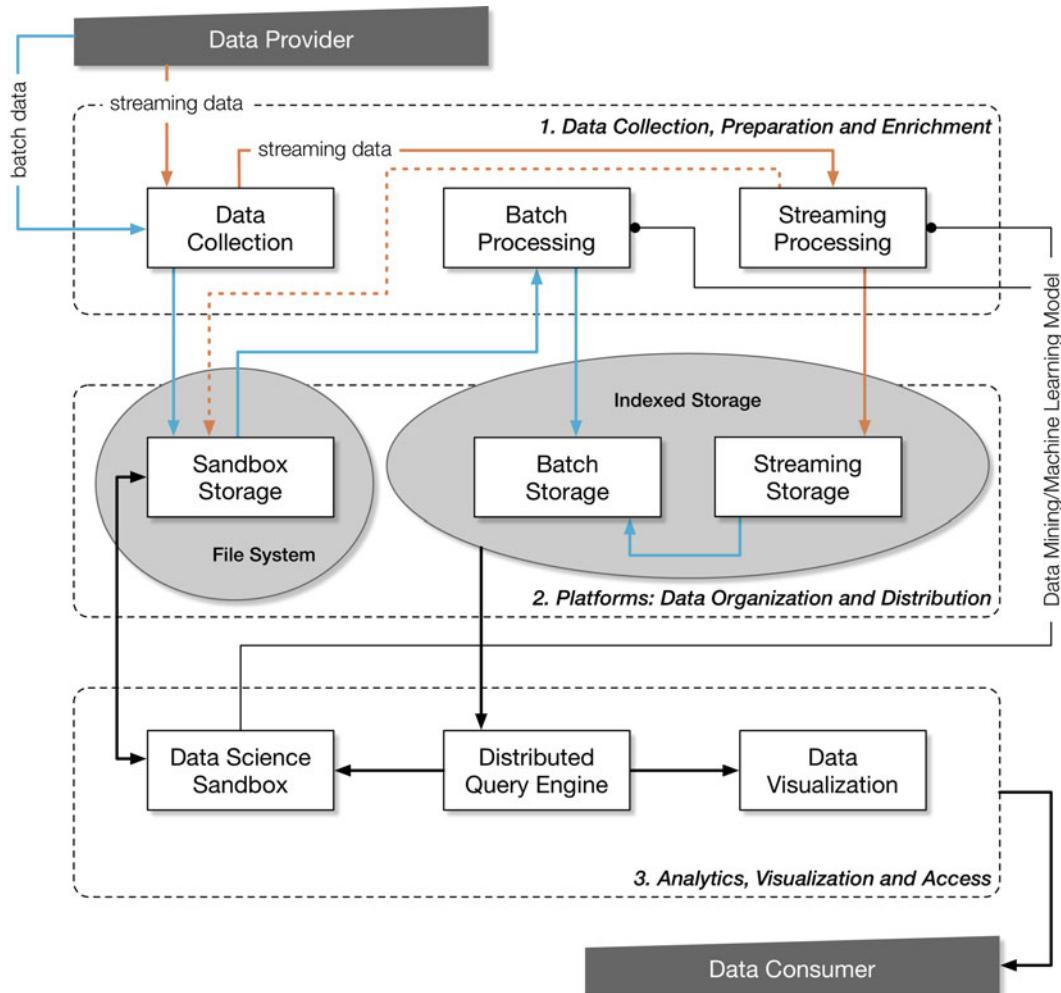

Data Collection, Preparation, and Enrichment (CPE)

Data arrives from the data provider component (e.g., users, legacy systems, Web, transactional systems, sensors), and it is collected in two distinct ways, either in batches or via streaming mechanisms. Batch data is firstly stored in the sandbox storage (distributed file system without schema restrictions) before being processed, while streaming data is immediately processed (prepared and enriched), since it typically holds more value when analyzed in near real time. Despite this, streaming data can also be stored in the sandbox storage through an optional alternative path, due to the value inherent in its raw and unprocessed state, or only as a backup strategy, for example. The Data Mining/Machine Learning models previously built by data scientists in the Data Science sandbox can be included in this stage, both in batch and streaming workloads. This works by applying the models to make predictions as data flows through the CPE workloads.

Platforms: Data Organization and Distribution

The BDW consists of three different storage areas classified into two categories: file system and indexed storage.

1. Sandbox storage – it is a highly flexible storage area without the need to rigorously define any kind of metadata. Data scientists (Costa and Santos 2017b) use the sandbox storage to “play with the data,” by identifying trends/patterns and elaborating predictions. Consequently, it is seen as a schema-less storage technology, mainly supported by highly scalable distributed file systems.
2. Batch storage – it is an indexed storage system used to store and process Big Data arriving in batches. Unlike the previous storage area, it is based on previously defined metadata to support structured analytics, although it uses a significantly more flexible data modeling technique than the typical relational DWs (see section “Data Modeling”). Its data modeling technique facilitates the integration of patterns, simulations, and predictions extracted

Big Data Warehouses for Smart Industries, Fig. 1 Big Data Warehouse architecture

and developed by data scientists. It is capable of processing huge amounts of data due to its fast sequential access capabilities.

3. Streaming storage – it is an indexed storage system that, instead of storing and processing data arriving in batches, deals with data arriving in a streaming fashion. It does not need to process the same amount of data as the batch storage, since it stores data temporarily, which is then moved to the batch storage after a certain period (e.g., 1 day, 1 week, 1 month). It can also include patterns, simulations, and predictions made by data scientists in near real time (e.g., machine learning included in

streaming processing). The streaming storage uses exactly the same data modeling technique as the batch storage, and the data stored in these two areas can be combined using an adequate distributed query engine (see Fig. 1). Ideally, for certain scenarios including update operations on data, the streaming storage technology must hold fast random access capabilities. Moreover, the streaming storage may also be supported by in-memory database technologies for fast operations on fast data, assuming that practitioners consider their level of interoperability with the chosen distributed query engine.

While the sandbox storage uses a distributed file system to act as a landing zone and as a place where data scientists can freely experiment, the batch and streaming storage areas are indexed storage systems (e.g., key-value stores, column-oriented stores, document-oriented stores) responsible for storing batch and streaming data, respectively. These two storage areas are indexed to adequately support Big Data Warehousing workloads in an effective and efficient manner. Such workloads may include ad hoc querying or self-service Business Intelligence (BI) over huge amounts of data, structured data visualization (e.g., dashboards, reports), highly intensive geospatial analytics, and visualizing simulations or predictions made by Data Mining/Machine Learning models.

Analytics, Visualization, and Access

The core component of this stage is the distributed query engine, which is able to query the data stored in the indexed storage systems, even combining batch and streaming data in a single query (see the distributed query engines in section “Technological Infrastructure”). The distributed query engine can be used to explore the data stored in the BDW but also serves the purpose of providing data to the data visualization component and to the Data Science sandbox when needed. The data consumer component represents the stakeholders interested in consuming data from the BDW (e.g., data scientists, data analysts, external users, external systems, top-level managers, operational managers).

Technological Infrastructure

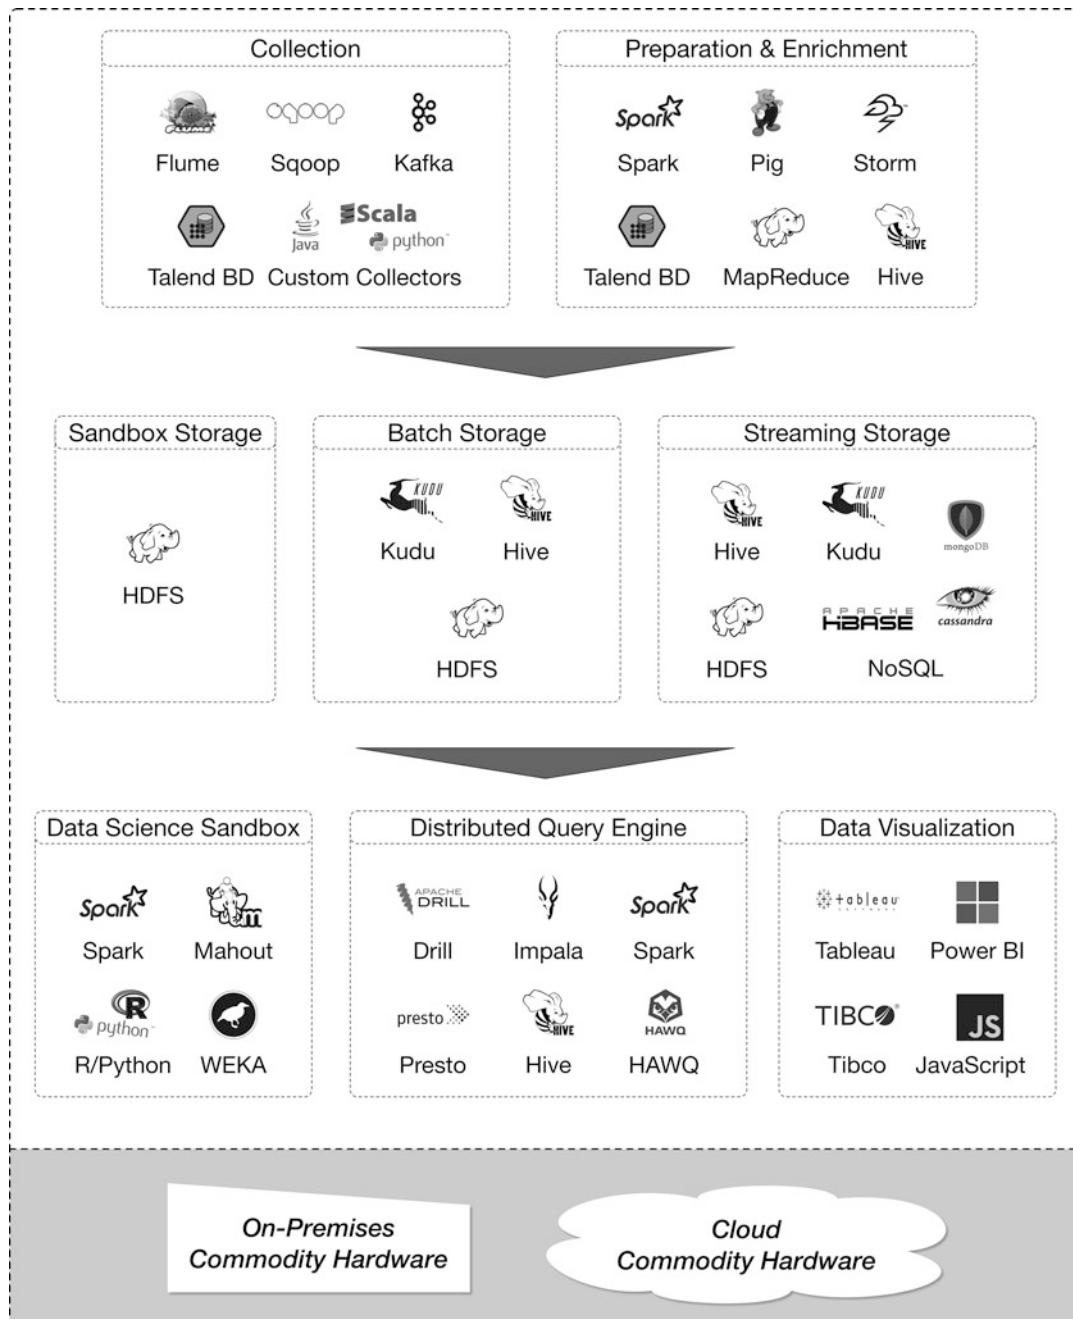

After designing the logical solution (architecture) to solve the problem, practitioners need to consider the suitable technologies to implement each logical component, in order to materialize the architecture into a physical system. Therefore, the technological infrastructure is presented in Fig. 2, which illustrates a vast set of possible technologies to implement the architecture presented above. One should be aware that there are several alternatives, as the Big Data ecosystem grows every day.

Regarding data CPE, the decision to adopt a certain technology mainly depends on the velocity of data flowing through the system. For batch data, using mechanisms such as Sqoop to collect data from relational databases, for example, custom connectors, or Talend Big Data is appropriate. However, if data flows via streaming mechanisms, it should be collected using efficient streaming systems like Kafka and Flume, for example. Once the data is collected, it is ready for preparation and enrichment. Technologies like Spark, Pig, Talend Big Data, MapReduce, and Hive are suitable for batch processing, while technologies like Spark Streaming and Storm are suitable for streaming processing. If some of these workloads include the application of previously trained Data Mining/Machine Learning models, practitioners should be aware of the level of integration between their predictive Data Science tools and the chosen technology for data preparation and enrichment.

Depending on the level of infrastructural complexity and the storage access needs (random access vs. sequential access), practitioners may consider three strategies:

1. HDFS for the sandbox storage and HDFS/Hive for the batch and streaming storage
2. HDFS for the sandbox storage, HDFS/Hive for the batch storage, and a NoSQL database for the streaming storage
3. HDFS for the sandbox storage and Kudu for the batch and streaming storage

According to laboratory experiments (Vale Lima 2017), the second strategy may offer less performance than the first one, as NoSQL databases are oriented toward online transaction processing (OLTP) applications (Cattell 2011). However, they facilitate random access operations on streaming data (e.g., updating a previously inserted record or accessing a specific record), as HDFS/Hive are sequential access-oriented systems, which typically requires recomputing entire tables/partitions to update specific records. Recently, efforts have been made to provide random access capabilities to Hive (Apache Hive 2017), but, currently, it

Big Data Warehouses for Smart Industries, Fig. 2 Technological infrastructure for Big Data Warehouses

is not a feature that can be typically seen in production environments, and it leads to several interoperability challenges (e.g., most of SQL-on-Hadoop engines lack the support to query transactional/ACID Hive tables).

Despite being faster, practitioners need to be aware that using HDFS/Hive to store streaming data accentuates the problem of having small files in Hadoop (Mackey et al. 2009). Small streaming processing intervals (micro-batches) lead to very

small files, causing severe stress on the Hadoop NameNode. Consequently, if practitioners do not want to sacrifice data timeliness, option 2 may be more suitable. If increasing streaming intervals to 30 s, 1, or 2 min, for example, does not hurt data timeliness, the HDFS files being generated will be bigger and therefore may not affect as much the performance and stability of the system. Finally, option 3 focuses on the use of technologies like Kudu for both batch and streaming data (Lipcon et al. 2015), which promises to support both scenarios without discarding the advantages of HDFS/Hive and NoSQL databases presented above. Kudu is still an emerging technology, but there is a lack of enough evidence of its performance in these scenarios.

Regarding analytical tasks, several technologies can contribute to support the Data Science sandbox, mainly in the training and testing of several Data Mining/Machine Learning models, such as Spark MLlib, Mahout, R/Python, and Weka, among many others. The distributed query engine responsible for processing data stored in the indexed storage systems of the BDW (batch and streaming storage areas) can be implemented using any SQL-on-Hadoop engine that adequately interoperates with the chosen storage technologies, including Presto, Impala, Hive, Spark SQL, Drill, and HAWQ, among others. Despite being frequently mentioned as SQL-on-Hadoop engines, these systems can process and combine data from multiple distributed systems, including NoSQL databases. Some of these engines provide interactive performance, i.e., near real-time query execution times over massive amounts of data, while others provide more robustness, scalability, and higher SQL compatibility levels. There are some scientific benchmarks available (Floratou et al. 2014; Santos et al. 2017), and practitioners are always encouraged to perform some benchmarking before adopting certain technologies for production environments. Finally, there are several data visualization technologies with appropriate connectors to these distributed query engines, such as Tableau, Power BI, and Tibco. For specific contexts, practitioners may even develop their own custom-made data

visualization platforms using JavaScript, for example.

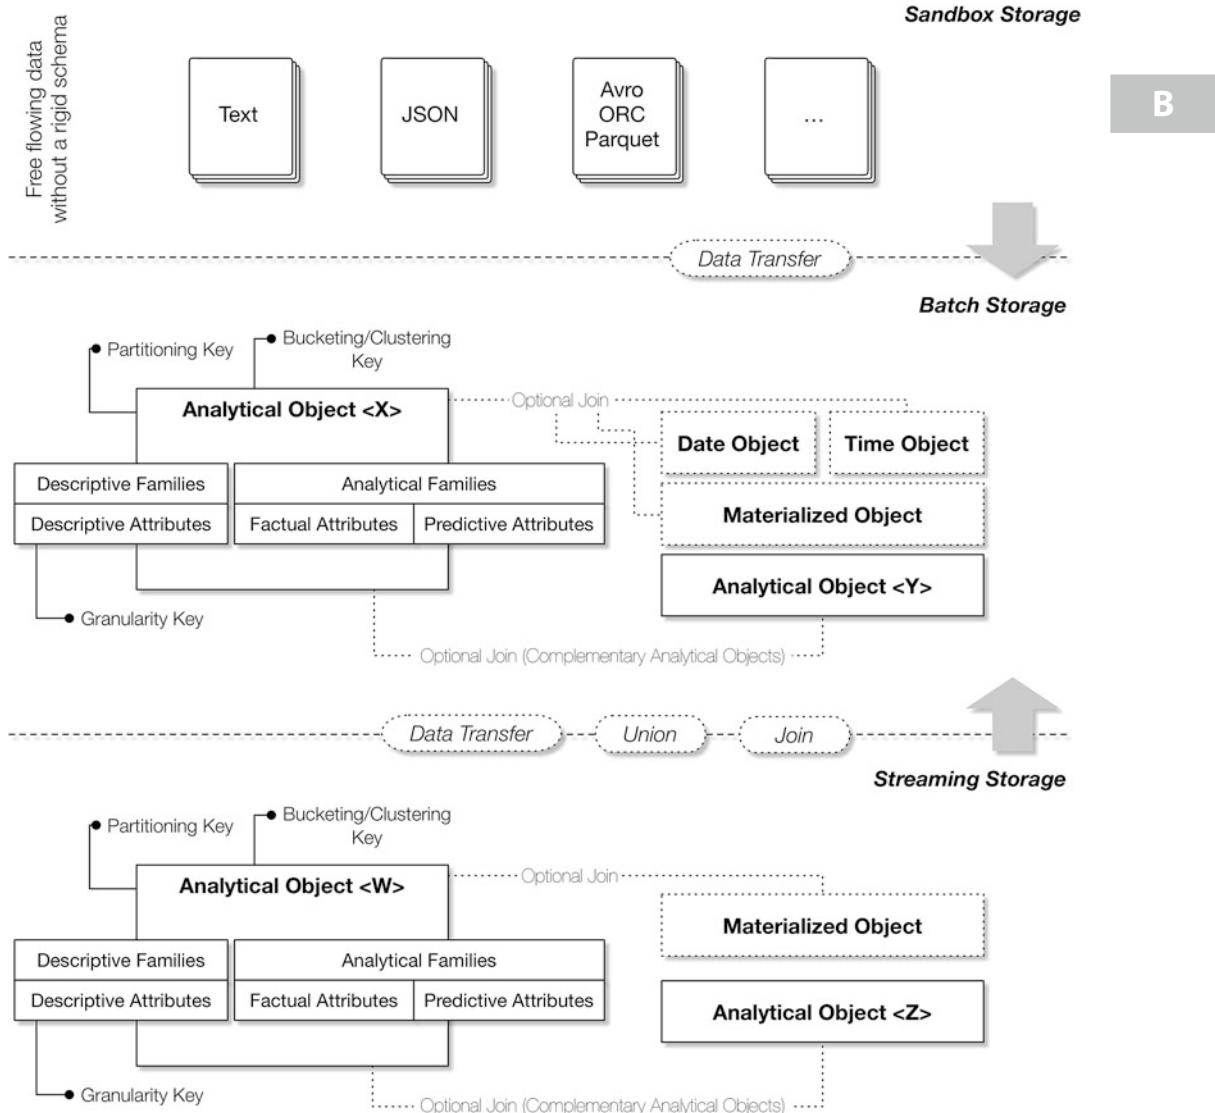

Data Modeling

The final and maybe central piece of a Big Data Warehousing system is the data modeling approach. Big Data systems are often mentioned as schema-less systems. However, for Big Data Warehousing in particular, at some point data should be structured to support the decision-making processes through adequate analytical mechanisms (e.g., data visualization of Data Mining/Machine Learning predictions, simulation results, and historical data). Having said that, this does not mean that the data model should not be flexible, quite the contrary, that is the reason why traditional ways of modeling data are not always the best solution for Big Data contexts (Costa et al. 2017), due to the volume, variety, and velocity of data sources. BDWs should have more flexible and scalable data modeling approaches, as the one depicted in Fig. 3.

Taking into consideration the description in section “Platforms: Data Organization and Distribution,” the sandbox storage can be seen as an analogy to a data lake (O’Leary 2014), where data flows in its raw form throughout a schema-less distributed file system, being stored for latter exploration and processing. Consequently, concerns with metadata and schema are not relevant at this stage. The content generated by source systems lands in this zone, despite its size or shape. As previously seen, that is mainly the case for batch data before being processed and moved to the batch storage system. In contrast, streaming data is typically processed immediately and then stored in the streaming storage, assuring latencies that satisfy the business requirements.

The batch and streaming storages use the same modeling approach, which is interpreted as follows:

1. An analytical object represents a subject of interest (e.g., sales transactions, inventory movements, social media posts, webpage clicks). It is an analogy to traditional fact tables (Kimball and Ross 2013).

Big Data Warehouses for Smart Industries, Fig. 3 Data model for Big Data Warehouses

2. Analytical objects contain descriptive and analytical families, which can be either logical or physical constructs, depending on the storage technology in use (see section “Technological Infrastructure”). These families contain a set of several attributes. Descriptive attributes are an analogy to traditional dimensions’ attributes. Factual attributes are an analogy to traditional facts in fact tables, while predictive attributes are predictions retrieved from the Data Science sandbox (e.g., sales forecasting,

customer segmentation, sentiment associated to social media post). In contrast to traditional DWs, these attributes are typically denormalized into a single analytical object (e.g., Hive table, HBase/Cassandra table) to avoid the cost of join operations on Big Data environments (Santos et al. 2017) and achieve better performance (Costa et al. 2017).

3. Despite the preference for fully denormalized structures, in certain contexts joining analyt-

ical objects may be significantly useful – see the data model in (Costa and Santos 2017a). This strategy is significantly useful when one of the analytical objects involved in the join is relatively small, it is not refreshed frequently, and/or it is reused by other analytical objects. For example, the information about customers of an organization will definitively be reused many times in different analytical objects. As mentioned above, if applicable, practitioners can create an analytical object for “customers.” This is not seen as a traditional dimension, as by itself it can contain factual and predictive attributes about customers. This strategy will save storage space (avoiding so much redundancy in Big Data environments) without significantly decreasing performance (sometimes even improving) for relatively small complementary analytical objects, as strategies like map/broadcast joins are a major selling point of several distributed query engines for Big Data (e.g., Presto).

4. For each analytical object, practitioners should define a granularity key, which may, or may not, be physically implemented through a primary key (depending on the technology being implemented), and partitioning and bucketing/clustering keys, which may significantly improve performance in certain scenarios by adequately distributing and organizing the data (Costa et al. 2017).
5. Besides analytical objects, there are three more types of optional objects. The date and time objects are responsible for storing the date and time attributes to be used by all analytical objects, which can then be used in join operations, as these objects are significantly small. Similarly to complementary analytical objects, besides standardizing information regarding date and time in the BDW, it reduces storage footprint and may even improve performance (Costa et al. 2017), as the small join operations compensate the amount of denormalized data to process. Materialized objects simply store long-running and complex queries that are frequently requested to the BDW. They can act

as a similar mechanism to traditional OLAP cubes with materialized results.

Examples of Application

This section discusses the implementation of a BDW in an organization that is working to be aligned with the Industry 4.0 initiative. In this context, a Big Data Warehousing project is being developed to help with operational and managerial decision-making. Several working areas of the factory are considered a priority in this project: customer complaints, internal defect costs, productivity associated with the several production lines, and lot release analysis. The BDW being developed follows the foundations presented in the previous sections:

- Data is collected, processed, and stored in batch and streaming storage environments.
- The technological infrastructure in use is aligned with the several technologies identified above.
- Analytical objects are adequately identified, as well as their descriptive and factual attributes. For example, Figs. 4 and 5 are data visualizations based on the “customer complaints (QCs)” analytical object, in which “customer” and “business unit” are descriptive families, and the factual information about the complaint is the analytical family.

The first dashboard (Fig. 4) aims to give a general overview about the QCs, considering several factors: the production date of the claimed parts, the business unit that produced these parts, the responsibility associated to the parts with defect (cluster), and the customers that made the complaints.

After a general analysis of the QCs, a detailed perspective on the customers that claimed some parts is presented in Fig. 5. In this dashboard, one can take conclusions regarding the relationship between the date in which the complaint was made and the production date of the claimed parts. For a simplified analysis, all complaints are colored according to the corresponding customer.

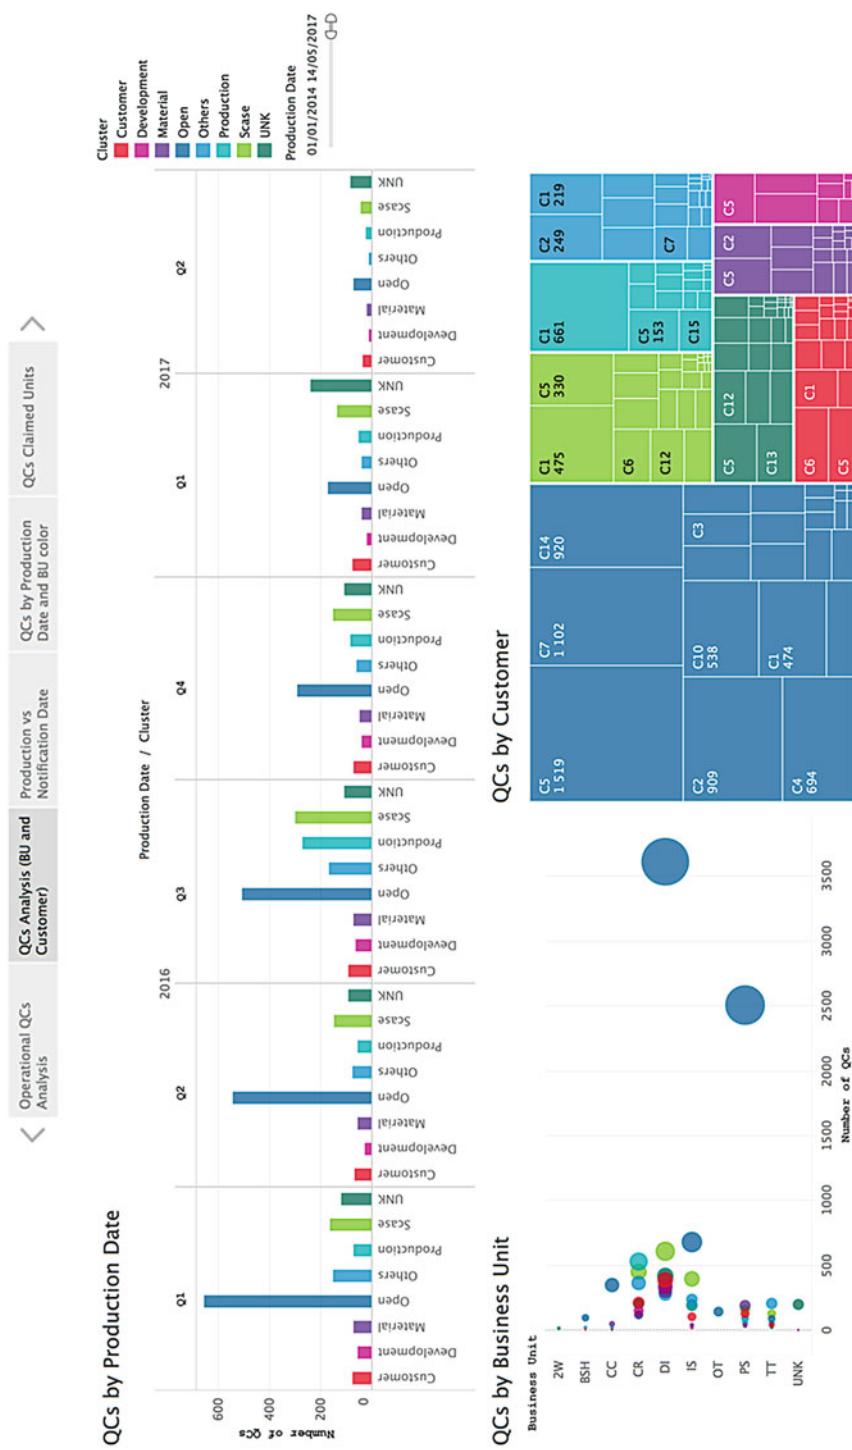

Fig. 4 General dashboard for complaints analysis (fictional data)

Big Data Warehouses for Smart Industries, Fig. 5 Complaints analysis by customer dashboard (fictional data)

Future Directions for Research

As BDWs start to be implemented in more contexts, and as technology evolves, methodological aspects may keep evolving. There are significant research contributions to be made to this topic, namely, new/extended techniques and technologies for data storage and processing. Sharing scientific benchmarks of emergent systems will also keep the community aware of different directions regarding possible architectural approaches.

Definitions

Big semantic data processing in the life sciences deals with a set of graph-based techniques and methods used to integrate or analyze empirical evidence obtained in the course of life sciences or biomedical research.

Overview

The twofold ambition behind biomedical research and development is to either create new knowledge or apply it for treatment and prevention of disease. In life sciences, much of the research is dedicated toward understanding living systems – not just for the sake of knowledge but also to harness and control them. The promise hidden in big biomedical data processing is its potential to accelerate those efforts with predictive analytics informed by empirical results.

The mutability and adaptability inherent in all living things means that medical success requires a deep understanding of genomics: knowing how the flu virus evolves helps devise vaccines to control it, understanding which genes are controlling the proliferation of cancer means that patients can receive targeted therapies with virtually no side effects, and measuring the rate of transfer of antibiotic resistance genes in bacteria can help reduce infection spread.

The interplay between genomes and observable phenotypes is driven by a complex set of

processes. Biomedical researchers therefore tend to specialize on single processes as this facilitates the collection and analysis of empirical data. As a result, raw experimental data in biomedical settings is very heterogeneous, creating difficulties in deriving sufficiently large training sets that can be used confidently for machine learning. In fact, many biomedical experts have noticed that data in their domain is not “big” because of its volume – instead, it is “big” primarily because of its variety and velocity (Almeida et al. 2014; Ruttenberg et al. 2007; Weber et al. 2014).

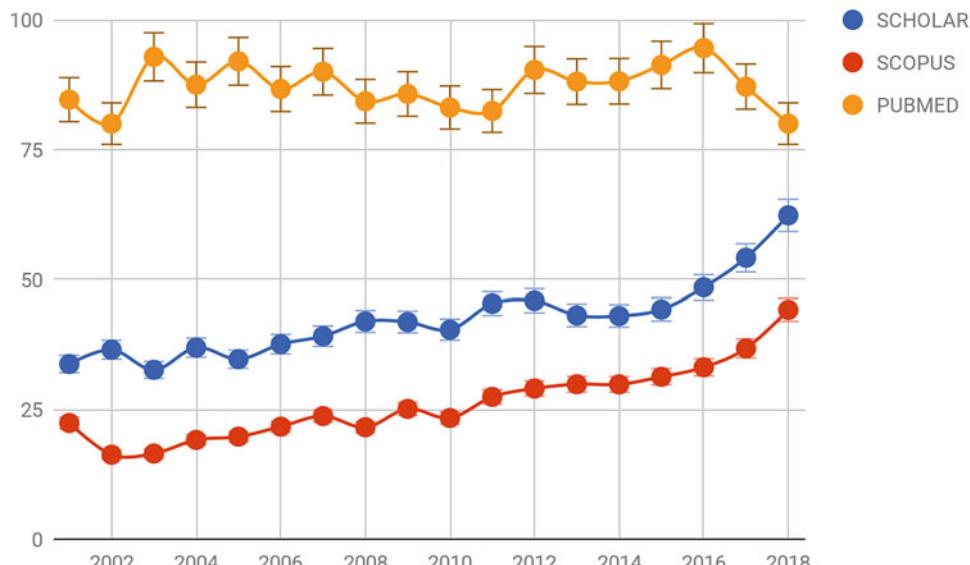

Knowledge graphs and semantic query (KG) offer a promising solution for the training set problem – if one could write a SPARQL query to recover treatment, survival time, and genetic information from cancer patients around the world, for example, it may be possible to create a training set and use it to predict which patients would likely benefit from which drugs. This chapter will present some of the KGs and research tools that have enabled and empowered biomedical scientists with such predictive biomedical analysis tools. The description in this chapter assumes a basic knowledge of semantic technologies, and whereas a knowledge of biological concepts is

not necessary, some biomedical problems will be discussed.

The KG Landscape in Biomedical Domains

The number of publications mentioning semantic web, SPARQL, knowledge graphs, or related concepts can be used as a proxy to understand where that technology sits in the “hype cycle” curve. According to google trends, the hype associated with semantic web and SPARQL peaked around 2006. However, interest in the topic has remained stable, and yearly dedicated conferences continue to attract hundreds of participants. Searches in Google Scholar, Scopus, and PubMed reveal an upward trend in the number of publications mentioning both KG and biomedical or related domains (Bio) when compared against KG across domains (Fig. 1), hinting perhaps that these technologies have achieved maturity.

KGs are also trending in industry: on January 2018 LinkedIn included the word “SPARQL” in 120 job positions and the phrase “semantic web” in 136 – many of which from very rec-

Big Semantic Data Processing in the Life Sciences Domain, Fig. 1 Percentage of papers on the topic of KG which are also in Bio domains. The decrease in PubMed for 2017 may be an artifact of incomplete indexing since the query was performed in early January 2018

ognizable biomedical industries (Eli Lilly, Amgen, Wolters Kluwer, Elsevier, Albert Einstein College of Medicine, Duke University Health System, and Clarivate). A total of 1990 Google patents results matched the word SPARQL – among which were patents from GlaxoSmithKline and Agfa HealthCare. There have also been setbacks and loss of interest in KG in Bio domains – the Conference on Semantics in Healthcare and Life Sciences (CSHALS), for example, was discontinued in 2015; the Cambridge Semantic Web Group, which was heavily influenced by the surrounding biotechnology hub, was discontinued in the summer of 2017. The latest version of the linked open data (LOD) cloud includes 332 KGs in the life sciences domain, or 28% of the whole set, but it is unclear from the Bio literature whether any of these are being used by the community. Nevertheless, the topic of KGs and SPARQL federation continues to grow and be used by a community of biomedical experts versed in these technologies. The next sections will introduce some of most successful KG in Bio domains as well as the problems they sought to address.

Gene Ontology

Founded in 1998, the gene ontology (GO) (Ashburner et al. 2000) was a visionary initiative to describe gene products across model organism databases. GO is in fact not one but three separate ontologies, all of which necessary to fully describe a gene product: biological processes, cellular components, and molecular functions. GO also includes annotations of gene products that link them to each of the three ontologies.

Usage trends: the term “gene ontology” appears 13 K times in PubMed, 156 K times in Google Scholar, and 18 K times in Scopus. It owes its popularity to the adoption by the bioinformatics community, who use it through R packages to enhance bioinformatics pipelines.

UniProt RDF

UniProt RDF is the KG exposing the UniProt protein database as a SPARQL endpoint. UniProt is the largest knowledgebase of protein sequence and annotations. Canonical

gene names are linked to associated proteins including those generated by alternative splicing (different proteins produced by the same gene), polymorphisms (variants occurring in at least 1% of the population), and/or posttranslational modifications (changes in the protein after its sequence is assembled). The key to the continued growth and popularity of UniProt has been its reliance on automated predictions that are manually curated by experts.

Usage trends: the terms “UniProt SPARQL” or variations appear 1430 times in Google Scholar, 40 times in Scopus, and 15 times in PubMed. UniProt (by itself) appears 8760 times in Scholar, 1128 times in Scopus, and 932 times in PubMed. The UniProt RDF developers have observed approximately 2000 different non-bot users querying the SPARQL endpoint, who use it as an API. The true potential of UniProt as a SPARQL endpoint has yet to be fully harnessed – however, the latest development in CRISPR–Cas9 and other gene editing technologies, together with a wish to custom design new proteins based on desired function, may become the use case that leads to an explosion in the number of uses for this endpoint.

Bio2RDF

Bio2RDF was probably the first project intentionally devised to deliver a query federation solution to the bioinformatics and systems biology communities. In 2008, when Bio2RDF was first released (Belleau et al. 2008), there were over 1000 online bioinformatics databases published annually in the NAR database issue. Frustrated by the need to create wrappers for multiple APIs, many bioinformatics organizations raised the issue of numerous obstacles to cross-database integration efforts (Haas et al. 2001; Stark et al. 2006; Fujita et al. 2010), the most significant of which was entity identifiers and attribute name alignment across sources. Bio2RDF’s main contribution was the definition of a URI creation convention which preserved the origin of the identifier or attribute while still respecting the requirement that URI is dereferenceable (<http://bio2rdf.org/<dataset>:<identifier>>, http://bio2rdf.org/<dataset>_vocabulary:<class> or

http://bio2rdf.org/<dataset>_<resource>:<identifier>_<identifier>).

Usage trends: the term “Bio2RDF” appears 1570 times in Google Scholar, 529 times in Scopus, and 20 times in PubMed. The majority of publications are in the domains of biomedical semantics or bioinformatics although some scientists working in immunology (Lamurias et al. 2017) and drug safety (Koutkias et al. 2017) have begun to explore the utility of such a valuable resource.

Linked TCGA

The Cancer Genome Atlas (TCGA) is a program initiated as a collaboration between the National Cancer Institute and the National Human Genome Research Institute and aimed at mapping genomic changes in 33 types of cancer. A total of 32K cancer cases and >3M genomic mutations were identified. The Linked TCGA project (Deus et al. 2010; Saleem et al. 2014) aimed at producing a RDF representation of the TCGA data and create links to clinical disease codes and gene identifiers. Other efforts to create RDF representation of TCGA include the project TCGA Roadmap (Robbins et al. 2013), which allows search for specific files, and the Seven Bridges Cancer Genomic Cloud also provides a SPARQL endpoint over the TCGA data with a schema very similar to Linked TCGA.

Usage trends: the terms TCGA and SPARQL appear 138 times in Google Scholar, 6 times in Scopus, and 3 times in PubMed.

Other Biomedical Knowledge Graphs

It is impossible to detail here all the KGs that have been made available to biomedical experts over the years. Some of them were never meant as more than proofs of concept and are no longer available. In other cases, those interested in recreating the work can use available RDFizers. According to the Mondeca Labs SPARQL endpoint monitor, only 37.9% of 565 SPARQL endpoints registered in datahub.io are available, and many of the unavailable ones were from biomedical domains.

In spite of setbacks, many other notable KGs are still online and more continue to be cre-

ated by consortia around the world – notably Eagle-I, a project funded by Harvard Catalyst and aimed at facilitating translational science research; the EBI RDF platform (Jupp et al. 2014), which supports a SPARQL endpoint for content in some EBI databases (BioSamples, BioModels, ChEMBL, Ensembl, Reactome, and Gene Expression Atlas), BioTea (Garcia et al. 2017), and Springer Nature SciGraph, both of which collate information about entities of significance to the research landscape. International consortia such as Allotrope, Europe’s ELIXIR initiative, Open PHACTS, and Pistoia Alliance actively seek to improve biomedical data access, interoperability, and integrity via semantic technologies.

Semantic Processing Solutions to Biomedical Problems

Some of the problems that have encouraged biomedical experts to seek KG solutions are described in this section. This is not a complete description since the field continues to evolve, yet it might provide the readers with a better understanding of this domain and how it benefits from KG processing.

Genome-Wide Association Studies (GWAS)

To understand the importance of KG processing for GWAS, it is necessary to understand how the dramatic drop in cost of genetic sequencing changed the way biomedical scientists create knowledge from empirical data. GWAS experiments are typically designed to find correlations between genes and phenotypes (e.g., cancer or diabetes). In disease cells, genes can be expressed at higher or lower concentrations than in normal cells. Statistical analysis reveals the lists of genes that may be driving the disease (i.e., gene expression signatures). GO terms associated with those lists help explain which processes are active in different components of the cell. For example, if the cell is undergoing division, cell cycle and chromosome biogenesis are more likely to come up in gene to GO mappings. Some Bio2RDF and EBI RDF datasets (e.g., Reactome) are also useful, namely, when identifying affected pathways

for drug targeting. This exploration is known as gene set enrichment analysis (GSEA). In one prominent example, GSEA was used to identify prognosis biomarkers and allow for better triaging of leukemia patients (Radich et al. 2006).

Drug Discovery and Drug Repurposing

Solutions for drug discovery and repurpose are probably two of the most well-described use cases for KGs in the Bio domain (Jentzsch et al. 2009; Chen et al. 2010; Wild et al. 2011). Before starting a clinical trial, most pharmaceutical companies first seek to understand its effect on biological entities. In many cases, the interaction between the drug and a known protein structure can be computationally predicted (i.e., in silico experiments). UniProt RDF is a key resource for this purpose, but others, including Chem2Bio2RDF and Open PHACTS, are also very relevant since they provide the necessary bridge between biological and chemical entities. Results from in silico models are often decisive in moving forward with more expensive preclinical experiments – an added incentive to aggregate extra information when building predictive models. In a recent in silico experiment (Hu et al. 2016), researchers used UniProt and the Protein Data Bank to identify five plant-based compounds and five FDA approved drugs that could target two cancer-causing genes. KGs in the chemical domain can also help biomedical experts achieve more accurate predictions by augmenting or filtering their models with chemical/biological properties such as toxicity (Kotsampasakou et al. 2017), pharmacodynamics, and absorption.

Mapping Genes to Gene Products to Phenotypes

Gene names are unique and nonoverlapping – the Human Genome Nomenclature Consortia provide scientists with a standard nomenclature. However, most protein names share a name with the gene from which they originate. Biomedical scientists adopted the convention of using italics when referring to the gene but not when referring to the protein (e.g., BRAF is the protein, and *BRAF* is the gene). This 1:1 gene/protein correspondence breaks down when

genes produce multiple proteins via alternative splicing (Black 2003). Another nomenclature issue arises when scientists uses protein family and individual protein names interchangeably (e.g., Ras is a protein family that includes H-Ras, K-Ras, and N-Ras, which are often referred to simply as “Ras proteins”). Finally, genes/proteins in different species often share a name if they share a function. MAP2K1, for example, exists in both rat (*Rattus norvegicus*) and in humans. The convention in biomedical publishing has been to use the symbol in its uppercase form (MAP2K1) when referring to the human variant but the capitalized form (Map2k1) when referring to nonhuman alternatives. This creates very obvious challenges for automated entity extraction.

The Bio2RDF KG has tackled the gene, protein, protein family, and transcript nomenclature problem with resort to a universal identifier schema that preserves the provenance of the identifiers while providing a dereferenceable description for each, including the entity type and links to related entities. With Bio2RDF, bioinformatics workflows can be simplified by resorting to a single source for identifier mapping. KGs also facilitate inference of attributes when the entities are similar – for example, knowledge that the Map2k1 protein in rat is responsible for activating cell growth can be easily inferred into its human equivalent by the use of semantic inference. At last, the problem of inconsistent phenotype and disease naming is a problem that has frustrated multiple attempts at information integration but one which has greatly benefited from KG-based solutions and is well described in Harrow et al. (2017).

Machine Learning in Bio with KGs

In the previous section, some of the most significant problems in processing of life science data were presented. The focus so far has been on data integration. This section goes a step further and explores how KGs are being used to create training sets for machine learning.

Knowledge Graphs as Aggregators of Biomedical Training Sets

The availability of graphical processing units (GPU) and cloud computing resources, coupled with easy to use machine learning libraries, is driving renewed interest in KG. Deep learning methodologies are powerful, yet they require large, clean, and standardized training sets. KGs show promise in addressing that problem. In Wang (2017), drug–drug interactions are predicted using an autoencoder network trained on a KG generated by aggregating Bio2RDF, DrugBank, and MEDLINE. In Yoshida et al. (2009), the authors describe the PosMed phenotype/candidate-gene matcher developed using curated relationships from aggregated data sources (OMIM, Reactome, MEDLINE). In Jiang et al. (2017), a “ground truth” KG of symptom–disease and examination–disease relationships from EMRs was used to identify diagnosis and misdiagnosis using machine learning. Neural networks are also being used to predict new compound–gene relationships from existing KGs (Vieira 2016).

Biomedical Ontologies and Word Embeddings

Biomedical ontologies have been used extensively to address data integration problems in the biomedical domain (Hasnain et al. 2012, 2014; Zeginis et al. 2014). Disease and phenotype ontologies are particularly helpful in grouping patients whose diagnosis may be sufficiently similar to include them in the same clinical trial cohort (Sioutos et al. 2007; Washington et al. 2009; Schriml et al. 2012). And in some cases, the optimal therapy for a patient can be inferred using a translational medicine ontology (Drolet and Lorenzi 2011). NCBO resources (Noy et al. 2009) provide significant aid to version control and reuse of existing classes and ontologies in biomedical domains. Notwithstanding, it is common for biomedical experts to work on problems for which ontologies do not exist. For example, thousands of genomic variants predictive of poor prognosis have been identified (Xu et al. 2015) but very rarely are they described in ontologies.

Word embeddings, such as Word2vec (Church 2017), can offer probabilistic approximations between keywords, which are useful and important when there is no curated ontology to resort to. Word embeddings (Yoshida et al. 2009) are being used for ontology learning from text corpora, significantly improving the rate of ontology creation and removing the burden of its creation from the domain experts (albeit curation of these automated relationships is still necessary).

Conclusions

Data in biomedical and life sciences is not “big” because of its volume – it is “big” because of its variety and heterogeneity. To engineer better therapies, study biodiversity, or prevent disease, biomedical experts need to know how changes in one dynamic system affect changes in another. Simulations are helpful, but when they are not informed and continuously updated by data, their usefulness quickly fades. Probabilistic and predictive techniques like GWAS or machine learning help automate well-defined tasks when large amounts of clean, homogeneous data are available. However, rarely are datasets large enough to address the broader – and likely more biomedically relevant – questions. The biomedical domain is rich in federated data warehouses which are diligently updated by the community. Solving the truly interesting biomedical problems may require federation of queries across them – a problem that RDF, KGs, and SPARQL technologies are well equipped to address.

Definitions

To speed up the progress in the field of materials design, a number of challenges related to big data

need to be addressed. This entry discusses these challenges and shows the semantic technologies that alleviate the problems related to variety, variability, and veracity.

Overview

Materials design and materials informatics are central for technological progress, not the least in the green engineering domain. Many traditional materials contain toxic or critical raw materials, whose use should be avoided or eliminated. Also, there is an urgent need to develop new environmentally friendly energy technology. Presently, relevant examples of materials design challenges include energy storage, solar cells, thermoelectrics, and magnetic transport (Ceder and Persson 2013; Jain et al. 2013; Curtarolo et al. 2013).

The space of potentially useful materials yet to be discovered – the so-called *chemical white space* – is immense. The possible combinations of, say, up to six different elements constitute many billions. The space is further extended by possibilities of different phases, low-dimensional systems, nanostructuring, and so forth, which adds several orders of magnitude. This space was traditionally explored by experimental techniques, i.e., materials synthesis and subsequent experimental characterization. Parsing and searching the full space of possibilities this way are however hardly practical. Recent advances in condensed matter theory and materials modeling make it possible to generate reliable materials data by means of computer simulations based on quantum mechanics (Lejaeghere et al. 2016). High-throughput simulations combined with machine learning can speed up progress significantly and also help to break out of local optima in composition space to reveal unexpected solutions and new chemistries (Gaultois et al. 2016).

This development has led to a global effort – known as the Materials Genome Initiative (<https://www.mgi.gov/>) – to assemble and curate databases that combine experimentally known and computationally predicted materials

properties. A central idea is that materials design challenges can be addressed by searching these databases for entries with desired combinations of properties. Nevertheless, these data sources also open up for *materials informatics*, i.e., the use of big data methodology and data mining techniques to discover new physics from the data itself. A workflow for such a discovery process can be based on a typical data mining process, where key factors are identified, reduced, and extracted from heterogeneous databases, similar materials are identified by modeling and relationship mining, and properties are predicted through evaluation and understanding of the results from the data mining techniques (Agrawal and Alok 2016). The use of the data in such a workflow requires addressing problems with data integration, provenance, and semantics, which remains an active field of research.

Even when a new material has been invented and synthesized in a lab, much work remains before it can be deployed. Production methods allowing manufacturing the material at large scale in a cost-effective manner need to be developed, and integration of the material into the production must be realized. Furthermore, life-cycle aspects of the material need to be assessed. Today, this post-invention process takes typically about two decades (Mulholland and Paradiso 2016; Jain et al. 2013). Shortening this time is in itself an important strategic goal, which could be realized with the help of an integrated informatics approach (Jain et al. 2013, Materials Genome Initiative <https://www.mgi.gov/>).

To summarize, it is clear that materials data, experimental as well as simulated, has the potential to speed up progress significantly in many steps in the chain starting with materials discovery, all the way to marketable product. However, the data needs to be suitably organized and easily accessible, which in practice is highly nontrivial to achieve. It will require a multidisciplinary effort and the various conventions and norms in use need to be integrated. Materials data is highly heterogeneous and much of it is currently hidden behind corporate walls (Mulholland and Paradiso 2016).

Big Data Challenges

To implement the data-driven materials design workflow, we need to deal with several of the big data properties (e.g., Rajan 2015).

Volume refers to the quantity of the generated and stored data. The size of the data determines the value and potential insight. Although the experimental materials science does not generate huge amounts of data, computer simulations with accuracy comparable to experiments can. Moreover, going from state-of-the-art static simulations at temperature $T=0\text{ K}$ toward realistic descriptions of materials properties at temperatures of operation in devices and tools will raise these amounts as well.

Variety refers to the type and nature of the data. The materials databases are heterogeneous in different ways. They store different kinds of data and in different formats. Some databases contain information about materials crystal structure, some about their thermochemistry, and others about mechanical properties. Moreover, different properties may have the same names, while the same information may be represented differently in different databases.

Velocity refers to the speed at which the data is generated and processed to meet the demands and challenges that lie in the path of growth and development. In computational materials science, new data is generated continuously, by a large number of groups all over the world. In principle, one can store summary results and data streams from a specific run as long as one needs (days, weeks, years) and analyze it afterward. However, to store all the data indefinitely may be a challenge. Some data needs to be removed as the storage capacity is limited.

Variability deals with the consistency of the data. Inconsistency of the data set can hamper processes to handle and manage it. This can occur for single databases as well as data that was integrated from different sources.

Veracity deals with the quality of the data. This can vary greatly, affecting accurate analysis. The data generated within materials science may contain errors, and it is often noisy. The quality of the data is different in different databases. It may be

challenging to have provenance information from which one can derive the data quality. Not all the computed data is confirmed by lab experiments. Some data is generated by machine learning and data mining algorithms.

Sources of Data and Semantic Technologies

Although the majority of materials data that has been produced by measurement or through predictive computation have not yet become organized in general easy-to-use databases, several sizable databases and repositories do exist. However, as they are heterogeneous in nature, semantic technologies are important for the selection and integration of the data to be used in the materials design workflow. This is particularly important to deal with variety, variability, and veracity.

Within this field the use of semantic technologies is in its infancy with the development of ontologies and standards. Ontologies aim to define the basic terms and relations of a domain of interest, as well as the rules for combining these terms and relations. They standardize terminology in a domain and are a basis for semantically enriching data, integration of data from different databases (variety), and reasoning over the data (variability and veracity). According to Zhang et al. (2015a) in the materials domain ontologies have been used to organize materials knowledge in a formal language, as a global conceptualization for materials information integration (e.g., Cheng et al. 2014), for linked materials data publishing, for inference support for discovering new materials, and for semantic query support (e.g., Zhang et al. 2015b, 2017).

Further, standards for exporting data from databases and between tools are being developed. These standards provide a way to exchange data between databases and tools, even if the internal representations of the data in the databases and tools are different. They are a prerequisite for efficient materials data infrastructures that allow for the discovery of new materials (Austin 2016). In several cases the standards formalize the

description of materials knowledge (and thereby create ontological knowledge).

In the remainder of this section, a brief overview of databases, ontologies, and standards in the field is given.

Databases

The Inorganic Crystal Structure Database (ICSD, <https://icsd.fiz-karlsruhe.de/>) is a frequently utilized database for completely identified inorganic crystal structures, with nearly 200 k entries (Belsky et al. 2002; Bergerhoff et al. 1983). The data contained in ICSD serve as an important starting point in many electronic structure calculations. Several other crystallographic information resources are also available (Glasser 2016). A popular open-access resource is the Crystallography Open Database (COD, <http://www.crystallography.net/cod/>) with nearly 400 k entries (Grazulis et al. 2012).

At the International Centre for Diffraction Data (ICDD, <http://www.icdd.com/>) a number of databases for phase identification are hosted. These databases have been in use by experimentalists for a long time.

Springer Materials (<http://materials.springer.com/>) contains among many other data sources, the well-known Landolt-Börnstein database, an extensive data collection from many areas of physical sciences and engineering. Similarly, The Japan National Institute of Material Science (NIMS) Materials Database MatNavi (http://mits.nims.go.jp/index_en.html) contains a wide collection of mostly experimental but also some computational electronic structure data.

Thermodynamical data, necessary for computing phase diagrams with the CALPHAD method, exist in many different databases (Campbell et al. 2014). Open-access databases with relevant data can be found through OpenCalphad (<http://www.opencalphad.com/databases.html>).

Databases of results from electron structure calculations have existed in some form for several decades. In 1978, Moruzzi, Janak, and Williams published a book with computed electronic properties such as, e.g., density of states, bulk modulus, and cohesive energy of all metals (Moruzzi et al. 2013). Only recently, however, the use of

such databases has become widespread, and some of these databases have grown to a substantial size.

Among the more recent efforts to collect materials properties obtained from electronic structure calculations publicly available, a few prominent examples include the Electronic Structure Project (ESP) (<http://materialsgenome.se>) with ca 60k electronic structure results, Aflow (Curtarolo et al. 2012, <http://aflowlib.org/>) with data on over 1.7 million compounds, the Materials Project with data on nearly 70k inorganic compounds (Jain et al. 2013, <https://materialsproject.org/>), the Open Quantum Materials Database (OQMD, <http://oqmd.org/>), with over 470k entries (Saal et al. 2013), and the NOMAD repository with 44 million electronic structure calculations (<https://repository.nomad-coe.eu/>). Also available is the Predicted Crystallography Open Database (PCOD, <http://www.crystallography.net/pcod/>) with over 1 million predicted crystal structures, which is a project closely related to COD.

As the amount of computed data grows, the need for informatics infrastructure also increases. Many of the databases discussed above have made their frameworks available, and well-known examples include the ones by Materials Project and OQMD. Other publicly available frameworks used in publications for materials design and informatics include the Automated Interactive Infrastructure and Database for Computational Science (AiiDA, <http://www.aiida.net/>) (Pizzi et al. 2016), the Atomic Simulation Environment (ASE, <https://wiki.fysik.dtu.dk/ase/>) (Larsen et al. 2017), and the high-throughput toolkit (httk, <http://www.httk.org>) (Faber et al. 2016).

Ontologies

We introduce the features of current materials ontologies from materials (Table 1) and a knowledge representation perspective (Table 2), respectively.

Most ontologies focus on specific sub-domains of the materials field (Domain in Table 1) and have been developed with a specific use in mind (Application Scenario in Table 1).

The Materials Ontology in Ashino (2010) was designed for data exchange among thermal property databases. Other ontologies were built to enable knowledge-guided materials design or new materials discovery, such as PREMAP ontology (Bhat et al. 2013) for steel mill products, MatOnto ontology (Cheung et al. 2008) for oxygen ion-conducting materials in the fuel cell domain, and SLACKS ontology (Premkumar et al. 2014) that integrates relevant product life-cycle domains which consist of engineering analysis and design, materials selection, and manufacturing. The FreeClassOWL ontology (Radinger et al. 2013) is designed for the construction and building materials domain and supports semantic search for construction materials. MMOY ontology (Zhang et al. 2016) captures metal materials knowledge from Yago. The ontology design pattern in Vardeman et al. (2017) models and allows for reasoning about material transformations in the carbon dioxide and sodium acetate productions by combining baking soda and vinegar. Some ontologies are generated (Data source in Table 1) by extracting knowledge from other data resources such as the Plinius ontology (van der Vet et al. 1994) which is extracted from 300 publication abstracts in the domain of ceramic materials, and MatOWL (Zhang et al. 2009) which is extracted from MatML schema data to enable ontology-based data access. The ontologies may also use other ontologies as a basis, for instance, MatOnto that uses DOLCE (Gangemi et al. 2002) and EXPO (Soldatova and King 2006).

From the knowledge representation perspective (Table 2), the basic terms defined in materials ontologies involve materials, properties, performance, and processing in specific sub-domains. The number of concepts ranges from a few to several thousands. There are relatively few relationships and most ontologies have instances. Almost all ontologies use OWL as a representation language. In terms of organization of materials ontologies, Ashino's Materials Ontology, MatOnto, and PREMAP ontology are developed as several ontology components that are integrated in one ontology. In Table 2 this is denoted in the modularity column.

Big Semantic Data Processing in the Materials Design Domain, Table 1 Comparison of materials ontologies from a materials perspective

Materials ontology	Data source	Domain	Application scenario
Ashino's Materials Ontology (Ashino 2010)	Thermal property databases	Thermal properties	Data exchange, search
Plinius ontology (van der Vet et al. 1994)	Publication abstracts	Ceramics	Knowledge extraction
MatOnto (Cheung et al. 2008)	DOLCE ontology ^a , EXPO ontology ^b	Crystals	New materials discovery
PREMAP ontology (Bhat et al. 2013)	PREMAP platform	Materials	Knowledge-guided design
FreeClassOWL (Radinger et al. 2013)	Eurobau data ^c , GoodRelations ontology ^d	Construction and building materials	Semantic query support
MatOWL (Zhang et al. 2009)	MatML schema data	Materials	Semantic query support
MMOY (Zhang et al. 2016)	Yago data	Metals	Knowledge extraction
ELSSI-EMD ontology (CEN 2010)	Materials testing data from ISO standards	Materials testing, ambient temperature tensile testing	Data interoperability
SLACKS ontology (Premkumar et al. 2014)	Ashino's Materials Ontology, MatOnto	Laminated composites	Knowledge-guided design

^aDOLCE stands for Descriptive Ontology for Linguistic and Cognitive Engineering

^bEXPO ontology is used to describe scientific experiments

^cEurobau.com compiles construction materials data from ten European countries

^dGoodRelations ontology (Hepp 2008) is used for e-commerce with concepts such as business entities and prices

Big Semantic Data Processing in the Materials Design Domain, Table 2 Comparison of materials ontologies from a knowledge representation perspective

Materials ontology	Ontology metrics	Language	Modularity
Ashino's Materials Ontology (Ashino 2010)	606 concepts, 31 relationships, 488 instances	OWL	✓
Plinius ontology (van der Vet et al. 1994)	17 concepts, 4 relationships, 119 instances ^a	Ontolingua code	
MatOnto (Cheung et al. 2008)	78 concepts, 10 relationships, 24 instances	OWL	✓
PREMAP ontology (Bhat et al. 2013)	62 concepts	UML	✓
FreeClassOWL (Radinger et al. 2013)	5714 concepts, 225 relationships 1469 instances	OWL	
MatOWL (Zhang et al. 2009)	(not available)	OWL	
MMOY (Zhang et al. 2016)	544 metal concepts, 1781 related concepts, 9 relationships, 318 metal instances 1420 related instances	OWL	
ELSSI-EMD ontology (CEN 2010)	35 concepts, 37 relationships, 33 instances	OWL	✓
SLACKS ontology (Premkumar et al. 2014)	34 concepts and 10 relationships at least ^b	OWL	

^a103 instances out of 119 are elements in the periodic system

^bThe numbers are based on the high-level class diagram and an illustration of instances' integration in SLACKS shown in Premkumar et al. (2014)

Standards

There are currently not so many standards yet in this domain. Early efforts including ISO standards and MatML achieved limited adoption according to Austin (2016). The standard ISO 10303-45 includes an information model for materials properties. It provides schemas for materials properties, chemical compositions, and measure values (Swindells 2009). ISO 10303-235 includes an information model for product design and verification. MatML (Kaufman and Begley 2003, <https://www.matml.org/>) is an XML-based markup language for materials property data which includes schemas for such things as materials properties, composition, heat, and production.

Some other standards that have received more attention are, e.g., ThermoML and CML. ThermoML (Frenkel et al. 2006, 2011) is an XML-based markup language for exchange of thermo-physical and thermochemical property data. It covers over 120 properties regarding thermodynamic and transport property data for pure compounds, multicomponent mixtures, and chemical reactions. CML or Chemical Markup Language (Murray-Rust and Rzepa 2011; Murray-Rust et al. 2011) covers chemistry and especially molecules, reactions, solid state, computation, and spectroscopy. It is an extensible language that allows for the creation of sub-domains through the convention construct. Further, the dictionaries construct allows for connecting CML elements to dictionaries (or ontologies). This was inspired by the approach of the Crystallographic Information Framework or CIF (Bernstein et al. 2016, <http://www.iucr.org/resources/cif>).

The European Committee for Standardization (CEN) organized workshops on standards for materials engineering data (Austin 2016) of which the results are documented in CEN (2010). The work focuses specifically on ambient temperature tensile testing and developed schemas as well as an ontology (the ELSSI-EMD ontology from above).

Another recent approach is connected to the European Centre of Excellence NOMAD (Ghirghelli et al. 2016). The NOMAD repository's (<https://repository.nomad-coe.eu/>)

metadata structure is formatted to be independent of the electronic-structure theory or molecular-simulation code that was used to generate the data and can thus be used as an exchange format.

Conclusion

The use of the materials data in a materials design workflow requires addressing several big data problems including variety, variability, and veracity. Semantic technologies are a key factor in tackling some of these problems. Currently, efforts have started in creating materials databases, ontologies, and standards. However, much work remains to be done. To make full use of these resources, there is a need for integration of different kinds of resources and reasoning capabilities should be used, as in the bioinformatics field in the 1990s (Lambrix et al. 2009). Databases could use ontologies to define their schemas and enable ontology-based querying. Integration of databases is enabled by the use of ontologies. However, when databases have used different ontologies, alignments between different ontologies are needed as well (Euzenat and Shvaiko 2007). Further, more effort should be put on connecting ontologies and standards (as started in the CML, CEN, and NOMAD approaches), which may also lead to connections between different standards. Reasoning can be used in different ways. When developing resources reasoning can help in debugging and completing the resources leading to higher-quality resources (Ivanova and Lambrix 2013). Reasoning can also be used during querying of databases as well as in the process of connecting different resources.

Definitions

A blockchain is a linked list of immutable tamper-proof blocks, which is stored at each participating node. Each block records a set of transactions and the associated metadata. Blockchain transactions act on the identical ledger data stored at each node. Blockchain was first perceived by Satoshi Nakamoto (Satoshi 2008), as a peer-to-peer money exchange system. Nakamoto referred to the transactional tokens exchanged among clients in his system as Bitcoins.

Overview

In 2008, Satoshi Nakamoto (Satoshi 2008) came up with the design of an unanticipated technology that revolutionized the research in the distributed systems community. Nakamoto presented the design of a peer-to-peer money exchange process that was shared yet distributed. Nakamoto named his transactional token as *Bitcoin* and brought forth design of a new paradigm *blockchain*.

The key element of any blockchain system is the existence of an immutable tamper-proof *block*. In its simplest form, a block is an encrypted aggregation of a set of transactions. The existence of a block acts as a guarantee that the transactions have been executed and verified.

A newly created block is appended to an existing chain of blocks. This chain of blocks is predominantly a *linked list* which associates one block with the other. The initial block of any such list is a *genesis block* (Decker and Wattenhofer 2013). Genesis block is a special block that is numbered zero and is hard-coded in the blockchain application. Each other block links to some previously existing block. Hence, a blockchain grows by appending new blocks to the existing chain.

A transaction in a blockchain system is identical to any distributed or OLTP transaction (TPP Council 2010) that acts on some data. Traditional blockchain applications (such as Bitcoin) consist of transactions that represent an exchange of money between two entities (or users). Each valid transaction is recorded in a block, which can contain multiple transactions, for efficiency. Immutability is achieved by leveraging strong cryptographic properties such as hashing (Katz and Lindell 2007). Figure 1 presents the structure of a simple blockchain.

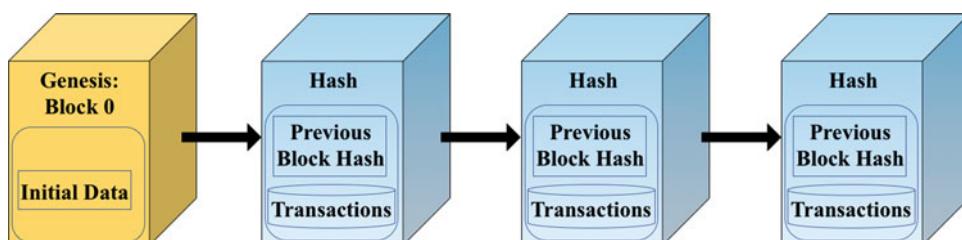

A blockchain is a *linked list* in a true sense, as each block stores the hash of the previous block in its chain. Each block also digitally signs its contents by storing the hash of its contents inside the block. These hashes provide cryptographic integrity, as any adversary intending to modify a block needs to also modify all the previous blocks in a chain, which makes the attack cryptographically infeasible. A key design strategy is to construct a Merkle tree (Katz and Lindell 2007) to efficiently store and verify the hashes. Thus, each block only stores the *root* of the Merkle tree, as given the root, it is easy to verify the immutability.

The preceding discussion allows us to summarize that a blockchain aims at securely storing a set of transactions. In the succeeding sections, we discuss in detail the transaction processing in a blockchain system. We also study mechanisms to validate these transactions and analyze some blockchain applications that employ the same.

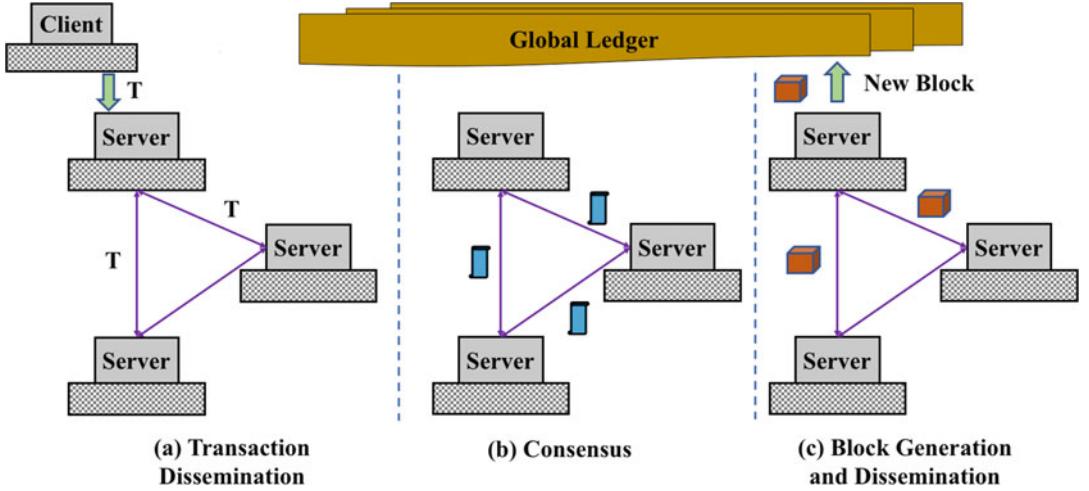

Key Research Findings

Transactions in a blockchain system are identical to their traditional database counterparts. These transactions are issued by the clients to the servers of the blockchain system (Nawab 2018). These transactions act on the data stored on all the participating servers. In its vanilla form, a blockchain transaction could be visualized as a set of *read/write* operations performed on each node of a replicated distributed database. To determine an ordering for all the incoming transactions, each blockchain application employs a consensus (Steen and Tanenbaum 2017) protocol.

A distributed consensus algorithm (Lamport 1998; Gray and Lamport 2006) allows a system to reach a common decision, respected by the majority of nodes. Recent blockchain technologies present several strategies for establishing consensus: Proof-of-Work (Jakobsson and Juels 1999; Satoshi 2008), Proof-of-Stake (King and Nadal 2012), Proof-of-Authority (Parity Technologies 2018), Practical Byzantine Fault Tolerance (Castro and Liskov 1999; Cachin 2016), and so on. To quantify the allowed set of nodes that can create a block (or participate in the consensus process), it is also necessary to characterize the topologies for blockchain systems.

Blockchain Transaction Processing, Fig. 1 Basic blockchain representations

Blockchain Transaction Processing, Fig. 2

Blockchain flow: Three main phases in any blockchain application are represented. (a) Client sends a transaction to one of the servers, which it disseminates to all the

other servers. (b) Servers run the underlying consensus protocol, to determine the block creator. (c) New block is created and transmitted to each node, which also implies adding to global ledger

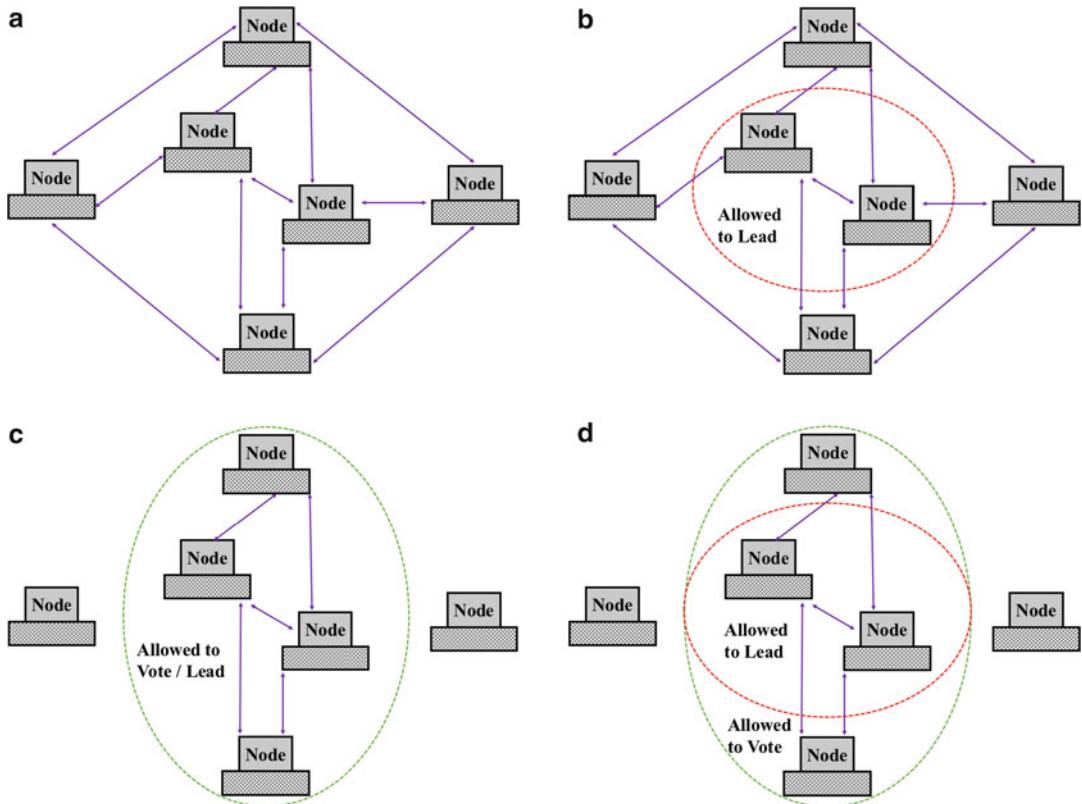

Blockchain Execution

Figure 2 illustrates the three main phases required by any blockchain application to create a new block. The client transmits a transactional request to one of the servers. This server multicasts the request to all other servers. We term this phase as *transaction dissemination*. Once all the servers have a copy of client request, they initiate a *consensus* protocol. The choice of underlying consensus protocol affects the time complexity and resource consumption. The winner of the consensus phase generates the next block and transmits it to all other servers. This transmission process is equivalent to adding an entry (block) to the global distributed ledger.

Blockchain Topologies

A key parameter that renders the design of a blockchain application is the categorization of nodes to be part of the application. Recent works (Pilkington 2015; Cachin and Vukolic 2017) categorize blockchain systems as either public, private, permissioned, or hybrid. Although the characteristics of a public blockchain is clearly stated in the community, there is no common consensus on the terminology pertaining to the other terms.

We categorize blockchain systems under four heads: public, private, permissioned, and hybrid. Figure 3 presents a pictorial representation of the different categories. In these figures nodes that are not allowed to participate in the activities pertaining to the network lack connections to any node in the network. We use different circles to demarcate different zones of operation; certain nodes are allowed to lead (or create the block), and some are allowed to participate in the consensus protocol. *Public blockchain* systems such as Bitcoin (Satoshi 2008) and Ethereum (Wood 2015) allow any node to participate in the consensus process, and any node can generate the next valid block. Hence, if all the nodes have same resources, then each node has equal probability of creating a block (We are assuming fair and ideal conditions, where each node works independently.). *Private blockchain* systems are at the other end of the spectrum, as they allow only some nodes to be part of the consensus process, and only a subset of these nodes can generate the next block. These systems could be utilized at a banking organization which only allows its customers to participate in the consensus, while its employees are only permitted to commit the results by creating a block.

Blockchain Transaction Processing, Fig. 3 Topologies for blockchain systems. (a) Public blockchain. (b) Hybrid blockchain. (c) Permissioned blockchain. (d) Private blockchain

Hybrid blockchain systems attain a middle ground between the two extremes. These systems allow any node to be part of the consensus process, but only some designated nodes are allowed to form the next block. Cryptocurrency Ripple (Schwartz et al. 2014) supports a variant of the hybrid model, where some public institutions can act as transaction validators. *Permissioned blockchain* systems are the restricted variant of public blockchain systems. These systems enlist few nodes as the members with equal rights, that is, each node as part of the system can form a block. These systems allow us to represent internal working of any organization, social media groups, and an early stage startup.

Blockchain Consensus

The common denominator for all the blockchain applications is the underlying distributed consensus algorithm. Nakamoto suggested **Proof-**

of-Work (Satoshi 2008) (henceforth referred as PoW) for achieving consensus among the participating nodes. PoW requires each node to demonstrate its ability to solve a nontrivial task. The participating nodes compete among themselves to solve a complex puzzle (such as computation of a 256-bit SHA value). The node which computes the solution gets the opportunity to generate the next *block*. It also disseminates the block to all the nodes, which marks as the *proof* that it performed some nontrivial computation. Hence, all other nodes respect the winner's ability and reach the consensus by continuing to chain ahead of this block.

In PoW the accessibility to larger computational resources determines the winner node(s). However, it is possible that multiple nodes could lay claim for the next block to be added to the chain. Based on the dissemination of the new block, this could lead to *branching* out of the

single chain. Interestingly, these branches are often short-lived, as all the nodes tend to align themselves to the longest chain, which in turn leads to pruning of the branches. It is important to understand that a node receives incentive when it is able to append a block to the longest chain. Hence, it is to their advantage to always align with the longest chain; otherwise they would end up spending their computational resources for zero gains. Note: PoW algorithm can theoretically be compromised by an adversary controlling at least 51% of computational resources in the network. This theoretical possibility has practical implications as a group of miners can share resources to generate blocks faster, skewing the decentralized nature of the network.

Proof-of-Stake (King and Nadal 2012) (henceforth referred at PoS) aims at preserving the decentralized nature of the blockchain network. In PoS algorithm a node with $n\%$ resources gets $n\%$ time opportunity to create a block. Hence, the underlying principle in PoS is that the node with higher stake lays claim to the generation of the next block. To determine a node's stake, a combination of one or more factors, such as wealth, resources, and so on, could be utilized. PoS algorithm requires a set of nodes to act as validators. Any node that wants to act as a validator needs to *lock out* its resources, as a proof of its stake.

PoS only permits a validator to create new blocks. To create a new block, a set of validators participate in the consensus algorithm. PoS consensus algorithm has two variants: (i) chain-based and (ii) BFT-style. *Chain-based* PoS algorithm uses a pseudorandom algorithm to select a validator, which then creates a new block and adds it to the existing chain of blocks. The frequency of selecting the validator is set to some predefined time interval. *BFT-style* algorithm runs a byzantine fault tolerance algorithm to select the next valid block. Here, validators are given the right to propose the next block, at random. Another key difference between these algorithms is the synchrony requirement; *chain-based* PoS algorithms are inherently synchronous, while *BFT-style* PoS is partially synchronous.

Early implementations of PoS such as Peercoin (King and Nadal 2012) suffer from non-convergence, that is, lack of single chain (also referred as “nothing-at-stake” attack). Such a situation happens when the longest chain branches into multiple forks. Intuitively, the nodes should aim at converging the branches into the single longest chain. However, if the participating nodes are incentive driven, then they could create blocks in both the chains, to maximize their gains. Such an attack is not possible on PoW as it would require a node to have double the number of computational resources, but as PoS does not require solving a complex problem, nodes can easily create multiple blocks.

Proof-of-Authority (Parity Technologies 2018) (henceforth referred as PoA) is designed to be used alongside nonpublic blockchain systems. The key idea is to designate a set of nodes as the authority. These nodes are entrusted with the task of creating new blocks and validating the transactions. PoA marks a block as part of the blockchain if it is signed by majority of the authorized nodes. The incentive model in PoA highlights that it is in the interest of an authority node to maintain its reputation, to receive periodic incentives. Hence, PoA does not select nodes based on their claimed stakes.

Proof-of-Space (Ateniese et al. 2014; Dziembowski et al. 2015) also known as *Proof-of-Capacity* (henceforth referred as PoC) is a consensus algorithm orthogonal to PoW. It expects nodes to provide a proof that they have sufficient “storage” to solve a computational problem. PoC algorithm targets computational problems such as *hard-to-pebble graphs* (Dziembowski et al. 2015) that need large amount of memory storage to solve the problem. In the PoC algorithm, the verifier first expects a prover to commit to a labeling of the graph, and then he queries the prover for random locations in the committed graph. The key intuition behind this approach is that unless the prover has sufficient storage, he would not pass the verification. PoC-based cryptocurrency such as SpaceMint (Park et al. 2015) claims PoC-based approaches more resource efficient to PoW as storage consumes less energy.

A decade prior to the first blockchain application, distributed consensus problem had excited the researchers. Paxos (Lamport 1998) and Viewstamped Replication (Oki and Liskov 1988) presented key solutions to distributed consensus when the node failures were restricted to *fail-stop*. Castro and Liskov (1999) presented their novel *Practical Byzantine Fault Tolerance* (henceforth referred as PBFT) consensus algorithm to handle byzantine failures. Interestingly, all of previously discussed consensus algorithms provide similar guarantees as PBFT. Garay et al. (2015) helped in establishing an equivalence between the PoW and general consensus algorithms. This equivalence motivated the community to design efficient alternatives to PoW.

PBFT runs a three-phase protocol to reach a consensus among all the non-byzantine nodes. PBFT requires a bound on the number of byzantine nodes. If “ n ” represents the total number of nodes in the system, then PBFT bounds the number of byzantine nodes “ f ” as $f \leq \lfloor \frac{n+1}{3} \rfloor$; PBFT-based algorithms have an advantage of reduced resource consumption but suffer from large message complexity (order $O(n^2)$). Hence, these algorithms are preferred for restricted or small blockchain systems, in order to have less message overhead.

The algorithm starts with a client sending a *request* to the primary node. The primary node verifies the request, assigns a sequence number, and sends a *pre-prepare* message to all the replicas. Each *pre-prepare* message also contains the client’s *request* and the current *view* number. When a replica receives a *pre-prepare* message, it first verifies the request and then transmits a *prepare* message to all the nodes. The *prepare* message contains the digest of client *request*, sequence number, and *view* number. Once a node receives $2f$ *prepare* messages, matching to the *pre-prepare* message, it multicasts a *commit* message. The *commit* message also contains the digest of client *request*, sequence number, and *view* number. Each replica waits for receiving identical $2f+1$ *commit* messages, before executing the request and then transmits the solution to the client.

The client needs $f + 1$ matching responses from different replicas, to mark the request as complete. If the client *timeouts* while waiting for $f + 1$ responses, then it multicasts the request to all the replicas. Each replica on receiving a request from the client, which it has not executed, starts a timer and queries the primary. If the primary does not reply until *timeout*, then the replicas proceed to change the primary. Note: PBFT heavily relies on strong cryptographic guarantees, and each message is digitally signed by the sender using his private key.

Zyzzyva (Kotla et al. 2007) is another interesting byzantine fault tolerance protocol aimed at reducing the costs associated with BFT-style protocols. Zyzzyva (Kotla et al. 2007) allows the replicas to reach *early consensus* by permitting speculative execution. In Zyzzyva, the replicas are relieved from the task of ensuring a global order for the client requests. This task is delegated to the client, which in turn informs the replicas if they are not in sync.

The protocol initiates with a client sending a request to the primary, which in turn sends a *pre-prepare* message to all the replicas. The structure of the *prepare* message is similar to its PBFT counterpart except that it includes a digest summarizing the *history*. Each replica, on receiving a request from the primary, executes the request and transmits the response to the client. Each response, in addition to the fields in the *pre-prepare* message, contains the digest of history and a signed copy of message from the primary. If the client receives $3f + 1$ matching responses, then it assumes the response is stable and considers the request completed. In case the number of matching responses received by the client are in the range $2f + 1$ and $3f$, then it creates a *commit certificate* and transmits this certificate to all the nodes. The *commit certificate* includes the history which proves to a receiving replica that it can safely commit the history and start processing the next request. All the replicas acknowledge the client for the *commit certificate*. If the client receives less than $2f + 1$ responses, then it starts a timer and informs all the replicas again about the impending request. Now, either

the request would be safely completed, or a new primary would be elected.

Although Zyzzyva achieves higher throughput than PBFT, its *client-based* speculative execution is far from ideal. Zyzzyva places a lot of faith on the correctness of the client, which is quite discomforting, as a malicious client can prevent the replicas from maintaining linearizability. **Aardvark** (Clement et al. 2009) studies the ill-effects of various fast, byzantine fault-tolerant protocols and presents the design of a *robust* BFT protocol. In Aardvark, the messages are signed by the client using both digital signatures and message authentication codes (Katz and Lindell 2007). This prevents malicious clients from performing a *denial-of-service* attack, as it is costly for the client to sign each message two times. Aardvark uses *point-to-point* communication, instead of multicast communication. The key intuition behind such a choice is to disallow a faulty client of replica from blocking the complete network. Aardvark also periodically changes the primary replica. Each replica tracks the throughput of the current primary and suggests replacing the primary, when there is a decrease in its throughput. The authors use a simple timer to track the rate of primary response.

RBFT (Aublin et al. 2013) is a simple extension to Aardvark. RBFT aims at detecting *smartly* malicious primary replica, which could avoid being detected malicious by other replicas. The key intuition behind RBFT is to prevent the primary from insinuating delays that are within the stated threshold. Hence, the primary could reduce the throughput without being ever replaced. To tackle this problem, RBFT insists running $f + 1$ independent instances of the Aardvark protocol on each node. One of the instances is designated as the “master instance,” and it executes the requests. The rest of the instances are labeled as the “backup instances,” and they order the requests and monitor the performance of the master instance. If any backup instance observes a degradation of the performance of the master instance, then it transmits a message to elect a new primary. Note: RBFT does not allow more than one primary on any node. Hence, each node can have at most one primary instance. RBFT

protocol has an additional step in comparison to the three phases in PBFT and Aardvark. The client node initiates the protocol by transmitting a request to all the nodes. Next, each node propagates this request to all other nodes, and then the three-phase protocol begins. This extra round of redundancy ensures that the client request reaches all the instances.

Blockchain Systems

Bitcoin (Satoshi 2008) is regarded as the first blockchain application. It is a cryptographically secure digital currency with the aim of disrupting the traditional, institutionalized monetary exchange. Bitcoin acts as the token of transfer between two parties undergoing a monetary transaction. The underlying blockchain system is a network of nodes (also known as *miners*) that take a set of client transactions and validate the same by demonstrating a *Proof-of-Work*, that is, generating a block. The process of generating the next block is nontrivial and requires large computational resources. Hence, the miners are given incentives (such as Bitcoins) for dedicating their resources and generating the block. Each miner maintains locally an updated copy of the complete blockchain and the associated ledgers for every Bitcoin user.

To ensure Bitcoin system remains fair toward all the machines, the difficulty of *Proof-of-Work* challenge is periodically increased. We also know that Bitcoin is vulnerable to 51% attack, which can lead to *double spending* (Rosenfeld 2014). The intensity of such attacks increases when multiple forks of the longest chain are created. To avoid these attacks, Bitcoin developers suggest the clients to wait for their block to be confirmed before they mark the Bitcoins as transferred. This wait ensures that the specific block is a little deep (nearly six blocks) in the longest chain (Rosenfeld 2014). Bitcoin critics also argue that its *Proof-of-Work* consumes huge energy (As per some claims, one Bitcoin transaction consumes power equivalent to that required by 1.5 American homes per day.) and may not be a viable solution for the future.

Bitcoin-NG (Eyal et al. 2016) is a scalable variant to Bitcoin’s protocol. Our preceding discussion highlights that Bitcoin suffers from throughput degradation. This can be reduced by either increasing the block size or decreasing the block interval. However, increasing the former increases the propagation delays, and the latter can lead to incorrect consensus. Bitcoin-NG solves this problem by dividing the time into a set of intervals and selecting one leader for each time interval. The selected leader autonomously orders the transactions. Bitcoin-NG also uses two different block structures: *key blocks* for facilitating leader election and *microblocks* for maintaining the ledger.

Ethereum (Wood 2015) is a blockchain framework that permits users to create their own applications on top of the Ethereum Virtual Machine (EVM). Ethereum utilizes the notion of smart contracts to facilitate development of new operations. It also supports a digital cryptocurrency, *ether*, which is used to incentivize the developers to create correct applications. One of the key advantages of Ethereum is that it supports a Turing complete language to generate new applications on top of EVM. Initially, Ethereum’s consensus algorithm used the key elements of both PoW and PoC algorithms. Ethereum made nodes solve challenges that were not only compute intensive but also memory intensive. This design prevented existence of miners who utilized specially designed hardware for compute-intensive applications.

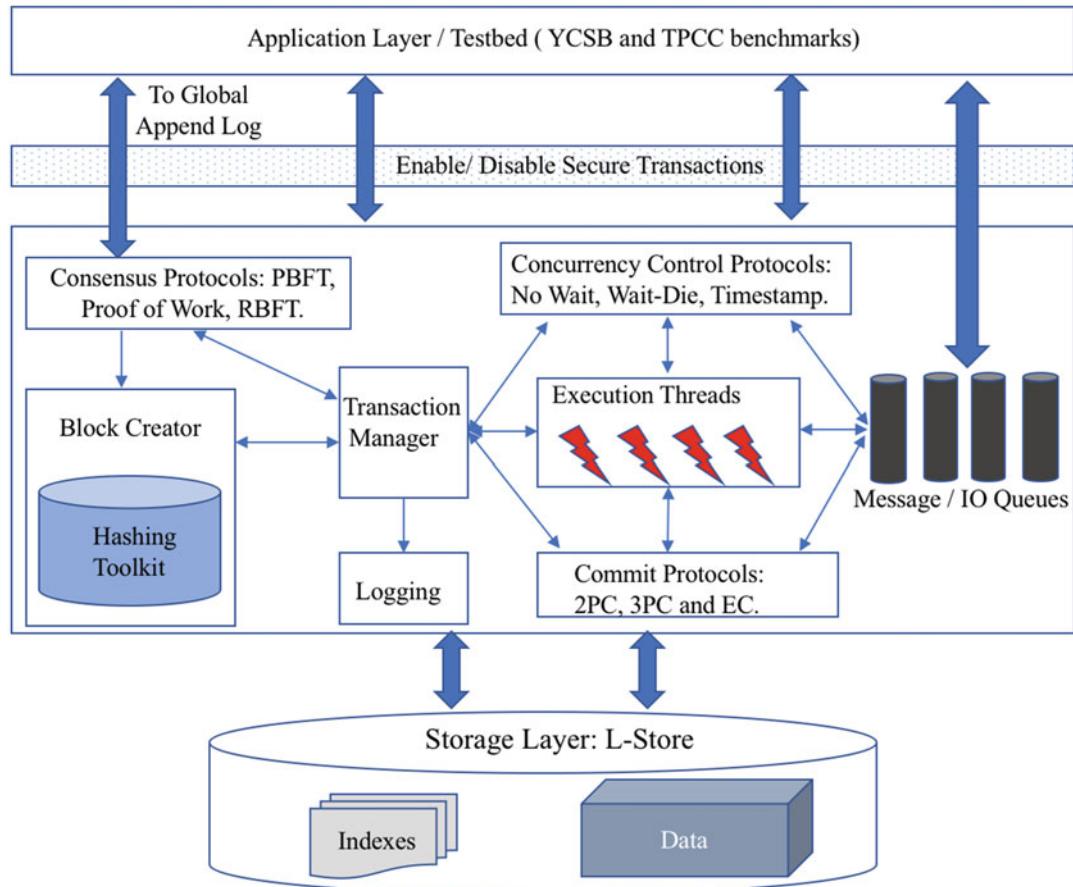

Recently, Ethereum modified its consensus protocol to include some notions of PoS algorithm. The modified protocol is referred as *Casper* (Buterin and Griffith 2017). Casper introduces the notion of *finality*, that is, it ensures that one chain becomes permanent in time. It also introduces the notion of *accountability*, that is, to penalize a validator, who performs the “nothing-at-stake” attack in PoS-based systems. The penalty leveraged on such a validator is equivalent to negating all his stakes.

Parity (Parity Technologies 2018) is an application designed on top of Ethereum. It provides an interface for its users to interact with

the Ethereum blockchain. Parity can be regarded as an interesting application for the blockchain community, as it provides support for both *Proof-of-Work* and *Proof-of-Authority* consensus algorithms. Hence, they allow mechanism for users of their application to set up “authority” nodes and resort to non-compute-intensive, POA algorithm.

Ripple (Schwartz et al. 2014) is considered as the third largest cryptocurrency after Bitcoin and Ethereum, in terms of market cap. It uses a consensus algorithm which is a simple variant of BFT algorithms. Ripple requires a number of failures f to be bounded as follows: $\leq (n - 1)/5 + 1$, where n represents the total number of nodes. Ripple’s consensus algorithm introduces the notion of a *Unified Node List* (UNL), which is a subset of the network. Each server communicates with the nodes in its UNL for reaching a consensus. The servers exchange the set of transactions they received from the clients and propose those transactions to their respective UNL for vote. If a transaction receives 80% of the votes, it is marked permanent. It is important to understand that if the generated UNL groups are a clique, then forks of the longest chain could coexist. Hence, UNLs are created in a manner that they share some set of nodes. Another noteworthy observation about Ripple protocol is that each client needs to select a set of validators or unique nodes that they trust. These validators next utilize Ripple consensus algorithm to verify the transactions.

Hyperledger (Cachin 2016) is a suite of resources aimed at modeling industry standard blockchain applications. It provides a series of application programming interfaces (APIs) for developers to create their own nonpublic blockchain applications. Hyperledger provides implementations of blockchain systems that uses RBFT and other variants of the PBFT consensus algorithm. It also facilitates the use and development of smart contracts. It is important to understand that the design philosophy of Hyperledger leans toward blockchain applications that require existence of nonpublic networks, and so, they do not need a compute-intensive consensus.

Blockchain Transaction Processing, Fig. 4 Architecture of ExpoDB

ExpoDB (Sadoghi 2017; Gupta and Sadoghi 2018) is an experimental research platform that facilitates design and testing of emerging database technologies. ExpoDB consists of a set of five layers providing distinct functionalities (refer to Fig. 4). *Application layer* acts as the test bed for evaluating the underlying database protocols (Gupta and Sadoghi 2018). It allows the system to access OLTP benchmarks such as YCSB Cooper et al. (2010), TPC-C TPP Council (2010), and PPS Harding et al. (2017). *Application layer* acts as an interface for the client-server interaction. *Transport layer* allows communication of messages between the client and server nodes.

Execution layer facilitates seamless execution of a transaction with the help of a set of threads.

These threads lie at the core of the execution layer as they run the transaction, abide by the rules of stated concurrency protocol, and achieve agreement among different transactional partitions. ExpoDB provides implementation for eight concurrency controls and three commit protocols. ExpoDB also characterizes a *storage layer* (Sadoghi et al. 2018) for storing the transactional data, messages, and relevant metadata.

ExpoDB extends blockchain functionality to the traditional distributed systems through a *secure layer*. To facilitate secure transactions, ExpoDB provides a cryptographic variant to YCSB – *Secure YCSB* benchmark. ExpoDB also contains implementations for a variety of consensus protocols such as PoW, PBFT, RBFT, and Bitcoin-NG.

Future Directions for Research

Although blockchain technology is just a decade old, it gained majority of its momentum in the last 5 years. This allows us to render different elements of the blockchain systems and achieve higher performance and throughput. Some of the plausible directions to develop efficient blockchain systems are as follows: (i) reducing the communication messages, (ii) defining efficient block structure, (iii) improving the consensus algorithm, and (iv) designing secure lightweight cryptographic functions.

Statistical and machine learning approaches have presented interesting solutions to automate key processes such as face recognition (Zhao et al. 2003), image classification (Krizhevsky et al. 2012), speech recognition (Graves et al. 2013), and so on. The tools can be leveraged to facilitate easy and efficient consensus. The intuition behind this approach is to allow learning algorithms to select nodes, which are fit to act as a block creator and prune the rest from the list of possible creators. The key observation behind such a design is that the nodes selected by the algorithm are predicted to be non-malicious. Machine learning techniques can play an important role in eliminating the human bias and inexperience. To learn which nodes can act as block creators, a feature set, representative of the nodes, needs to be defined. Some interesting features can be geographical distance, cost of communication, available computational resources, available memory storage, and so on. These features would help in generating the dataset that would help to train and test the underlying machine learning model. This model would be ran against new nodes that wish to join the associated blockchain application.

The programming languages and software engineering communities have developed several works that provide semantic guarantees to a language or an application (Wilcox et al. 2015; Leroy 2009; Kumar et al. 2014). These works have tried to formally verify (Keller 1976; Leroy 2009) the system using the principles of programming languages and techniques such as fi-

nite state automata, temporal logic, and model checking (Grumberg and Long 1994; Baier and Katoen 2008). We believe similar analysis can be performed in the context of blockchain applications. Theorem provers (such as Z3 De Moura and Bjørner 2008) and proof assistants (such as COQ Bertot 2006) could prove useful to define a certified blockchain application. A certified blockchain application can help in stating theoretical bounds on the resources required to generate a block. Similarly, some of the blockchain consensus has been shown to suffer from denial-of-service attacks (Bonneau et al. 2015), and a formally verified blockchain application can help realize such guarantees, if the underlying application provides such a claim.

BSP Programming Model

Zuhair Khayyat

Lucidya LLC, Jeddah, Saudi Arabia

Synonyms

Bulk synchronous parallel; BSPlib

Definitions

It is an iterative share-nothing parallel computing model that abstracts the parallelization of applications into three stages: computation, communication, and synchronization. As illustrated in Fig. 1, each iteration, or superstep, runs the three steps in order and repeats them until the application completes its calculations. The input of the first iteration is loaded from the user's input dataset. After that, the input for each subsequent iteration is collected from the previous one.

Overview

This model is first proposed by Valiant (1990) as a generic parallel programming concept that is not bound to a specific to a programming model or hardware. There have been several modifications to the original design of BSP, such as extended BSP (Juurlink and Wijshoff 1996), decomposable BSP (Beran 1999), oblivious BSP (Gonzalez et al. 2000), CREW BSP (Goodrich 1999), heterogeneous BSP (Williams and Parsons 2000), and (d,x)-BSP (Blelloch et al. 1995). These variations try to improve the communication cost, increase data locality, and reduce synchronizations costs

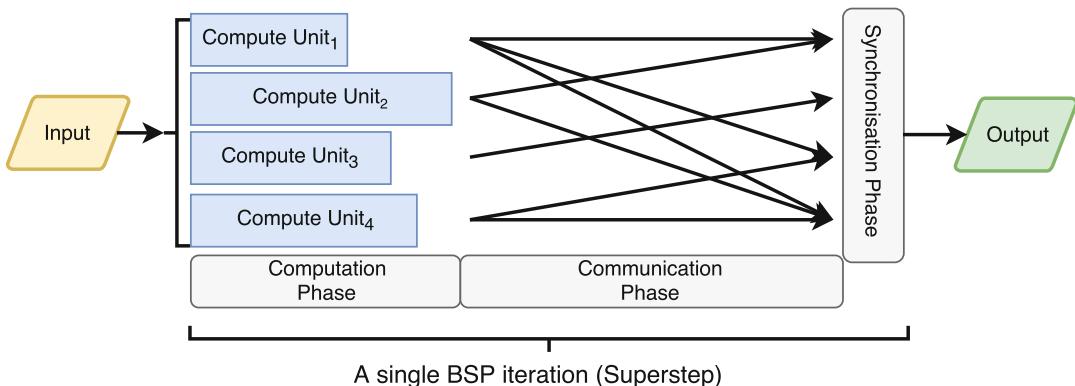

by subdividing the BSP system into smaller independent systems that run concurrently. BSP can be used for various applications including point-to-point message passing between different entities, fast Fourier transforms, data sorting, PageRank, and graph coloring. Although MPI may be used to implement BSP, several communication libraries, such as BSPlib (Hill et al. 1998), have been introduced to support the BSP model with customized message passing protocols naively.

Computation

This phase executes the user's logic. It generates multiple independent computing units from the user's code and runs them concurrently on the input dataset. Each computing unit has a unique ID and is assigned a distinct subset of the input. It has the capability of conducting computations on its data and can only access its local memory that is persistent through the life cycle of the application. The total number of computing units depends on the granularity of their input. To ensure the autonomy of computing units, the user's code must be self-contained, i.e., does not depend on explicit synchronization with other units. As a result, a computing unit may be randomly scheduled on any available resource without affecting the correctness of the user's code.

Communication

This phase allows a computing unit to send fixed-size messages directly to others (point-to-point communication). This stage handles buffering techniques, object serialization, and routing protocols for the messages to ensure a successful delivery to computing units. Messages sent in an iteration are only available to the destination computing units in the next iteration. Moreover, the execution of the communication phase can be overlapped with the computation one, to improve the overall performance of the system, as soon as a computing unit starts sending messages. Several research studies (Salihoglu and Widom 2013; Li et al. 2016; Yan et al. 2015; Goodrich 1999) proposed various techniques to improve the performance of this phase including message aggregation, broadcasting, and utilizing remote

BSP Programming Model, Fig. 1 The BSP compute model

direct memory access (RDMA) to reduce network costs.

Synchronization

The synchronization phase ensures the consistency of the BSP computations and helps to avoid deadlocks. It concludes the end of an iteration by strictly blocking the system from starting the next iteration until all computing units complete their current execution and the outgoing messages reach their destination successfully. It may use one or more synchronization barriers (Khayyat et al. 2013) depending on the nature of the BSP system. For applications with lower consistency requirements (Gonzalez et al. 2012; Xiao et al. 2017), Stale Synchronous Parallel (SSP) (Cui et al. 2014) model may be used to reduce the waiting time for each iteration. This is done by boundingly relaxing the strictness of the synchronization barriers to enable computing units to start the next iteration without waiting for stragglers to finish their current iteration.

Advantages

The BSP model simplifies parallel computations. It allows users to implement parallel applications without worrying about the challenges of parallel environments. The workload of a BSP application can be automatically balanced by increasing the number of computing units. More sophisticated load balancing techniques can also

be used (Bonorden 2007a,b; Khayyat et al. 2013) to ensure a balanced workload of the BSP during runtime. Such explicit load balancing techniques employ the restrictive nature of the BSP model to predict the behavior of the user's code (González et al. 2001) and transparently reassign computing units without affecting the application's correctness. Since computing units are independent, they can be parallelized in shared memory multi-core systems (Valiant 2011; Yzelman et al. 2014), distributed shared-nothing environments (Hill et al. 1998), graphics processing units (GPU) (Hou et al. 2008), parallel system on chip (Bonorden 2008), and heterogeneous clusters (Bonorden 2008).

Limitations

The main disadvantage of BSP is that not all applications can be programmed in its restrictive model. The autonomy and independence of computing units in BSP hinder programmers from developing applications that require high data dependency within its data partitions. Similarly, explicitly synchronizing the state of different computing units may require sophisticated implementation of the user's logic (Sakr et al. 2017; Abdelaziz et al. 2017; Teixeira et al. 2015) or significant modifications to the underlying workflow of the BSP system (Salihoglu and Widom 2014).

BSP also suffers from **strugglers**, i.e., slow computing units as its strict synchronization barriers restrict the execution of the next iteration until all computing units finished and all messages are delivered. The cost of each iteration in BSP is the sum of the execution time of the most delayed computing unit, the cost to transmit or receive the largest messages buffer for a computing unit, and the latency of the synchronization barrier. As a result, the performance of a BSP iteration becomes as fast as its slowest computing unit. Asynchronous iterations or less strict barriers may be used to improve the performance of BSP at the expense of the algorithm's accuracy and convergence rate (Gonzalez et al. 2012). Another way to avoid strugglers is either by excluding expensive computing units from the computation (Abdelaziz et al. 2017), utilizing replication to reduce their load (Salihoglu and Widom 2013; Gonzalez et al. 2012), or shuffling the CPU assignment of expensive computing units (Bonorden 2007a; Khayyat et al. 2013).

Applications

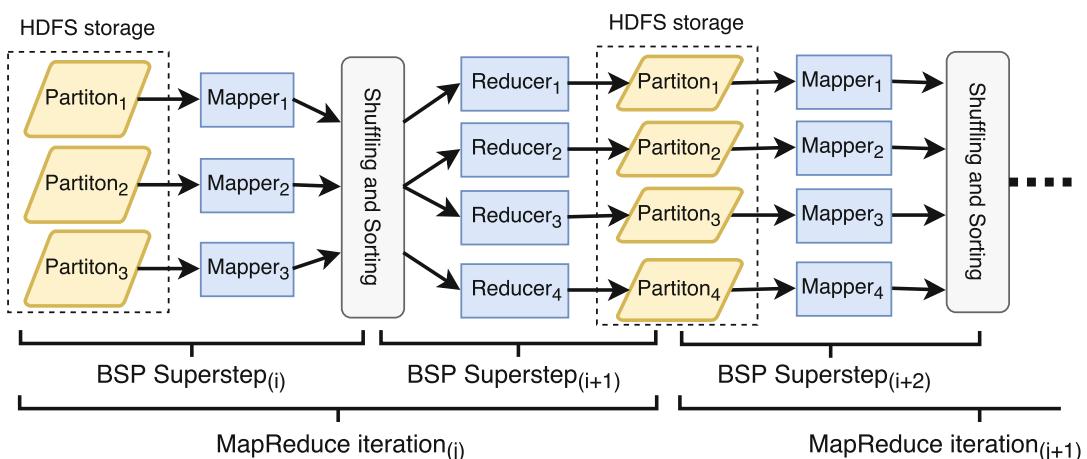

MapReduce

It is a general-purpose distributed system (Dean and Ghemawat 2008) that provides automatic scalability and fault tolerance to programmers through two operators: a **mapper** and a

reducer. Although MapReduce is not originally designed to run as a traditional BSP systems, its execution model follows BSP. That is, mappers and reducers can be considered as computing units of two consecutive supersteps for BSP, while intermediate data shuffling and HDFS I/O play the role of communication and synchronization phases in BSP. As shown in Fig. 2, each MapReduce iteration contains two BSP supersteps. The mapper function is used to generate the distributed computing units of the first superstep ($superstep_{(i)}$), where the execution of the next superstep is held by the shuffling and sorting phase until all mappers finish their execution. The reducer's supertep ($superstep_{(i+1)}$) starts once the shuffling phase completes and the next superstep ($superstep_{(i+2)}$) is blocked until all reducers write their data to HDFS. Alongside mappers and reducers, programmers may also implement a **combiner** that is executed on the output of mappers, i.e., in $superstep_{(i)}$ and $(superstep_{(i+2)})$, to reduce the size of the exchanged messages and thus reduce the network overhead.

Apache Hama

Similar to MapReduce, Apache Hama (Siddique et al. 2016) is also a generalized system that enables automatic parallelization and fault tolerance. It supports a much more comprehensive

BSP Programming Model, Fig. 2 The BSP compute model within MapReduce

range of applications in which it explicitly models its computations on top of the BSP programming model. Apache Hama provides three abstractions to its computing units: general, vertex-based for graph processing, and neuron-based for machine learning. As a result, Apache Hama is able to customize its optimizations to the communication phase and synchronization barriers based on the underlying BSP application.

Pregel

Pregel (Malewicz et al. 2010) and its clones are a typical example of a BSP application that is customized to scale large graph computation distributed systems. Each vertex in the input graph is assigned a distinct compute unit. In each graph iteration, vertices exchange messages about their state and the weights of their graph edges to achieve a newer meaningful state. The communication pattern of a typical Pregel application is usually predictable; a vertex only sends messages to its direct neighbors. As a result, some Pregel clones (Gonzalez et al. 2014) utilized this predictability to improve the overall performance of the BSP's communication phase. Pregel also utilizes aggregators, which is a commutative and associative function, to reduce the size of messages exchanged between the graph vertices. Graph algorithms on Pregel proceed with several BSP iterations until the state of its vertices converge to specific values or reach a maximum predefined limit for the allowed number of iterations.

- Business process analytics is a body of concepts, methods, and tools that allows organizations to understand, analyze, and predict the performance of their business processes and their conformance with respect to normative behaviors, on the basis of data collected during the execution of said processes. Business process analytics encompasses a wide range of methods for extracting, cleansing, and visualizing business process execution data, for discovering business process models

from such data, for analyzing the performance and conformance of business processes both in a postmortem and in an online manner, and finally, for predicting the future state of the business processes based on their past executions.

Overview

This entry provides an overview of the general context of business process analytics and introduces a range of concepts and methods, all the way from the extraction and cleansing of business process event data, to the discovery of process models, the evaluation of the performance and conformance of business processes both offline and online, as well as the management of collections of business process models. These concepts and methods are discussed in detail in subsequent entries of this encyclopedia.

The Context of Business Process Analytics

The context of business process analytics is spanned by a few essential concepts. Below, we start by reviewing the notion of a business process as a means to structure the operations of an organization. We then discuss how the execution of a business process on top of modern enterprise software systems leads to the accumulation of detailed data about the process, which provide the basis for business process analytics. We then discuss the concept of business process model, which plays a central role in the field of business process management in general and business analytics in particular.

Business Processes

The business process management (BPM) discipline targets models and methods to oversee how work is performed in an organization (Dumas et al. 2018). It aims at ensuring consistent outcomes and strives for materializing improvement opportunities. The latter may refer to various operational aspects. Depending on the objectives of an organization, improvement may be defined

as a reduction of costs, execution times, or error rates but may also refer to gaining a competitive advantage through innovation efforts. The essence of BPM, though, is that improvement is not limited to individual steps of an organization's operations. Rather, improvement shall take a holistic view and consider the scope of processes, entire chains of business events, activities, and decisions.

Adopting this view and the definition brought forward by Dumas et al. (2018), a business process is a *collection of inter-related events, activities, and decision points that involve a number of actors and objects, which collectively lead to an outcome that is of value to at least one customer*. Typically, a business process has a well-defined start and end, which gives rise to a notion of an *instance* of the process, also known as *case*. Such a case is the particular occurrence of business events, execution of activities, and realization of decisions to serve a single request by some customer.

The way in which a business process is designed and performed affects both the *quality of service* that customers perceive and the *efficiency* with which services are delivered. An organization can outperform another organization offering similar kinds of service, if it has better processes and executes them better. However, the context of business processes in terms of, for instance, organizational structures, legal regulations, and technological infrastructures, and hence the processes themselves, is subject to continuous change. Consequently, to ensure operational excellence, one-off efforts are not sufficient. Rather, there is a need to continuously assess the operation of a process, to identify bottlenecks, frequent defects and their root causes, and other sources of inefficiencies and improvement opportunities. Business process analytics is a body of techniques to achieve this goal.

Business Process Event Data

Modern companies use dedicated software tools, called *enterprise software systems*, to record, coordinate, and partially conduct everyday work. Specifically, an enterprise software system supports the conduct of a business process by au-

tomating and coordinating business events, activities, and decisions involved in each case of the process. The former means that the reaction to business events, the conduct of activities, or a routine for decision-making may directly be provided by a software system. As an example, one may consider the scenario of a bank processing student loans. Here, a database transaction may be executed to store a loan request after it has been received. This transaction corresponds to an automated activity that is performed immediately in response to the event of receiving the request. Subsequently, a Web service call may be made to check the data provided as part of the request for plausibility, which corresponds to an automated activity that is triggered by reaching a particular state in the respective case.

On the other hand, enterprise software systems coordinate the (potentially manual) efforts of *workers*, people of an organization that are in charge of the conduct of specific activities of the process. In that case, workers see only activities for which they are directly responsible, while the enterprise software system hides the complexity of coordinating the overall process. A worker then faces a number of *work items* that need to be handled. In the above example, a loan officer might see a list of student loan applications that need to be assessed (i.e., accepted or rejected). The assessment of one loan application is a work item, which corresponds to a single activity. However, it also belongs to a specific case, i.e., a specific loan request. A single worker may therefore have multiple work items to handle, all related to the same activity yet belonging to different cases.

An enterprise software system keeps track of the state of each case at any point in time. To this end, it creates a data record, commonly referred to as an *event*, whenever an automated activity is executed, a business event occurs, a worker starts or finishes working on a work item, or a decision is made. Each of these events typically includes additional data, e.g., as it has been provided as a result of executing an activity, whether it was automated (e.g., the response message of a Web service call) or conducted manually (e.g., data inserted by a worker in a Web form). For ex-

ample, after triggering an automated plausibility check of a loan request, an enterprise software system decides whether to forward the request to a worker for detailed inspection. If so, a worker manually determines the conditions under which a loan is offered. A definition of these conditions is then submitted to the system when completing the respective work item.

By coordinating and conducting the activities related to the cases of a business process, an enterprise software system produces an *event stream*. Each event denotes a state change of a case at a particular point in time. Such an event stream may directly be used as input for business process analytics. For instance, using stream processing technology, compliance violations (loans are granted without a required proof of identity of the requester) or performance bottlenecks (final approval of loan offers delays the processing by multiple days) can be detected.

In many cases, however, business process analytics is done in a postmortem manner. In other words, events are recorded and stored in a so-called *event log*, which is analyzed later using a range of techniques. An event log is a collection of events recorded during the execution of (all) cases of a business process during a period of time.

In order to understand what type of analysis we are able to do using an event log, we need to introduce first the concept of business process model. Indeed, a subset of the analysis techniques that can be applied to an event log also involve process models as input, as output, or both. These techniques are commonly known under the umbrella term of *process mining* (van der Aalst 2016).

Business Process Models

A business process model is a representation of a business process, i.e., the way an organization operates to achieve a goal, as outlined above. It represents the activities, business events, and decisions of a process along with their causal and temporal execution dependencies. To this end, a typical business process model is a graph consisting of at least two types of nodes: task nodes and control nodes. Task nodes describe ac-

tivities, whether they are performed by workers or software systems, or a combination thereof. Control nodes along with the structure of the graph capture the execution dependencies, therefore determining which tasks should be performed after completion of a given task. Task nodes may also represent business events that guide the execution of a process, e.g., in terms of delaying the execution until an external trigger has been observed. Decisions, in turn, are commonly represented by dedicated control nodes that define branching conditions for process execution.

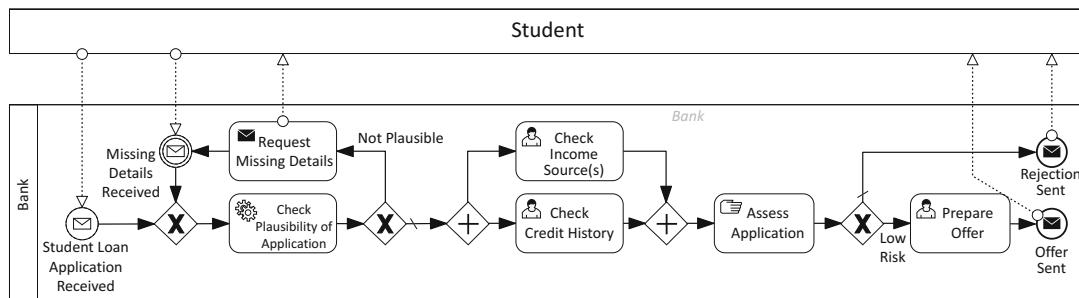

Beyond these essential concepts, process models may capture additional perspectives of a process. They may model the data handled during processing, e.g., by including nodes called data objects that denote inputs and outputs of tasks. Additionally, business process models may include a resource perspective, which captures the roles of involved workers or the types of supporting information systems. In the above example of handling student loan requests, a process model may define the actual application as a data object that is used as input for the activity of checking its plausibility. In addition, the model could specify which specific service provided by which system implements this check.

There are many visual languages that can be used for business process modeling. As an example, Fig. 1 shows a model of the aforementioned student loan process captured in a language called BPMN (Business Process Model and Notation; see also <http://www.bpmn.org/>). An instance of this process, a specific case, is triggered by the

receipt of a student loan application, which is visualized by the leftmost node in the model that represents the respective business event. Subsequently, the application is checked for plausibility, functionality which is provided by an external Web service. Based on the result of this check, the application being plausible or not, a decision is taken. The latter is represented by control node (diamond labeled with “x”). If the application is not plausible, missing details are quested from the applying student, and the plausibility check is conducted again, once these details have been received. The default case of a plausible application (flow arc with a cross bar) leads to two activities being conducted by one or more workers in parallel, i.e., checking the income source(s) and the credit history. This concurrent execution and synchronization are indicated by a pair of control nodes (diamonds labeled with “+”). Subsequently, the application is manually assessed, and a decision is taken, whether to prepare and send an offer or to reject the application.

Business Process Analytics Techniques

Business process analytics comprises a collection of techniques to investigate business processes, based on their representations in the form of event data and/or business process models. Figure 2 provides a general overview of these techniques and the context in which they are defined. This

Business Process Analytics, Fig. 1 A business process model in BPMN that captures the process of applying for a student loan

context is given by a business process as it is supported by an enterprise system, the event data that is recorded during process execution (available as logs or streams), and the models that capture various aspects of a business process.

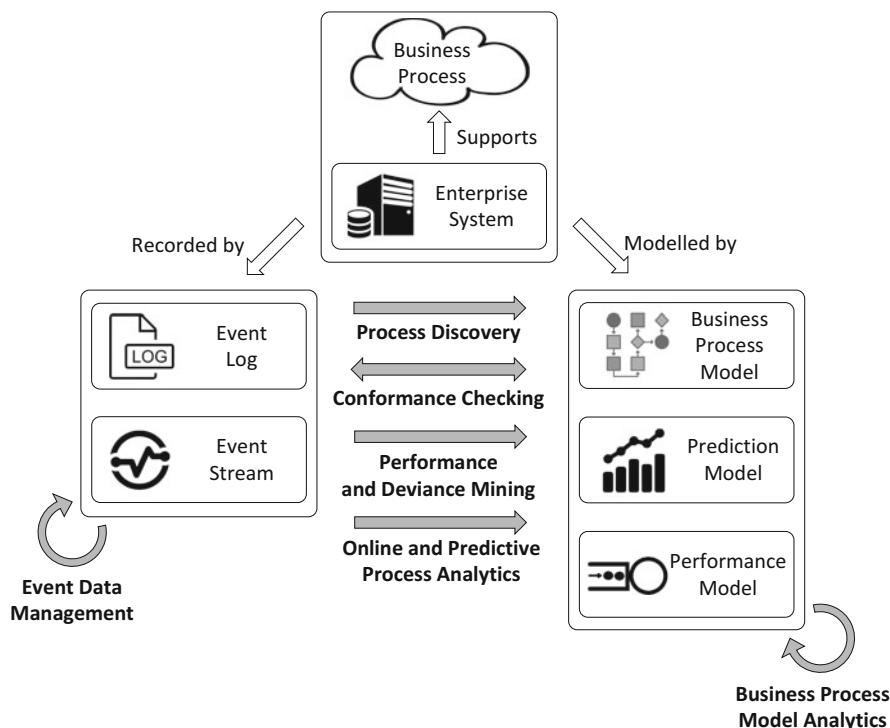

In the remainder of this section, we discuss major categories of techniques for business process analytics techniques indicated in bold in Fig. 2. We further point to other entries in this encyclopedia, which introduce each of these techniques in more detail.

Event Data Management

The left-hand side of Fig. 2 illustrates that the starting point for business process analytics is the availability of event streams and/or event logs generated by the execution of business processes. These event logs can be represented in various ways as will be discussed in the entry *Business Process Event Logs and Visualization*.

The latter entry will also discuss a number of methods for visualizing an event log in order to get a bird's-eye view of the underlying business process.

In their raw form, event streams and event logs suffer from various data quality issues. For example, an event log might be incomplete: some events might be missing altogether, while some events might be missing some attributes (e.g., the time stamp). Due to recording errors, the data carried by some of the events might be incorrect or inconsistent. Also, different events might be defined at different levels of abstraction. For example, some events might correspond to business-level events (e.g., the acceptance of a loan request), while others might be system-level events (e.g., a system-level fault generated by a Web service call to check the plausibility of the data provided as part of a loan request). These data quality issues will also be discussed in the entry on *Business Process Event Logs and Visualization*

Business Process Analytics, Fig. 2 Overview of business process analytics techniques

Visualization, and various techniques to detect and handle them will be presented in the entry on *Event Log Cleaning for Business Process Analytics*.

Process Discovery and Conformance Checking

Assuming that we have a suitably cleaned event log, a first family of business process analytics techniques allows us to either discover a process model from the event stream/log or to compare a given event stream/log to a given process model. These two latter types of techniques are discussed in the entries on *Automated Process Discovery* and *Conformance Checking*, respectively (cf. Fig. 2). Automated process discovery techniques take as input an event log and produce a business process model that closely matches the behavior observed in the event log or implied by the traces in the event log. Meanwhile, conformance checking techniques take as input an event log and a process model and produce as output a list of differences between the process model and the event log. For example, the process model might tell us that after checking the plausibility of a loan application, we must check the credit history. But maybe in the event log, sometimes after the plausibility check, we do not see that the credit history had been assessed. This might be because of an error, or more often than not, it is because of an exception that is not captured in the process model. Some conformance checking techniques take as input an event log and a set of business rules instead of a process model. These techniques check if the event log fulfills the business rules, and if not, they show the violations of these rules.

When comparing an event log and a process model (using conformance checking techniques), various discrepancies might be found between the model and the log. Sometimes these discrepancies are due to data quality issues in the event log, in which case they can be corrected by adjusting the event log, but sometimes it may turn out that the process model is incorrect or incomplete. In this latter case, it might be necessary to adjust (or repair) the process model in order to better fit the event log. Techniques for repairing

a process model with respect to an event log will be discussed in the entry on *Process Model Repair*.

When applied to complex event logs, the output of automated process discovery techniques might be difficult to understand. Oftentimes, this is because the event log captures several variants of the business process rather than just one. For example, an event log of a loan request process might contain requests for various different types of loan and from different types of applicants. If we try to discover a single process model for all these variants, the resulting process model might contain too many execution paths, which makes it difficult to grasp at once. One approach to deal with this complexity is to split the traces in the event log into multiple sub-logs, and to discover one process model for each of the sub-logs. Intuitively, each of these sub-logs contains a set of similar traces and hence represents one possible variant of the process. Techniques for splitting an event log into sub-logs are presented in the entry on *Trace Clustering*.

Trace clustering is only one of several alternative techniques to handle complex event logs. Another approach is to use process modeling notations that are well adapted for capturing processes with high levels of variability. Such approaches are discussed in the entry *Declarative Process Mining*. Another approach is to discover process models with a modular structure. Such approaches are discussed in the entries on *Artifact-Centric Process Mining* and on *Hierarchical Process Discovery*.

Sometimes, event logs are not only complex but also excessively large, to the extent that automated process discovery and conformance checking techniques do not scale up. Divide-and-conquer approaches to deal with such scalability issues are discussed in the entry on *Decomposed Process Discovery and Conformance Checking*.

Finally, closely related to the problem of discovering process models from event logs is that of discovering the business rules that are used in the decision points of the process model. A dedicated entry on *Decision Discovery in Business Processes* deals specifically with this latter problem.

Performance and Deviance Analysis

Another core set of business process analytics techniques are focused on business process performance and deviance analysis (cf. Fig. 2). A prerequisite to be able to analyze process performance is to have a well-defined set of process performance measures. A dedicated entry in the encyclopedia on *Business Process Performance Measurement* deals specifically with this question.

Once we have defined a set of performance measures, it becomes possible to analyze the event log from multiple dimensions (e.g., on a per variant basis, on a per state basis, etc.) and to aggregate the performance of the process with respect to the selected performance measure. A framework for analyzing the performance of business processes with respect to multiple dimensions using so-called *process cubes* is presented in the entry on *Multidimensional Process Analytics*.

Waiting time is a prominent performance measure in the context of business processes, as it plays a role in the perceived quality of a process, and is related to the amount of resources available in a process and hence to the cost of the process. Low waiting times are associated with a leaner and more responsive process. However, low waiting times are not easily achievable when demand is high and when the amount of available resources is limited. When the demand for resources exceeds the available capacity, queues build up, and these queues give rise to waiting times. Understanding the buildup of queues is a recurrent question in business process analytics. Techniques for analyzing queues on the basis of event logs are discussed in the entry on *Queue Mining*.

Naturally, the performance of the process can vary significantly across different groups of cases. For example, it may be that the cycle time 90% of cases of a process is below a given acceptable threshold (e.g., 5 days). However, in some rare cases, the cycle time might considerably exceed this threshold (e.g., 30+ days). *Deviance mining* techniques help us to diagnose the reasons why a subset of the execution of a business process deviate with

respect to the expected outcome or with respect to established performance objectives. Deviance mining techniques are discussed in a dedicated entry of this encyclopedia's section.

Online and Predictive Process Analytics

All the techniques for business process analytics mentioned above are primarily designed to analyze the current “as-is” state of a process in a postmortem setting.

Equally important is the detection of deviations with respect to conformance requirements in real time, as the process unfolds. The entry on *Streaming Process Discovery and Conformance Checking* deals with the question of how automated process discovery and conformance checking can be performed in real time based on a stream of events (as opposed to doing so over an event log collected during a period of time). Such techniques allow us, for example, to detect deviations with respect to the normative behavior (captured by a process model) in real time, thereby enabling immediate implementation of corrective actions.

Sometimes though, it is desirable to be able to preempt undesired situations, such as violations of performance objectives, before these situations happen. This can be achieved by building predictive models from historical event logs and then using these predictive models to make predictions (in real time, based on an event stream) about the future state of running cases of the process. Various techniques to build and validate such predictive models are discussed in the entry on *Predictive Business Process Monitoring*.

When the performance of a business process does not fulfill the objectives of the organization, it becomes necessary to adjust it, for example, by redeployment of resources from some tasks to other tasks of the process, by eliminating or automating certain tasks, or by changing the sequence of execution of the tasks in the process. Business process simulation techniques allow us to evaluate the effects of such changes on the expected performance of the process. In a nutshell, business process simulation means that we take a business process model, enhance it with

simulation parameters (e.g., the rate of creation of process instances, the processing times of tasks in the process, the number of available resources, etc.), and execute it in a simulated environment a large number of times, in order to determine the expected cycle time, cost, or other performance measures. Traditionally, simulation parameters are determined manually by domain experts, based on a sample of cases of a process, or by observing the execution of the process during a certain period of time. However, the availability of event logs makes it possible to build more accurate simulation models by extracting the simulation parameters directly from an event log. The question of how to use event logs for process simulation is discussed in the entry on *Data-Driven Process Simulation*.

Business Process Model Analytics

Business process analytics is not confined to the analysis of event logs. It also encompasses techniques for analyzing collections of process models, irrespective of the availability of data about the execution of a process (Beheshti et al. 2016). We call the latter family of techniques *business process model analytics* techniques (cf., right-hand side of Fig. 2).

The entries on *Business process model matching* and *Business process querying* deal with two families of business process model analytics techniques. The first of these entries deals with the problem of comparing two or more process models in order to characterize their commonalities (or similarities) and their differences. This is a basic operation that allows us, for example, to merge multiple process models into a single one (e.g., to consolidate multiple variants of a process). It also allows us to find process models in a repository that are similar to a given one, which is also known as similarity search. However, business process querying provides a much broader view on how to manage process models. That includes languages to define queries related to particular aspects and properties of processes, along with efficient evaluation algorithms for such queries. As such, business process

querying provides concepts and techniques to make effective use of large collections of process models.

Definitions

Business process deviance mining refers to the problem of (automatically) detecting and explaining deviant executions of a business process based on the historical data stored in a given *Business Process Event Log* (called hereinafter *event log* for the sake of conciseness). In this context, a deviant execution (or “deviance”) is one that deviates from the normal/desirable behavior of the process in terms of performed activities, performance measures, outcomes, or security/compliance aspects.

Usually, the given event log is regarded as a collection of process *traces*, encoding each the history of a single process instance, and the

task amounts to spotting and analyzing the traces that likely represent deviant process (execution) instances.

In principle, this specific process mining task can help recognize, understand, and possibly prevent/reduce the occurrence of undesired behaviors.

Overview

Historically, in a business process mining/intelligence context, the term “deviance mining” was first used in Nguyen et al. (2014). Since then increasing attention has been given to this research topic, owing to two main reasons: (i) deviances may yield severe damages to the organization, e.g., in terms of monetary costs, missed opportunities, or reputation loss; (ii) process logs may be very large and difficult to analyze with traditional auditing approaches, so that automated techniques are needed to discover deviances and/or actionable deviance patterns.

Abstracting from the common idea of exploiting event log data, approaches developed in this field look quite variegated. Indeed, in addition to possibly resorting to different data mining techniques, they may also differ in two fundamental aspects: the analysis *task* and the kinds of *available information*.

Two main deviance mining tasks (often carried out together) have been pursued in the literature: deviance *explanation* and deviance *detection*. The former is devoted to “explain the reasons why a business process deviates from its normal or expected execution” (Nguyen et al. 2014, 2016). In the latter, it must be decided whether a given process instance (a.k.a. *case*) is deviant or not. This task can be accomplished in two fashions: (i) *run-time* detection, each process instance must be analyzed as it unfolds, based on its “premortem” trace; and (ii) *ex post* detection, only “postmortem” traces (i.e., just one fully grown trace for each finished process instance) must be analyzed to possibly discover deviances.

As to the second aspect (namely, available information), two deviance mining settings can be considered, which differ for the presence of auxiliary information, in addition to the given log traces:

- *Supervised*: All the traces are annotated with some deviance label/score, which allows to regard them as examples for learning a deviance detector/classifier or to extract deviance patterns.
- *Unsupervised*: No a priori deviance-oriented information is given for the traces, so that an unsupervised deviance mining method needs to be devised, based on the assumption that all/most deviances look anomalous with respect to the mainstream process behavior.

The rest of this chapter focuses on **ex post** deviance mining approaches. In fact, the exploitation of supervised learning methods to detect deviances at run-time has been considered in the related field of *predictive business process monitoring*.

More specifically, the two following sections discuss supervised and unsupervised deviance mining approaches, respectively. The last section provides some concluding remarks and draws a few directions for future research in this field. All the approaches discussed are summarized in Table 1.

Supervised Deviance Mining

The great majority of supervised deviance mining approaches assume that each log trace is associated with a binary class label telling whether the trace was deemed as deviant or not and try to induce a deviance-oriented classification model for discriminating between these two classes (i.e., deviant vs. normal traces). These approaches are named *classification-based* and described in section “[Classification-Based Deviance Mining](#)”. A few non-classification-based approaches to the discovery of deviance-explanation patterns, from deviance-annotated traces, are then presented in

section “[Other Supervised Deviance Explanation Approaches](#)”.

Classification-Based Deviance Mining

Based on a given collection of example traces, labeled each as either “deviant” or “normal,” these approaches try to induce a deviance-oriented classification model, capable to *detect* whether any new (unlabeled) trace is deviant or not. Moreover, if the model has (or can be easily turned into) a human readable form (e.g., classification rules), it can be used to *explain* the given deviances. In fact, most classification-based approaches tried to pursue both goals (i.e., detection and explanation), by inducing rule/tree-based classifiers.

Three main issues make the induction of a deviance-oriented classification model challenging: (i) process traces are complex sequential data that must be brought to some suitable abstraction level, in order to possibly capture significant discriminative patterns; (ii) obtaining a sufficiently informative training set is difficult, since manually labeling the traces is often difficult/costly and most log traces remain *unlabeled*; and (iii) as in many scenarios, deviant behaviors occur more rarely than normal ones; the training set is often *imbalanced* ([Japkowicz and Stephen 2002](#)).

To cope with the first issue, and reuse standard classifier-induction methods, most approaches adopt a two-phase mining scheme: (1) *log encoding*, the example traces are turned into vectors/tuples in some suitable feature space; and (2) *classifier induction*, the transformed traces (equipped each with a class label) are then made to undergo a propositional classifier-induction algorithm.

In addition to possibly considering global case attributes, most of the encoding schemes adopted in the literature rely on extracting behavioral patterns from the traces and using these patterns as features. As a preliminary step, each event e of a trace is usually abstracted into the associated activity (i.e., the activity executed/referenced to in e), so that the trace is turned into an activity sequence.

The main kinds of patterns used in the literature are as follows ([Nguyen et al. 2016](#)):

- *Individual activities* (IA) (Suriadi et al. 2013): each activity a is regarded as a “singleton” pattern and turned into a numeric feature counting how frequently a occurs in the trace (this corresponds to using a “bag-of-activity” encoding).
- *Activity sets* (SET) (Swinnen et al. 2012): the patterns incorporate subsets of activities that frequently co-occur in the traces (regarded each as an event set, thus abstracting from the execution order).
- *Sequence patterns*: the patterns represent frequent/relevant sequences of activities. The following families of sequence patterns have been considered: *maximal repeats* (MR), *tandem repeats* (TR), *super maximal repeats* (SMR), *near super maximal repeats* (NSMR), the set-oriented (“alphabet”-like) versions of the former (i.e., AMR, ATR, etc.) (Bose and van der Aalst 2013), and (*closed unique*) *iterative patterns* (IP) (Lo et al. 2009) (possibly covering non-contiguous activity subsequences).

In Suriadi et al. (2013), an IA-based log encoding is used to train a decision tree for discriminating and explaining deviances defined as traces with excessively long durations. The discovered rules are then exploited to analyze how the presence of single or multiple activities impacted on deviant behaviors.

A semiautomatic deviation analysis method was proposed in Swinnen et al. (2012), which combines process mining and association rule mining methods, and addresses a scenario where the deviances are cases that deviate from the mainstream behavior, captured by a process model discovered with *automated process discovery* techniques. An association-based classifier is used to characterize deviant cases, based on a set-oriented representation of the traces (which keeps information on both activities and nonstructural case properties).

Bose and van der Aalst (2013) face the discovery of a binary classification model in a scenario where deviances correspond to fraudulent/faulty cases. The traces are encoded propositionally

using one among the following pattern types: TR, MR, SMR, NSMR, the respective *alphabet* versions of the former types, and IA patterns. For the sake of explanation, only association-based classifiers and decision trees are employed. To deal with unlabeled traces, the authors envisaged the possibility to label them automatically in a preprocessing step (with *one-class SVM* and nearest-neighbor methods).

Lo et al. (2009) focus on the case where the deviances are those traces affected by a failure, among those generated by a software process, and introduce the notion of *closed unique iterative patterns* (IPs), as encoding features. These patterns are extracted through an a priori-like scheme and then selected based on their discriminative power (according to *Fischer’s score* Duda et al. 1973). To mitigate the effect of imbalanced classes, a simple oversampling mechanism is exploited.

Nguyen et al. (2014, 2016) define a general scheme uniforming previous pattern-based deviance mining works, which consists of the following steps (to be precise, steps 1 and 3 are only considered in Nguyen et al. 2016): (1) oversampling (to deal with class imbalance), (2) pattern mining, (3) pattern selection (based on Fischer’s score), (4) pattern-based log encoding, and (5) classifier induction. As to the former three steps, the authors used one among the pattern types described above (namely, IA, SET, TR, MR, ATR, AMR, and IP) in isolation. In addition, a few heterogeneous encodings are explored in Nguyen et al. (2014), mixing IA patterns with one of the other *composite* patterns (i.e., SET, TR, MR, ATR, AMR, and IP). Three standard induction methods are used to implement the last step: the decision-tree learning algorithm J48, a nearest-neighbor procedure, and a neural-network classifier. Different instantiations of this scheme (obtained by varying the kind of patterns and the induction method) are tested in Nguyen et al. (2016) on several real datasets.

To assess the explanatory power of the models discovered, the authors evaluate the rulesets obtained by applying J48 to each of the pattern-based encodings. Rulesets discovered with composite pattern types (especially IP,

MRA, and SET) looked more interesting than IA-based ones. As to the capability to correctly classify new test traces, composite patterns do not seem to lead to substantial gain when the process analyzed is lowly structured and/or the deviance is defined in terms of case duration. Composite patterns conversely looked beneficial on the logs of structured processes, but there is no evidence for bestowing a pattern type as the winner.

In fact, the predictiveness of different pattern types may well depend on the application domain. In principle, even on the same dataset, a pattern type might be better at detecting a certain kind of deviance than another type and vice versa. On the other hand, even selecting the classifier-induction method is not that simple, if one relaxes the requirement that the classification model must be self-explaining. Indeed, higher-accuracy results can be achieved by using more powerful classifiers than those considered in the approaches described above. These observations explain the recent surge of multi-encoding hybrid methods, like those described next.

An ensemble-based deviance mining approach is proposed in Cuzzocrea et al. (2015, 2016b) that automatically discovers and combines different kinds of patterns (namely, the same as in Nguyen et al. 2014) and different classifier-induction algorithms. Specifically, different base classifiers are obtained by training different algorithms against different pattern-based encodings of the log. The discovered base classifiers are then combined through a (context-aware) stacking procedure. An oversampling mechanism is applied prior to pattern extraction, in order to deal with class imbalance.

The approach is parametric to the pattern types and learners employed and can be extended to incorporate other encoding/learning methods. In fact, a simplified version of this approach was combined in Cuzzocrea et al. (2016a) with a conceptual event clustering method (to automatically extract payload-aware event abstractions).

A simple semi-supervised learning scheme is used in Cuzzocrea et al. (2016b) to acquire some feedback from the analyst, on the classifications

made by the discovered model on new unlabeled traces, and eventually improve the model.

Other Supervised Deviance Explanation Approaches

Fani Sani et al. (2017) propose to extract explanations from labeled (deviant vs. normal) traces by applying classic subgroup discovery techniques (Atzmueller 2015), instead of rule-based classifier-induction methods, after encoding all the traces propositionally. As a result, a number of interesting logical patterns (namely, conjunctive propositional formulas) are obtained, identifying each a trace “subgroup” that looks unusual enough w.r.t. the entire log (in terms of class distribution).

Folino et al. (2017a) consider instead a setting where interesting self-explaining deviance scenarios are to be extracted from training traces associated with numerical deviance indicators (e.g., concerning performance/conformance/risk measures). The problem is stated as the discovery of a deviance-aware conceptual clustering, where each cluster needs to be defined via descriptive (not a priori known) classification rules – specifically, conjunctive formulas over (both structural and nonstructural) trace attributes and context factors.

Unsupervised Deviance Mining

Unsupervised deviance mining approaches can be divided in two main categories (Li and van der Aalst 2017), namely, *model-based* and *clustering/similarity-based*, which are discussed next in two separate subsections.

Model-Based Approaches

Since, in general, there may be no a priori process model that completely and precisely defines deviance/normality behaviors, model-based approaches rely on inducing mining such a model from the given traces and then classifying as deviant all those that do not comply enough with the model. These approaches are next described in separate paragraphs, according to the kind of behavioral model adopted.

Approaches using a workflow-oriented model

Most model-based approaches employ a control-flow model, combined with conformance checking techniques (van der Aalst et al. 2005). Earlier approaches (e.g., Bezerra et al. 2009) simply mined the model by directly applying traditional control-flow-oriented techniques developed in the related field of *automated process discovery*. However, as generally the log is not guaranteed to only contain normal behavior, the effectiveness of such an approach suffers from the presence of outliers. To better deal with outliers, one could think of applying methods for automatically filtering out infrequent behavior, like the one proposed in Conforti et al. (2017). In particular, in Conforti et al. (2017), first an automaton is induced from the log, in order to approximately model the process behavior, in terms of direct follow dependencies; infrequent transitions are then removed from the automaton; in a final replay of the traces, any behavior that cannot be mapped on the automaton is deemed as an outlying feature.

Bezerra and Wainer (2013) propose three ad hoc algorithms to detect deviant traces in a log L , named “threshold,” “iterative,” and “sampling” algorithm, respectively. All the algorithms rely on comparing each trace t with a model M_t induced from a subset of L (namely, $L - \{t\}$ in the threshold and iterative algorithms and a random sample of L in the sampling algorithm). The anomalousness of t is estimated by either checking if t is an instance of M_t or considering the changes needed to allow M_t to represent t . The last algorithm achieved the best results.

All the works above focused on control-flow aspects only while disregarding other perspectives (e.g., timestamps and resources/executors). Some efforts have been spent recently to detect anomalies pertaining such nonfunctional aspects.

In the two-phase multi-perspective approach of Böhmer and Rinderle-Ma (2016), a (“basic likelihood”) graph encoding the likelihood of a transition between two activities is first induced from the log, assuming that the latter only stores normal behaviors. This graph is then extended by inserting nodes representing resources and ab-

stracted timestamps (extracted from log events), to model the execution of each activity in a more refined way. The resulting graph G is used to assess whether a new trace t is anomalous or not, possibly at run-time. Precisely, the likelihood of t w.r.t. G is compared to the lowest one of the (presumed normal) traces in the training log: if the former is lower than the latter, the trace is marked as anomalous/deviant.

The work in Rogge-Solti and Kasneci (2014) is meant to recognize temporal anomalies concerning activity durations – precisely, cases where a group of interdependent activities shows an anomalous run-time. To detect such anomalies, a stochastic Petri net (Rogge-Solti et al. 2013) is exploited, which can capture statistical information for both decision points (modeled as *immediate transitions*) and the duration of activities (modeled as *timed transitions*). Any new trace is confronted to this model (in terms of log-likelihood) to decide whether it is deviant or not.

Approaches using non-workflow-oriented models

Anomalies concerning the sequence of activities in a trace are detected in Linn and Werth (2016) by reusing variable order Markov models: a sequence is anomalous if at least one activity of the sequence is predicted with a probability value lower than a certain threshold.

A one-class SVM strategy is exploited in Quan and Tian (2009), after converting the contents of the given log into vectorial data. This way, a hypersphere is determined for the training set, assuming that normal behaviors are much more frequent than deviant ones. Any (possibly unseen) data instance lying outside this hypersphere is eventually classified as deviant.

A multi-perspective approach has been proposed in Nolle et al. (2016), which hinges on the induction of an autoencoder-based neural network. The network is meant to play as a (black box) general-enough behavioral model for the log, trained to reproduce each trace step by step. If an input trace and the corresponding reproduced version are not similar enough (w.r.t. a manually defined threshold), the former is classified as deviant. The capacity of the auto-encoding

layers is kept limited, in order to make the network robust to both outliers and noise.

Similarity/Clustering-Based Approaches

These approaches rely on the assumption that normal traces occur in dense neighborhoods or in big enough clusters, rather than on using behavioral models (for normal/deviant traces). Consequently, a trace that is not similar enough to a consistent number of other traces is deemed as deviant. This requires some suitable similarity/distance/density function and/or clustering algorithm to be defined for the traces – see the *Trace Clustering* entry for details on this topic.

Similarity-based approaches In general, kNN-based methods (where NN stands for nearest neighbor) detect outliers by comparing each object with its neighbors, based on a distance measure. In Hsu et al. (2017) the distance measure is defined in terms of activity-level durations and contextual information. More specifically, contextual information is represented in a fuzzy way, and associated membership functions are used to adjust activity-level durations. Distances are then calculated using the differences between adjusted durations, and a kNN scheme is eventually used to identify anomalous process instances.

A local outlier factor (LOF) method is adopted instead in Kang et al. (2012) to spot process instances with abnormal terminations. Notably, the method can be applied to future enactments of the process.

A profile-based deviation detection approach is proposed in Li and van der Aalst (2017), which relies on deeming as deviant any case that is not similar enough to a set CS of mainstream cases in the log. Specifically, a preliminary version of CS is first sampled according to a (dynamically modified) “norm” function, biased toward “more normal” cases. Then, the similarity between each log case and CS is computed, by using some suitably defined “profile” function – in principle, this function can be defined as to capture different perspectives, but the authors only show the application of two alternative control-flow-oriented profile functions. As a result, the log is

partitioned into two sets: normal cases (CN) and deviating cases (CD). Then, the norm function is adjusted as to increase (resp., decrease) the likelihood that normal (resp., deviating) cases are sampled. These two steps (i.e., sampling and profile-based classification) can be iterated, in order to improve the partitioning scheme, before eventually returning the deviant cases.

Clustering-based approaches As noticed in Li and van der Aalst (2017), model-based approaches (especially those hinging on control-flow models) work well on regular and structured processes but have problems in dealing with less structured ones exhibiting a variety of heterogenous behaviors.

By contrast, clustering-based anomaly/outlier detection approaches assume that normal instances tend to form large (and/or dense) enough clusters, and anomalous instances are those belonging to none of these clusters.

In Ghionna et al. (2008) and Folino et al. (2011), log traces are first clustered in a way that the clusters reflect normal process execution variants, so that a case is labeled as deviant if it belongs either to a very small cluster (w.r.t. a given cardinality threshold) or to no cluster at all. To capture normal execution schemes, a special kind of frequent structural (i.e., control-flow oriented) patterns is discovered; the traces are then clustered based on their correlations with these patterns – specifically, the clustering procedure follows a co-clustering scheme, focusing on the associations between traces and patterns, rather than using a pattern-based encoding of the traces. To possibly unveil links between the discovered structural clusters and nonstructural features of the process, a decision tree is discovered (using an ad hoc induction algorithm), which can be used to classify novel process instances at run-time. In principle, the clustering procedure could be performed by using other methods (cf. *Trace Clustering*). However, as noticed in Folino et al. (2011), one should avoid algorithms, like k-means, that are too sensitive to noise/outliers, and may hence fail to recognize adequately the groups of normal instances.

Hybrid solutions All the unsupervised approaches described so far focus on the detection of deviances, without paying attention to their explanation. Clearly, one could perform ex post explanation tasks by simply resorting to supervised classification techniques, after having annotated deviant and normal traces with different class labels, as done in Swinnen et al. (2012). For approaches returning a numerical anomaly score, one could also think of directly applying a rule-based regression method or a conceptual clustering method like that proposed in Folino et al. (2017a) (cf. section “[Other Supervised Deviance Explanation Approaches](#)”).

A hybrid discovery approach (both model-based and clustering-based) was defined in Folino et al. (2017b), which synergistically pursues both detection and explanation tasks. Given a set of traces, associated each with stepwise performance measurements, a new kind of performance-aware process model is searched for, consisting of the following components: (i) a list of easily interpretable classification rules defining distinguished “deviance” scenarios for the process that generated the traces; (ii) a state-based performance model for each discovered scenario and one for the “normal” executions belonging to no deviance scenario. The discovery problem is stated as that of optimizing the model of normal process instances while ensuring that all the discovered performance models are both general and readable enough. The approach mainly exploits a conceptual clustering procedure (addressed to greedily spot groups of traces that maximally deviate from the current normality model M_0), embedded in an greedy optimization scheme (which iteratively tries to improve the normality model M_0 , initially learnt from the entire log).

Discussion and Directions of Future Research

For the sake of summarization and of immediate comparison, some major features of the deviance

mining techniques discussed so far are reported in Table 1.

Notably, these techniques can turn precious in many application scenarios, such as those concerning the detection/analysis of software systems’ failures (Lo et al. 2009), frauds (Yang and Hwang 2006), network intrusions (Jalali and Baraani 2012), SLA violations, etc.

In general, in dynamical application scenarios, supervised techniques should be extended with incremental/continuous learning mechanisms, in order to deal with concept drift issues. In particular, in security-oriented scenarios where deviances correspond to attacks of ever-changing forms, the risk that the classifier induced with supervised techniques is obsolete/incomplete may be very high.

In such a situation, unsupervised deviance mining techniques could be a valuable solution, especially when the analyst is mainly interested in curbing the number of false negatives (i.e., undetected deviances). Among unsupervised deviance detection approaches, those based on clustering/similarity methods are likely to fit better lowly structured business processes (Li and van der Aalst 2017) than those relying on a (possibly extended) control-flow model.

The opportunity to use unlabeled data for classification-based deviance mining has been given little attention so far (Cuzzocrea et al. 2016b). Extending current approaches with semi-supervised learning methods (Wang and Zhou 2010), to exploit such information, is an interesting direction for future research. On the other hand, cost-sensitive learning methods (Elkan 2001) could help deal with imbalanced data more flexibly and allow to make the learner pay more attention to one kind of misclassification (i.e., either false deviances or missed deviances).

Finally, it seems valuable to extend outlier-explanation methods (Angiulli et al. 2009) to extract readable explanations for the deviances found with unsupervised deviance mining techniques.

Business Process Deviance Mining, Table 1 Summary of the approaches described here

Setting	Task	Strategy	Reference
Supervised (label-driven)	Detection, explanation	Classifier induction (IA patterns)	Suriadi et al. (2013)
	Detection, explanation	Classifier induction (SET patterns)	Swinnen et al. (2012)

Definitions

In the context of business process analytics, an *event log* is a collection of time-stamped event records produced by the execution of a business process. Each event record tells us something about the execution of a work item (a task) of the process. For example, an event record may tell us that a given task started or completed at a given point in time, or it tells us that a given message event, escalation event, or other relevant event has occurred in a given case in the process.

Overview

The execution of business processes is often supported by software systems. These systems can support isolated tasks, facilitate coordination, or record observations from sensors. All these systems have in common is that they store event data. These events bear valuable information that informs us about how a business process was executed and about its performance. However, such event data is often not directly available in a format that it can be used for business process analytics. For this reason, we typically have to create an event log from the event data that is stored in various systems.

An *event log* is a collection of time-stamped event records. Each event record tells us something about the execution of a work item (and hence a task) of the process (e.g., that a task has started or has been completed), or it tells us that a given message event, escalation event, or other relevant event has occurred in the context of a given case in the process. For example, an event record in an event log may capture the fact that Chuck has confirmed a given purchase order at a given point in time.

Figure 1 illustrates what data is typically stored in an event log. We can see that a single event has a unique event ID. Furthermore, it refers to one individual case, it has a timestamp, and it shows which resources executed which task. These may be participants (e.g., Chuck and Susi) or software systems (SYS1, SYS2, DMS). For most techniques discussed in this chapter, it

is a minimum requirement that for each event in the log, we have three attributes (i) in which case the event occurred (*case identifier*), (ii) which task the event refers to (herein called the *event class*), and (iii) when the event occurred (i.e., a *timestamp*). In practice, there may be other event attributes, such as the resource who performed a given task, the cost, or domain-specific data such as the loan amount in the case of a loan origination process.

Business process event logs such as the above one can be processed and analyzed using process mining tools (cf. entry on Business Process Analytics). These tools provide various approaches for visualizing event logs in order to understand their performance, in particularly, with respect to time-related performance measures.

In the rest of this entry, we discuss how event logs are usually represented (file formats), and we then discuss different approaches for visualizing event logs.

The XES Standard

The event log of Fig. 1 is captured as a list in a tabular format. Simple event logs such as this one are commonly represented as tables and stored in a comma-separated values (CSV) format. This representation is suitable when all the events in the log have the same set of attributes. However, in event logs where different events have different sets of attributes, a flat CSV file is a less suitable representation. For example, in an event log of a loan application process, some events may have customer-related attributes (e.g., age of the customer, income, etc.), while other events contain attributes about the loan application assessment (e.g., the credit risk score). If we represented this event log in a CSV file, we would have to use (null) values to denote the fact that some attributes are not relevant for a given event. Also, in CSV files, the types of the attributes are not explicitly represented, which can be error-prone, for example, when dealing with dates, spatial coordinates, etc.

A more versatile file format for storing and exchanging event logs is the *extensible*

event stream (XES) format (<http://www.xes-standard.org>) standardized by the *IEEE Task Force on Process Mining* and published as IEEE 1849 (Acampora et al. 2017) (<http://www.win.tue.nl/ieeetfpm>). The majority of process mining tools can handle event logs in XES. The structure of an XES file is based on a data model, partially depicted in Fig. 2. An XES file represents an event log. It contains multiple traces, and each trace can contain multiple events. All of them can contain different attributes. An attribute has to be either a string, date, int, float, or Boolean element as a key-value pair. Attributes have to refer to a global definition. There are two global elements in the XES file: one for defining trace attributes and the other for defining event attributes. Several classifiers can be defined in XES. A classifier maps one of more attributes of an event to a label that is used in the output of a process mining tool. In this way, for instance, events can be associated with tasks.

Figure 3 shows an extract of an XES log corresponding to the event log in Fig. 1. The first global element (scope = “trace”) in this log tells us that every trace element should have a child element called “concept:name.” This sub-element will be used to store the case identifier. In this example, there is one trace that has a value of 1 for this sub-element. At the level of individual events, there are three expected elements (i.e., “global” element with scope = “event”): “concept:name,” “time:timestamp,” and “resource.” The “concept:name” sub-element of an event will be used to store the name of the task to which the event refers. The “time:timestamp” and “resource” attributes give us the time of occurrence of the event and who performed it, respectively. The rest of the sample XES log represents one trace with two events. The first one refers to “check stock availability,” which was completed by SYS1 on the 30 July 2012 at 11:14. The second event captures “retrieve product from warehouse” conducted by Rick at 14:20.

The XES standard also supports an attribute “lifecycle:transition” that is meant to describe the transition of a task from one execution state to another. An extensive table of predefined transitions is included in the standard. The most prominent

Business Process Event Logs and Visualization, Fig. 1 Example of an event log for the order-to-cash process

transitions are “assign” to indicate that a task has been assigned to a resource; “start” to record that work on the task has started; “complete” signalling that a task is done; “ate_abort” to indicate that a task was canceled, closed, or aborted; and “pi_abort” to indicate that a whole process instance is aborted.

Challenges of Extracting Event Logs

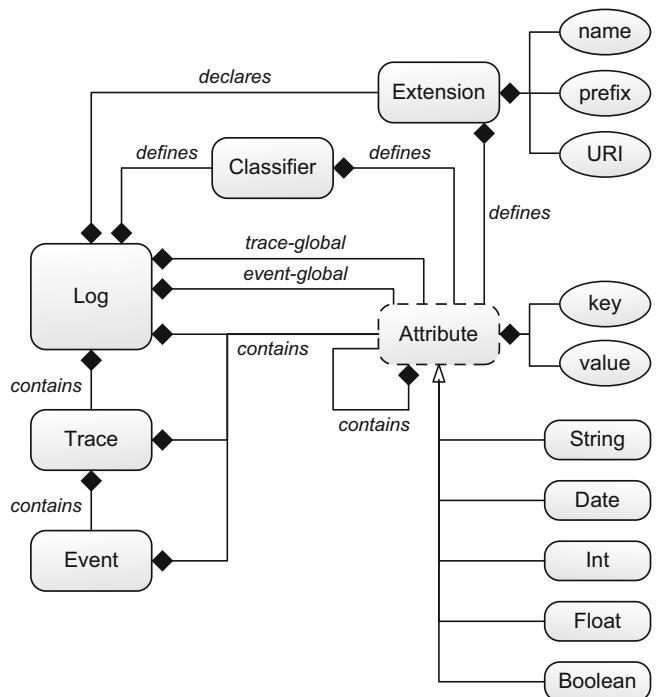

Event data that is available in tabular format as in Fig. 1 can be readily converted to XES. In many cases though, the data which is relevant for event logs is not directly accessible in the required for-

mat but has to be extracted from different sources and integrated. This extraction and integration effort is generally not trivial. A list of 27 potential issues is described in Suriadi et al. (2017). We focus here on four major challenges for log data extraction:

Correlation Challenge

This refers to the problem of identifying the case an event belongs to. Many enterprise systems do not have an explicit notion of process defined. Therefore, we have to investigate which attribute of process-related entities might serve as a case identifier. Often, it is possible to utilize entity identifiers such as order number, invoice number,

Business Process Event Logs and Visualization,
Fig. 2 Metamodel of the XES format

or shipment number. Approaches to infer missing case identifiers are presented in Bayomie et al. (2015) and Pourmirza et al. (2017).

Timestamping Challenge

The challenge to work properly with timestamps stems from the fact that many systems do not consider logging as a primary task. This means that logging is often delayed until the system has idle time or little load. Therefore, we might find sequential events with the same timestamp in the log. This problem is worsened when logs from different systems potentially operating in different time zones have to be integrated. Partially, such problems can be resolved with domain knowledge, for example, when events are known to always occur in a specific order. An approach to repair logs with incomplete or inaccurate timestamps is presented in Rogge-Solti et al. (2013). For estimating the exact timestamp, we can use knowledge about the typical order of tasks and their typical temporal distance.

Longevity Challenge

For long running processes (e.g., processes with cycle times in the order of weeks or months),

we might not yet have observed all cases that started during a recent time period (e.g., cases that started in the past 6 months) up to their completion. In other words, some cases might still be incomplete. Mixing these incomplete cases with completed cases can lead to a distorted picture of the process. For example, the cycle times or other performance measures calculated over incomplete cases should not be mixed with those of the completed ones, as they have different meaning. In order to avoid such distortions, we should consider the option of excluding incomplete cases from an event log. Also, we should ensure that the time period covered by an event log is significantly longer than the mean cycle time of the process so that the event log contains samples of both short-lived and long-lived cases.

Granularity Challenge

Typically, we are interested in conducting event log analysis on a conceptual level for which we have process models defined. In general, the granularity of event log recording is much finer such that each task of a process model might map to a set of events. For example, a task like “retrieve

```

product from warehouse” on the abstraction level of a process model maps to a series of events like “work item #1,211 assigned,” “work item #1,211 started,” “purchase order form opened,” “product retrieved,” and “work item #1,211 completed.” Often, fine-granular events may show up repeatedly in the logs, while on an abstract level, only a single task is executed. Therefore, it is difficult to define a precise mapping between the two levels of abstraction. The problem of abstracting from low-level event data to activities in the business process model is proposed in Baier et al. (2014) by annotating, matching, and clustering. Other related techniques aim at discovering repetitive patterns of low-level events such that every occurrence of a discovered pattern can be abstracted as one occurrence of a higher-level event (Mannhardt and Tax 2017).

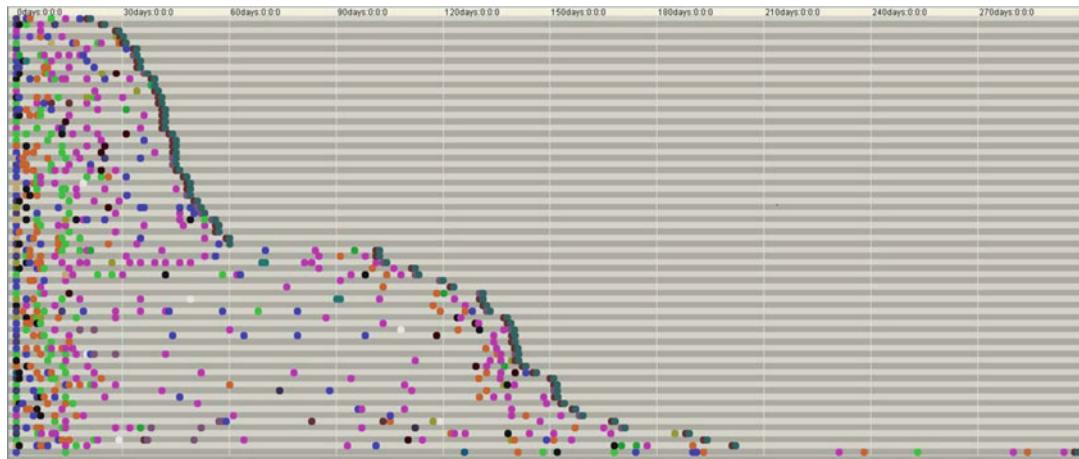

Once we have overcome the above data quality challenges, we are able to produce an event log consisting of *traces*, such that each trace contains the perfectly ordered sequence of events observed for a given case, each event refers to a task, and every task in the process is included in the event log. An event log with these prop-

erties can be rewritten in a simplified representation, called a *workflow log*. A workflow log is a set of distinct traces, such that each trace consists of a sequence of symbols and each symbol represents an execution of a task. For example, given a set of tasks represented by symbols $\{a, b, c, d\}$, a possible workflow log is $\{\langle a, b, c, d \rangle, \langle a, c, b, d \rangle, \langle a, c, d \rangle\}$.

Event Log Visualizations

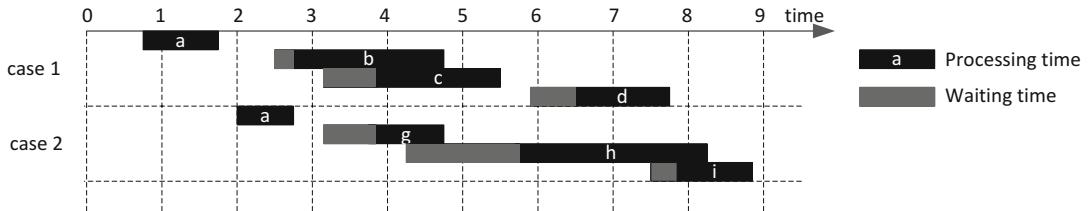

Visualization techniques for business process event logs can be broadly classified into two categories: *time-based* and *graph-based techniques*. Time-based techniques rely on charts where 1 on the axis (typically the horizontal axis) is used to denote the time. The vertical axis is then divided into stripes, each of which is used to represent the events observed in one trace of the log.

Graph-based techniques on the other hand show relations between tasks, resources, or possibly other objects involved in the process. Each node in the graph represents a task, resource,

B

Business Process Event Logs and Visualization, Fig. 4 Dotted chart of an event log

Business Process Event Logs and Visualization, Fig. 5 Example of timeline chart

or other object, while the edges represent control-flow relations (e.g., precedence).

Below are two representative time-based techniques, namely, dotted and timeline charts, and two graph-based techniques: dependency graphs and handoff graphs.

Dotted Charts

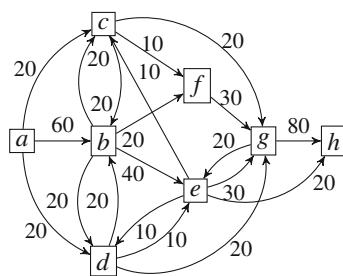

In a dotted chart (Song and van der Aalst 2007), each event is plotted on a two-dimensional canvas with the first axis representing its occurrence in time and the second axis as its association with a classifier like a case ID. There are different options to organize the first axis. Time can be represented either *relative*, such that the first event is counted as zero or *absolute* such that later cases with a later start event are further right in comparison to cases that started earlier. The second axis can be sorted according to different criteria. For instance, cases can be shown according to their historical order or their overall cycle time.

Figure 4 shows the dotted chart of the event log of a healthcare process. The events are plotted according to their relative time and sorted according to their overall cycle time. It can be seen that there is a considerable variation in terms of cycle time. Furthermore, the chart suggests that there might be three distinct classes of cases: those that take no more than 60 days, those taking 60 to 210 days, and a small class of cases taking longer than 210 days.

Timeline Charts

If the event log contains timestamps capturing both the start and the end of each task, we can plot tasks not as dots but as bars as shown in Fig. 5. This type of a visualization is called a *timeline chart*. A timeline chart shows the waiting time (from activation until starting) and the processing time (from starting until completion) for each task.

10 × a,b,c,g,e,h
 10 × a,b,c,f,g,h
 10 × a,b,d,g,e,h
 10 × a,b,d,e,g,h
 10 × a,b,e,c,g,h
 10 × a,b,e,d,g,h
 10 × a,c,b,e,g,h
 10 × a,c,b,f,g,h
 10 × a,d,b,e,g,h
 10 × a,d,b,f,g,h

Business Process Event Logs and Visualization, Fig. 6
Event log and corresponding dependency graph

Dependency Graphs

A *dependency graph* (also known as a *directly follows graph*) is a graph where each node represents one event class (i.e., a task) and each arc represents a “directly follows” relation. An arc exists between two event classes A and B if there is at least one trace in which B comes immediately after A. The arcs in a dependency graph may be annotated with an integer indicating the number of times that B directly follows A (hereby called the *absolute frequency*). In some process mining tools, it is also possible to annotate each arc with a temporal delay, e.g., the average time between an occurrence of task A and an occurrence of task B, among all occurrences of B that immediately follow an occurrence of A. This temporal delay gives an indication of the waiting time between a given pair of tasks in the process.

For example, Fig. 6 shows an event log (left) and a corresponding dependency graph (right). The event log consists of 10 distinct traces, each of which occurs 10 times in the log (hence 100 traces in total). We observe that the arc from task *a* to task *c* has an absolute frequency of 20. This is because the event log has two distinct traces where *c* occurs immediately before *a* and each of these distinct traces occurs 10 times.

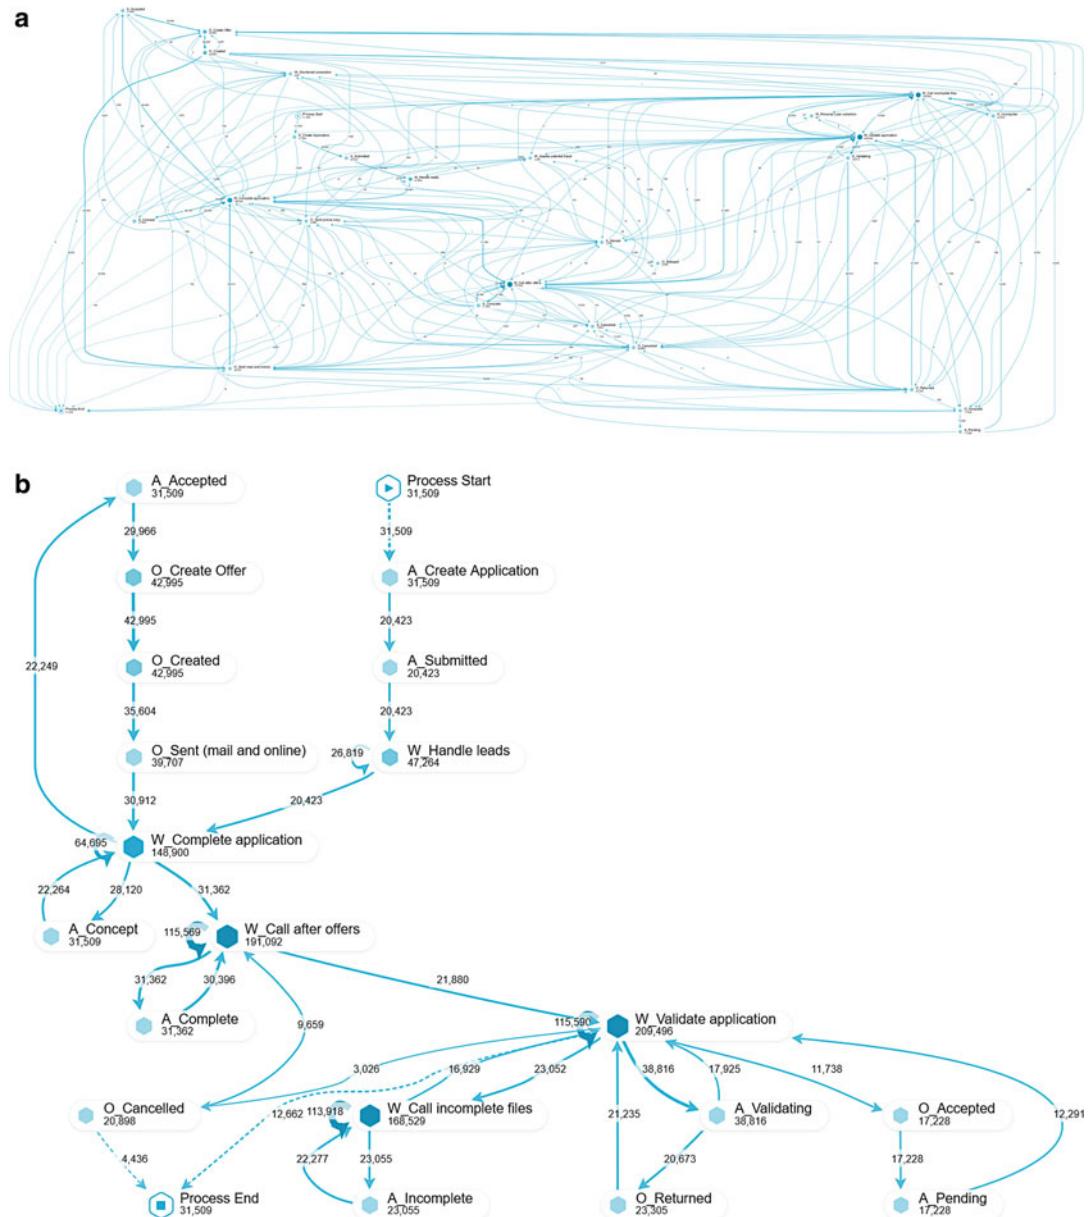

Owing to their simplicity, dependency graphs are supported by most commercial process mining tools. They are also supported by the *Fuzzy Miner* plugin of ProM (<http://www.promtools.org>) and by Apromore (<http://apromore.org>), two open-source process mining tool sets. All these tools provide visual cues to enhance the read-

ability of dependency graphs. For example, the color and the thickness of the arcs may be used to encode how frequently a task in a pair directly follows the other (e.g., a thick and dark-blue arc may represent a frequent directly follows relation relative to a thin, light-blue arc). These tools also offer visual zoom-in operations that allow users to explore specific parts of a dependency graph in detail.

Besides their simplicity, one of the most appealing features of dependency graphs is that they are amenable to *abstraction*. In this context, abstraction refers to removing a subset of the nodes or arcs in a dependency graph in order to obtain a smaller dependency graph of a given event log. For example, process mining tools allow us to remove the most infrequent nodes or arcs from a dependency graph in order to obtain a simpler map that is easier to understand. Abstraction is an indispensable feature when we want to explore a real-life event log, as illustrated below.

To illustrate how abstraction works, we consider the event log of the Business Process Intelligence Challenge 2017 (Available at: <https://doi.org/10.4121/uuid:5f3067df-f10b-45da-b98b-86ae4c7a310b>). This is an event log of a loan origination process at a Dutch financial institution. The event log covers the application-to-approval and the offer-to-acceptance subprocesses of a loan origination process, meaning that it starts when a loan application is submitted by a customer and it ends when the customer accepts (or refuses) the corresponding loan offer. The full dependency graph produced by the Celonis web-based tool on this event log is shown in Fig. 7a. This map is too detailed to be understandable by a user. Even if we visually zoom in to inspect specific parts of this map, it will be very difficult to understand what is going on in this process. For this reason, process mining tools can abstract away the map by retaining only the most frequent arcs. Figure 7b shows the filtered map produced by Celonis when setting the task abstraction slider to 98% and the arc abstraction slider to 90%.

While abstraction is a useful mechanism when visualizing large event logs, it is not sufficient to handle the full complexity of real-life event

Business Process Event Logs and Visualization, Fig. 7 Example of a full dependency graph and an abstracted version thereof. (a) Full dependency graph. (b) Filtered dependency graph

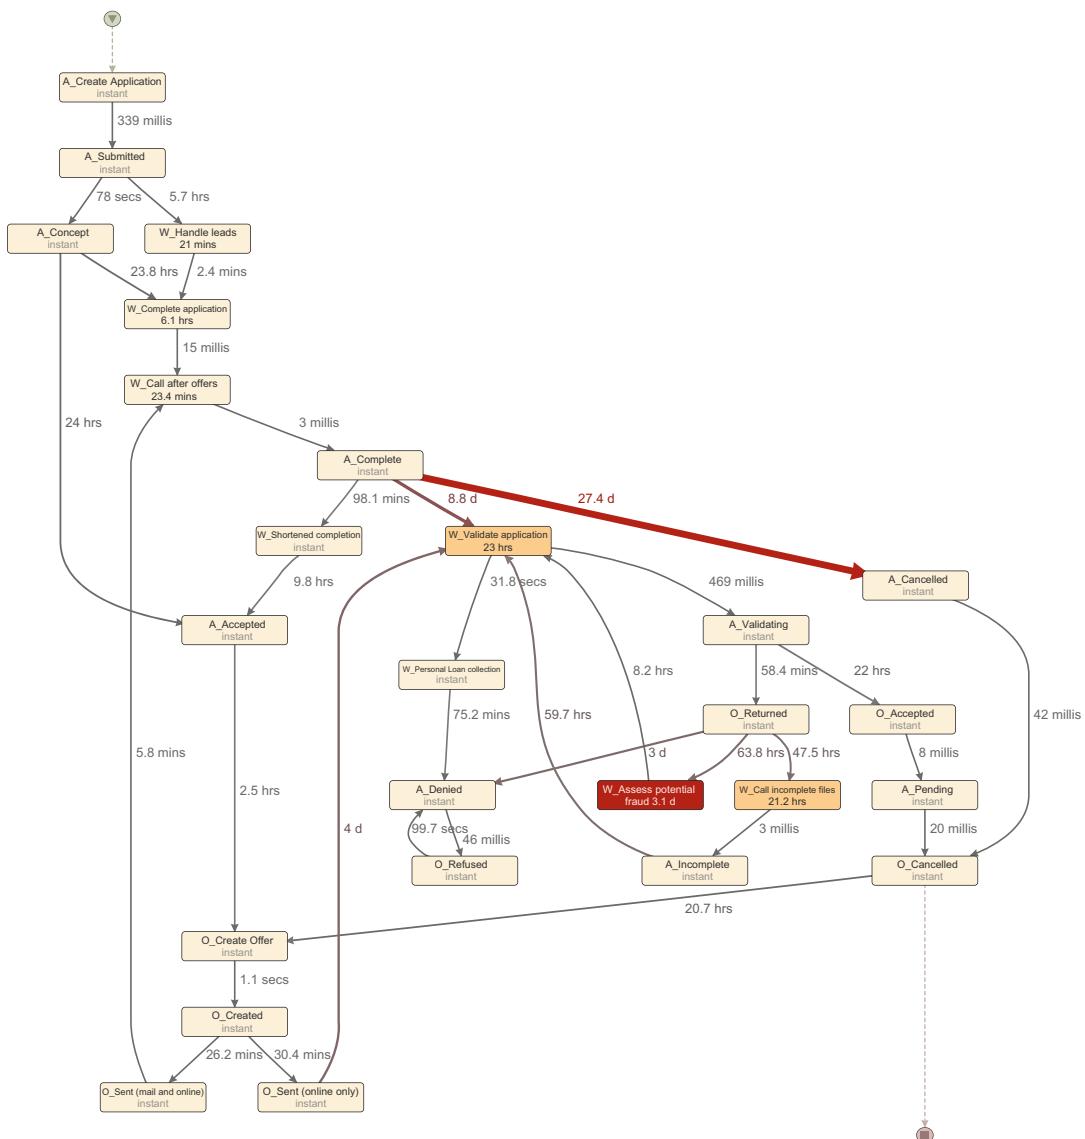

logs. Accordingly, process mining tools also offer a second type of simplification operation called *event log filtering*. Filtering an event log means removing a subset of the traces, events, or pairs of events in order to obtain a simpler log. Note that filtering and abstraction have different inputs and outputs. Whereas filtering transforms an event log

into a smaller log, abstraction only affects the dependency graph, not the log.

Dependency graphs can also be used to visualize temporal delays (e.g., waiting times or processing times) via color-coding or thickness-coding. Concretely, arcs in the dependency graph may be color-coded by the corresponding tem-

poral delay between the source event and the target event of the arc. This visualization allows us to identify the longest waiting times in the process – also known as *bottlenecks*. Meanwhile, the nodes in a dependency graph can be color-coded with the processing times of each task. The latter requires that each task captured in the log has both a start timestamp and an end timestamp so that the processing time can be computed.

Figure 8 shows the *performance view* produced by Disco when applied to the BPI Challenge 2017 log. The most infrequent arcs have been removed to avoid clutter. The task and the arc with the highest times are indicated in red. If we visually zoom in, in the tool, we are able to see that the task with the slowest processing time is “W_Assess Potential Fraud” (3.1 days) and the highest inter-event time is the one between “A_Complete” and “A_Cancelled” (27.4 days).

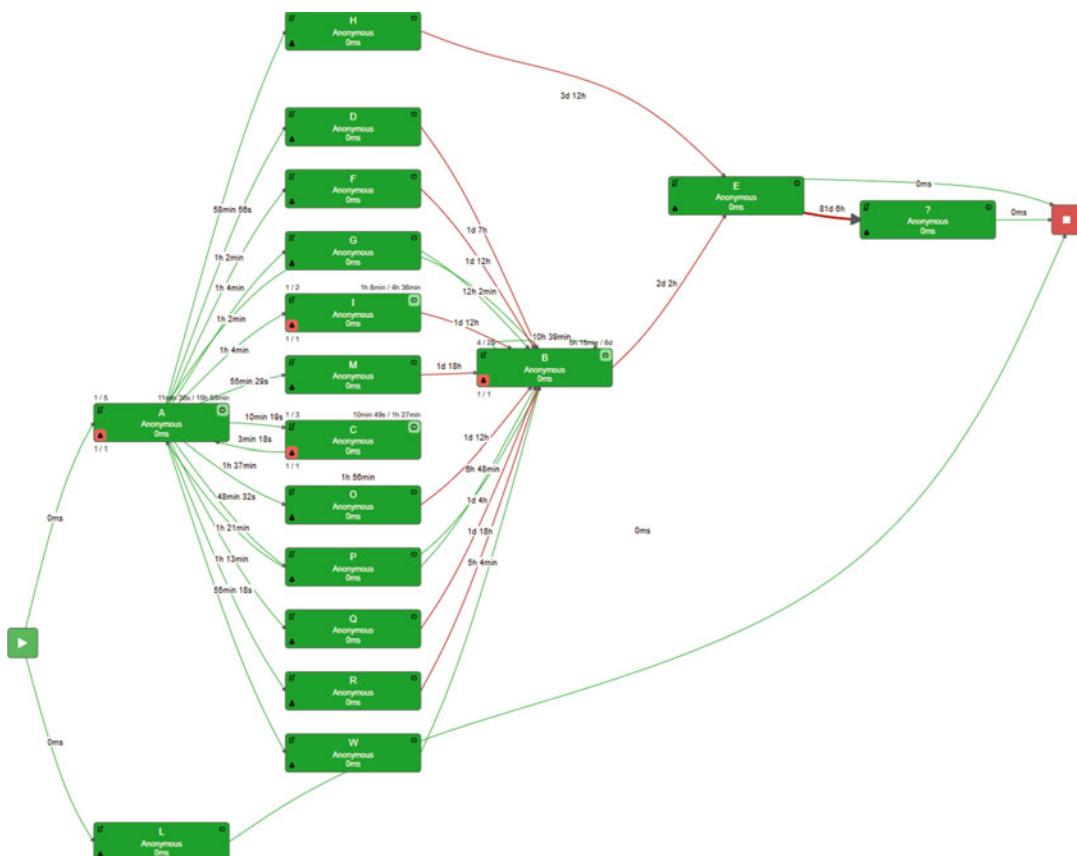

Business Process Event Logs and Visualization, Fig. 8 Performance view of the BPI Challenge 2017 event log in Disco

Handoff Graphs

Dependency graphs can also be used to analyze delays resulting from handoffs between process participants (van der Aalst and Song 2004; Pentland et al. 2017). When discussing the structure of event logs, we pointed out that an event record in an event log should have at least a case identifier, a timestamp, and an event class (i.e., a reference to a task in the process), but there can be other event attributes, too, like, for example, the *resource* (process participant) who performed the task in question. The event class is the attribute that is displayed in each node of a dependency graph. When importing an event log into a tool that supports dependency graphs, the tool gives an option to specify which event attribute should be used as the event class. We can set the tool so as to use the *resource* attribute as the event class. If we do so, the resulting dependency

graph will contain one node per resource (process participant), and there will be one arc between nodes A and B if resource B has performed a task immediately after resource A in at least one trace in the log. This map captures all the handoffs that have occurred in the process. We can then apply filters and abstraction operations to this map of handoffs. The handoff map can also be color-coded, with the colors corresponding either to the frequency of each handoff or the waiting time between handoffs.

Figure 9 shows a fragment of the *average duration view* produced by the myInvenio process mining tool when applied to an event log of a process for treating sepsis cases at a Dutch hospital (Log available at: <https://doi.org/10.4121/uuid:915d2bfb-7e84-49ad-a286-dc35f063a460>). The handoff map shows that when a case starts (rightmost node), it is first handled

Business Process Event Logs and Visualization, Fig. 9 Handoff map

by resource A. After a few minutes or about an hour, resource A hands off to resource H or to resources D, F, ..., R. Resource H hands off to E, while , F, ..., R hand over to B who later hands off to E. Handoffs that take longer than one day are shown in red.

Pentland et al. 2017 propose an extension of dependency graphs (namely, *narrative networks*) for visualizing handoffs and identifying routines. The main idea is to show not only handoffs between process participants but also handoffs between systems (applications), for example, situations where the a process participant needs to use multiple systems to perform a task.

Other Log Visualization Techniques

Besides dotted and timeline charts, other examples of time-based log visualization techniques include *time series charts* and *cumulative flow diagrams*, which stem from the Kanban process management tradition (<https://kanbantool.com/kanban-library/introduction>). A time series chart is a line chart that displays the evolution of a quantitative variable over time. In the context of event logs, this variable is typically the number of ongoing cases – the so-called work-in-process (WIP). A point in the line represents the WIP at a time point. A cumulative flow diagram (CFD), on the other hand, shows the number of cases that have reached a given stage in the process (including cases that have reached the “completed” stage). In order to draw a CFD, we need to be able to decompose the tasks of the process into stages (Nguyen et al. 2016). Note that time series charts and cumulative flow charts are aggregate log visualization techniques: they do not display each event in the process, but rather they display how a quantity (e.g., WIP) evolves over time. In contrast, dotted and timeline charts display each event individually. Another aggregate log visualization technique, namely, rhythm-eyes views, uses a circular representation of time (Gulden 2016). Instead of time flowing linearly from left to right, it flows clockwise along a ring. Each segment of the ring denotes the mean cycle time of a given activity of the process.

As discussed above, dependency graphs can be simplified by means of abstraction operations,

which retain only the most frequent nodes and edges. Two alternative techniques for simplifying process maps are *node clustering* and *graph reduction*. In node clustering, a cluster of nodes is replaced by a single one. This approach is implemented in the Fuzzy Miner (Günther and van der Aalst 2007). In graph reduction techniques, the user designates a set of important nodes, and other nodes are then abstracted in such a way that the control-flow relations between the designated nodes remains visible (Daenen 2017). The groups of abstracted nodes are then replaced by special (thick) edges.

Business Process Model Matching

Definitions

The comparison and integration of different representations of reality, which is often referred to as *matching*, is a long-standing problem in computer science. Matching techniques have been developed for various representations, including database schemas (Rahm and Bernstein 2001; Gal 2011; Sagi and Gal 2013), ontologies (Noy 2004; Shvaiko and Euzenat 2013; Euzenat et al. 2007), and, more recently, also business process models (Dijkman et al. 2009; Weidlich et al. 2010; Leopold et al. 2012). In the context of process models, matching techniques aim to automatically identify activity correspondences that represent similar behavior in both models.

Overview

To get an understanding of the challenges that are associated with business process model matching, consider Fig. 1. It shows two recruiting processes from two different companies. The gray shades denote the activity correspondences for the two models. For example, the activity *Evaluate* from company B corresponds to the activities *Check grades* and *Examine employment references* from company A. The correspondences show that the two models differ with respect to the terms they use (e.g., *eligibility assessment* versus *aptitude test*) as well as their level of detail (e.g., *Evaluate* is described in more detail in the model from company A). Given such differences, the proper recognition of the correspondences

Business Process Model Matching, Fig. 1 Two process models and possible correspondences

between two process models can become a complex and challenging task (Mendling et al. 2015). The main difference to other matching problems, such as schema and ontology matching, is the temporal dimension of process models. Two activities with the exact same label may refer to different streams of action in reality if they occur at different moments of time in the process.

Key Research Findings

The research in the area of business process model matching has focused on two main aspects: defining automatic techniques for process model matching and developing appropriate mechanisms to evaluate these techniques. This section discusses the key findings from both streams.

Process Model Matching Techniques

Current process model matching techniques exploit a variety of techniques to automatically identify activity correspondences. Most of them, however, leverage either the activity labels or the model structure of process models.

Leveraging Activity Labels

Activity labels capture the main semantics of process models. Hence, they are also the primary source of process model matching techniques for identifying activity correspondences. However, the way in which the similarity between two activity labels is quantified differs considerably. There are two types of measures that can be employed: syntactic measures and semantic measures.

Syntactic measures relate to simple string comparisons and do not take the meaning or context of words into account. The most prominently employed syntactic measure is the *Levenshtein distance*. Given two labels l_1 and l_2 , the Levenshtein distance counts the number of edit operations (i.e., insertions, deletions, and substitutions) that are required to transform l_1 into l_2 . Although the Levenshtein distance is rather simplistic, it is used by a variety of matching techniques (cf. Dijkman et al. 2009; Liu et al. 2014; Belhoul et al. 2012). Many matching techniques, however, also rely on plain word comparisons (cf. Fengel 2014; Antunes et al. 2015; Cayoglu et al. 2013). Very common measures include the *Jaccard* and the *Dice*

coefficient, which both compute the similarity between two activity labels based on the number of shared words. An alternative approach based on word comparisons is the *cosine similarity* (cf. Weidlich et al. 2010; Makni et al. 2015). To compute the cosine similarity, activity labels are transformed into vectors, typically by weighing words with their frequency of occurrence. The cosine similarity is then derived from the cosine of the angle between the two activity vectors.

Semantic measures take the meaning of words into account. A very common strategy to do so is the identification of synonyms using the lexical database WordNet (Miller 1995). Typically, matching techniques check for synonyms as part of a prepossessing step and then apply other, often also syntactic, similarity measures (cf. Antunes et al. 2015). The most prominent semantic measure is the Lin similarity (Lin 1998). The Lin similarity is a method to compute the semantic relatedness of words based on their information content according to the WordNet taxonomy. To use Lin for measuring the similarity between two activities (which mostly contain more than a single word), matching techniques typically combine the Lin similarity with the bag-of-words model (see e.g., Klinkmüller et al. 2013; Leopold et al. 2012). The bag-of-words model transforms an activity into a multiset of words that ignores grammar and word order. The Lin similarity can then be obtained by computing the average of the word pairs from the two bags with the highest Lin score. Other measures based on the WordNet dictionary include the ones proposed by Wu and Palmer (1994) and Lesk (1986). The former computes the similarity between two words by considering the path length between the words in the WordNet taxonomy. The latter compares the WordNet dictionary definitions of the two words. Some approaches also directly check for hypernym relationships (i.e., more common words). For instance, Hake et al. (described in Antunes et al. 2015) consider *car* and *vehicle* as identical words because *vehicle* is a hypernym of *car*.

Leveraging Model Structure

Despite of the predominant role of activity labels for identifying correspondences, many pro-

cess model matching techniques also exploit the model structure. Typically, structural features of the model are used to guide the matching process based on the computed activities' similarities or to rule out unlikely constellations.

One of the most prominent strategies to take the model structure into account is the *graph edit distance* (cf. Dijkman et al. 2009; Gater et al. 2010). It applies the notion of string edit distance as used by the Levenshtein distance to graphs. In the context of process model matching, the graph edit distance is used to obtain a set of correspondences that is as similar as possible from a structural perspective. An alternative way of taking the structure in account is to leverage the notion of single-entry-single-exit fragments. As described by Vanhatalo et al. (2009), a process model can be decomposed into a hierarchy of fragments with a single entry and a single exit node. The resulting fragment hierarchy is useful for both identifying candidates for one-to-many relationships as well as identifying correspondences that have similar depth in the model. Notable examples exploiting the fragment hierarchy include the ICoP Framework from Weidlich et al. (2010) and the matching techniques from Gerth et al. (2010) and Branco et al. (2012).

Some approaches also use the structure of a process model to derive constraints. For instance, Leopold et al. (2012) derive behavioral constraints from the model structure that must not be violated in the final set of correspondences. That means if two activities a_1 and a_2 from model A are in a strict order relation and two activities b_1 and b_2 from model B are in a strict order relation as well, the final set of correspondences cannot include a correspondence between a_1 and b_2 and between a_2 and b_1 . A similar notion is used in the matching approach from Meilicke et al. (2017).

Alternative Techniques

Most existing process model matching techniques combine the algorithms discussed above in a specific way. Some techniques, such as the ICoP framework (Weidlich et al. 2010), also allow the user to configure the matching technique by selecting the desired

algorithms. However, there are also techniques that consider alternative strategies to identify activity correspondences. More specifically, there are techniques building on user feedback, prediction, and matching technique ensembles.

Klinkmüller et al. (2014) proposed a semiautomated technique that incorporates *user feedback* to improve the matching performance. The main idea of their approach is to present the automatically computed correspondences to the user, let the user correct incorrect correspondences, and then, based on the feedback, adapt the matching algorithm. Weidlich et al. (2013) proposed a technique that aims at *predicting* the performance of a matching technique based on the similarity values it produces for a given matching problem. In this way, the approach can help to select the most suitable matching technique for the problem at hand. Meilicke et al. (2017) proposed an *ensemble-based* technique that runs a set of available matching systems and then selects the best correspondences based on a voting scheme and a number of behavioral constraints. This strategy has the advantage of combining the strengths of multiple matching techniques.

While all these techniques are able to improve the matching results in certain settings, they also come with their own limitations. Incorporating user feedback as proposed by Klinkmüller et al. (2014) means that the results can no longer be obtained in a fully automated fashion. The process model prediction technique from Weidlich et al. (2013) may simply conclude that available techniques are not suitable for computing correspondences. In the same way, the ensemble-matching technique from Meilicke et al. (2017) relies on the availability of matching techniques that can actually identify the complex relationships that may exist between two models.

Approaches for Evaluating Process Model Matching Techniques

The evaluation of process model matching techniques is a complex task. To illustrate this, reconsider the correspondences from Fig. 1. While

one can argue that the activity *Invite for eligibility assessment* from Company A corresponds to the activity *Ask to attend aptitude test* because both activities have a similar goal, one can also bring up arguments against it. We could, for instance, argue that the *eligibility assessment* in the process of Company A is optional, while the *aptitude test* in the process of Company B is mandatory. What is more, an *aptitude test* appears to be way more specific than an *eligibility assessment*. This example illustrates that correspondences might be actually disputable and that clearly defining which correspondences are correct can represent a complex and challenging task. This is, for instance, illustrated by the gold standards of the Process Model Matching Contests 2013 and 2015. The organizers of the contests found that there was not a single model pair for which two independent annotators fully agreed on all correspondences (Cayoglu et al. 2013; Antunes et al. 2015).

The standard procedure for evaluating process model matching techniques builds on a *binary gold standard*. Such a gold standard is created by humans and clearly defines which correspondences are correct. By comparing the correspondences produced by the matching technique and the correspondences from the gold standard, it is then possible to compute the well-established metrics precision, recall, and F measure. At this point, the evaluation based on a binary gold standard is widely established and was also used by two Process Model Matching Contests. The advantage of using a binary gold standard is that the notion of precision, recall, and F measure is well-known and easy to understand. However, it also raises the question why the performance of process model matching techniques is determined by referring to a single correct solution when not even human annotators can agree what this correct solution is. A binary gold standard implies that any correspondence that is not part of the gold standard is incorrect and, thus, negatively affects the above mentioned metrics.

Recognizing the limitations of a binary gold standard, Kuss et al. (2016) recently introduced

the notion of a *non-binary gold standard*. The overall rationale of a non-binary gold standard is to take the individual opinion of several people independently into account. Therefore, several people are asked to create a binary gold standard based on their own opinion. By considering each individual opinion as a vote for a given correspondence, it is then possible to compute a support value for each correspondence between 0.0 and 1.0. Based on these support values, Kuss et al. (2016) proposed non-binary notions of the metrics precision, recall, and F measure that take the uncertainty of correspondences into account. While the resulting metrics are not as intuitive to interpret as their binary counterparts, they can be considered as a fairer assessment of quality of a matching technique. Following that argument, the results from non-binary evaluation were recently presented next to the results of the binary evaluation in the Process Model Matching Track of the Ontology Alignment Evaluation Initiative 2016 (Achichi et al. 2016).

Examples of Application

The activity correspondences produced by process model matching techniques often serve as input for advanced process model analysis techniques. Examples include the analysis of model differences (Küster et al. 2006), the harmonization of process model variants (La Rosa et al. 2013), the process model search (Jin et al. 2013), and the detection of process model clones (Uba et al. 2011). Many of these techniques require activity correspondences as input and, therefore, implicitly build on process model matching techniques. However, the application of process model matching techniques also represents an analysis by itself. The identified correspondences inform the user about similarities and dissimilarities between two models (or sets of models). From a practical perspective, process model matching techniques can, among others, provide valuable insights for identifying overlap or synergies in the context of

company mergers or for analyzing the evolution of models.

B

Future Directions for Research

As indicated by the results of the two Process Model Matching Contests, the main challenge in the area of process model matching remains the rather moderate and unstable performance of the matching techniques. The best F measures in the Process Model Contest 2015 ranged between 0.45 and 0.67. A recent meta-analysis by Jabeen et al. (2017) suggests that this can be mainly explained by the predominant choice for syntactic and simplistic semantic activity label similarity measures. These measures are simply not capable of identifying complex semantic relationships that exist between process models. These observations lead to three main directions for future research:

1. *Identify better strategies to measure activity label similarity:* There is a notable need for more intelligent strategies to measure the similarity between activity labels. Syntactic similarity measures are useful for recognizing correspondences with identical or very similar labels. The sole application of these measures, however, has been found to simply result in a high number of false positives (Jabeen et al. 2017). Also the current use of semantic technology is insufficient. Comparing activity labels by computing the semantic similarity between individual word pairs does not account for the cohesion and the complex relationships that exist between the words of activity labels. Here, a first step would be the proper consideration of compound nouns such as *eligibility assessment*. A more advanced step would be to also consider the relationship between nouns and verbs (Kim and Baldwin 2006). The fact that two activities use the same verb does not necessarily imply that they are related. Possible directions to account for these complex relationships are technologies such as distributional semantics (Bruni et al.

- 2014). They have been found to considerably improve the results in other matching contexts (Leopold et al. 2015).
2. *Incorporate machine learning:* Existing process model matching techniques hardly consider the use of machine learning. However, in the domain of ontology and schema matching, this seems to be a promising direction (cf. Doan et al. 2004; Spohr et al. 2011; Berlin and Motro 2002). Looking into the shortcomings of existing matching techniques, it seems that machine learning could help in two specific ways. First, they could be used to improve the detection of relationships between domain-specific words. This could be accomplished by training matching techniques on domain-specific dictionaries or other textual resources. Second, they could be used to better filter out unlikely correspondences. While first approaches have exploited simple behavioral rules to avoid certain correspondence constellations (cf. Leopold et al. 2012), the actual patterns might be more complex and context-dependent. Machine learning techniques might be able to detect those.
 3. *Increase the focus on the use case:* Currently, process model matching techniques are designed as general-purpose tools and do not take into account how the generated correspondences will be used later on. Depending on the actual use case, however, both the level of acceptable human interaction as well as the way how the technique needs to be evaluated might change. Consider, for example, the use case of identifying the operational overlap between two large process model repositories of two different organizations. While this use case certainly requires a fully automated solution, it probably does not need to be perfectly accurate in terms of precision. The manual work that is saved by pointing at potentially similar processes makes the matching technique already useful in a practical setting. This example shows that it might be worth tailoring matching techniques to specific use cases instead of designing general-purpose tools.

University of Seville, Sevilla, Spain

Definitions

Business process performance measurement, commonly shortened to process performance measurement (PPM), aims at checking the achievement of strategic and operational goals and supporting decision-making for the continuous optimization of business processes. It involves the definition, gathering, visualization, and analysis of a set of indicators that evaluate performance-relevant data of one or several business processes. These indicators, usually known as process performance indicators (PPIs), are quantifiable metrics that allow an evaluation of the efficiency and effectiveness of business processes and can be measured directly by data generated within the process flow. For instance, one could have a PPI for an order-to-cash process that specifies that its cycle time should be less than 20 working days in order to keep customer satisfaction.

Overview

Traditionally, process performance measurement (PPM) focused on the strategic and tactical level most frequently taking into account only financial measures. However, toward the early 1990s, a more balanced and integrated approach that involved the identification and use of performance indicators emerged due to the challenges posed by the rapidly changing technological and so-

cietal environment (Van Looy and Shafagatova 2016).

In this context, new definitions of performance measurement models arose. They intend to provide guidelines to evaluate the performance of an organization or a part of it, by considering different performance perspectives for which specific PPIs should be further defined. Depending on their focus, two categories can be distinguished. Organizational performance measurement models, like the balance scorecard (Kaplan and Norton 1996) or the European Foundation for Quality Management excellence model (EFQM 2010), provide a holistic view of an organization's performance and usually include financial and non-financial measures (related to the customer and other stakeholders, to processes and products, or to the strategy, among others). On the other hand, business process performance measurement models, such as statistical process control or the Devil's Quadrangle (Jansen-Vullers et al. 2008), have generally a less holistic focus, more specific to business processes, and include performance dimensions like time, cost, quality, or flexibility.

Defining PPIs

Regardless of the performance perspective to which a PPI applies, a collection of attributes have to be specified in its definition, namely, an *identifier* to uniquely designate the PPI, a descriptive *name* that helps to identify the PPI in an user-friendly manner, the *process* to which the PPI is related to or defined over, the strategic and/or operational *goals* with which the PPI is aligned, its *measure definition* that describes the way in which the indicator has to be calculated, a *target* value that must be reached to meet the pursued goals, and a *scope* that specifies the subset of process instances that must be considered to compute the PPI value and is frequently, though not necessarily, defined as a time frame. Furthermore, there are some other attributes that can be defined and provide additional information. Some examples are the *source of information* that refers to the data source used to gather the information to calculate the PPI, for instance, an event log or attributes related to some involved

human resources like *responsible*, *accountable*, or *informed*.

When defining PPIs with the just-introduced attributes, there is a set of requirements that need to be fulfilled. (1) A PPI must satisfy the SMART criteria, which stands for: specific, it has to be clear what the indicator exactly describes; measurable, it has to be possible to measure a current value and to compare it to the target one; achievable, its target must be challenging but achievable because it makes no sense to pursue a goal that will never be met; relevant, it must be aligned with a part of the organization's strategy, something that really affects its performance; and time-bounded, a PPI only has a meaning if it is known in the time period in which it is measured so that its evolution in time can be evaluated. (2) The PPIs themselves must be efficient, i.e., since the measurement itself requires human, financial, and physical resources, it must be worth the effort from a cost/benefit viewpoint. In addition, the amount of PPIs to define also must be efficient, following the less-is-more rule, where a balance between information need and information overload has to be met. (3) PPIs must be defined in an understandable way, according to the vocabulary used in the specific domain and in a language comprehensible by the different stakeholders involved in the PPI management. (4) They must keep traceability to the business process they are defined for, to avoid consistency issues when, for instance, the business process evolves but PPI definitions are not consequently updated and become obsolete. (5) They must be amenable to automation in order to avoid the need for a redefinition to a computable language, which could lead to the introduction of errors in the redefinition process.

Types of PPIs

PPIs can be broadly classified into two categories, namely, *lag* and *lead indicators*, also known as outcomes and performance drivers, respectively. The former establishes a goal that the organization is trying to achieve and is usually linked to a strategic goal. For instance, the previously introduced PPI example for the order-to-cash process: its cycle time should be less than 20 working

days in order to keep customer satisfaction. The problem of lag indicators is that they tell the organization whether the goal has been achieved, but they are not directly influenceable by the performers of the process. On the contrary, lead indicators have two main characteristics. First, they are predictive in the sense that if the lead indicators are achieved, then it is likely that the lag indicator is achieved as well. Second, they are influenceable by the performers of the process, meaning that they should refer to something that the performers of the process can actively do or not do (McChesney et al. 2012). For instance, if we think that one major issue that prevents fulfilling the aforementioned lag indicator is missing information from the customer when the order is created, double checking with the customer the order within the first 24 h could be a lead indicator for such lag indicator. Furthermore, it is important to distinguish PPIs from other similar concepts like activity metrics or risk indicators. Activity metrics measure business activity related to PPIs but do not have targets and goals associated with them because it does not make sense by definition, for instance, "top ten customers by revenue." They provide additional context that helps business people to make informed decisions. Finally, risk indicators measure the possibility of future adverse impact. They provide an early sign to identify events that may harm the continuity of existing processes (Van Looy and Shafagatova 2016).

Evaluating PPIs

Once a system of PPIs has been defined taking into consideration all the aforementioned information, data sources, methods, and instruments need to be established in order to gather the required data to calculate their values. Gathering methods can be classified into two big groups: evidence-based methods and subjective methods. The former includes the analysis of existing documentation, the observation of the process itself, and the use of data recorded by existing information systems that support the processes. The latter includes interviews, questionnaires, or workshops, where domain experts are queried to obtain the required information.

Evidence-based methods are less influenced by the individuals involved in the measurement than subjective ones; however they come with some weaknesses: people acting different because they are being observed, the existence of inaccurate or misleading information, or the unavailability of important data. Therefore, sometimes it can be a good decision to use a combination of them.

Analysis with PPIs

The last part of PPM is the visualization and analysis of performance data. This visualization and analysis serve two purposes. First, monitoring the process performance to keep it under control and to be able to quickly learn whether the performance is moving to the right direction so that appropriate actions are taken. Second, diagnosing the process performance in order to be able to spot points of potential improvement. Consequently, the techniques used to visualize and analyze the process performance vary depending on its purpose.

Dashboards are mainly used for the first purpose. According to Few (2006), dashboards are visual displays of the most important information needed to achieve one or more objectives that fit on a single computer screen so it can be monitored at a glance. Therefore, in PPM, dashboards are used for presenting the PPIs and their degree of fulfilment. In addition, they can depict other activity metrics or historic information that are necessary to give PPIs the context that is necessary to achieve the objectives for which the dashboard has been designed.

On the contrary, visual interfaces designed for data exploration and analysis are used for diagnosing the process performance. These interfaces offer all sorts of facilities to filter, group, or drill down data and to create different types of graphs that enable the comparison and analysis that are necessary to make sense of the performance data. Also, techniques such as statistical hypothesis testing or multivariate analysis and methods such as statistical process control can complement these visual interfaces to help identify causes of process performance variation.

Usually these two purposes go hand in hand. Ideally, visualization tools should have the ability

to go from the dashboard to an environment for exploration and analysis to learn insights from data and take action.

Regardless of the purpose, visualization designers should exploit well-known knowledge on visual perception to create effective visualizations that serve the aforementioned purposes. This knowledge include taking into account the limited capacity of people to process visual information: the use of color, form, position, and motion to encode data for rapid perception and the application of the Gestalt principles of visual perception that reveal the visual characteristics that incline us to group objects together (Few 2006). Furthermore, especially in the case of dashboards, simplicity is a key aspect to strive for since dashboards require to squeeze a great amount of information in a small amount of space while preserving clarity.

Key Research Findings

Performance Measurement Models

One specific stream of work that is particularly relevant to PPM is that related to performance measurement frameworks or models. Without a doubt, one of the most widely recognized performance measurement models is the balanced scorecard proposed by Kaplan and Norton (1996). They introduced a four-dimensional approach: (1) financial perspective, (2) customer perspective, (3) internal business process perspective, and (4) learning and growth perspective. It is, however, only one of several proposals in this area. For example, Keagan et al. (1989) proposed their performance measurement matrix which tries to integrate different business performance perspectives: financial and nonfinancial and internal and external. Brignall et al. (1991) developed the results and determinants framework, based on the idea of the two types of PPIs, lag, which relate to results (competitiveness, financial performance), and lead indicators, which relate to determinants (quality, flexibility, resource utilization, and innovation). The performance pyramid presented by Lynch and Cross (1991)

considers four levels, from top to down: (1) vision; (2) market and financial; (3) customer satisfaction, flexibility, and productivity; and (4) quality, delivery, cycle time, and waste. Adams and Neely (2002) used a performance prism with five facets to represent their proposal: stakeholder satisfaction, strategies, processes, capabilities, and stakeholder contribution. Another popular model is EFQM (2010), which distinguishes between enablers such as leadership, people, strategy, or processes, among others, and results, including customer, people, society, and key results. So far, the presented models are focused on the organization in a hierarchical way, but there are some others that advocate following a more horizontal approach, i.e., focused on the business processes. Two well-known examples are the framework proposed by Kueng (2000) for conceptualizing and developing a process performance measurement system and the Devil's quadrangle by Brand and Kolk (1995), which distinguishes four performance dimensions: time, cost, quality, and flexibility. These four dimensions have been established as the typical perspectives of business process performance measurement (Dumas et al. 2013; Jansen-Vullers et al. 2008).

PPI Definition Approaches

There is another research stream that has gained a great interest in PPM, mainly because the models mentioned above define different perspectives for which specific PPIs should be further defined but provide little guidance on how to define and operationalize them. Therefore, this research line is focused on the definition of PPIs, which has been addressed from different perspectives. In the formalization perspective, the work by Soffer and Wand (2005) proposes a set of formally defined concepts to enable the incorporation of measures and indicators (referred to as criterion functions for soft goals) into process modelling and design methods. Wetzstein et al. (2008), in their framework for business activity monitoring, describe a KPI ontology using the web service modelling language to specify PPIs over semantic business processes. Popova and Sharpanskykh (2010) formalize the definitions of PPIs as well

as their relationships with goals and among them using different variants of order-sorted predicate logic, which also enables formal analysis and verification. Finally, del Río-Ortega et al. (2013) present a metamodel for the definition of PPIs and its translation to a formal language (description logic) that allows a set of design-time analysis operations.

Regarding the provision of more user-friendly approaches for the definition of PPIs, while maintaining a formal foundation that allows further reasoning on those PPI definitions, several works can be named. Castellanos et al. (2005) propose the use of templates provided by a graphical user interface to define business measures related to process instances, processes, resources, or the overall business operations, which can be subject to posterior intelligent analysis to understand causes of undesired values and predict future values. del Río-Ortega et al. (2016) introduce a template-based approach that uses linguistic patterns for the definition of PPIs and is based on the PPINOT metamodel, thus enabling their automated computation and analysis. Saldivar et al. (2016) present a spreadsheet-based approach for business process analysis tasks that include writing metrics and assertions, running performance analysis and verification tasks, and reporting on the outcomes. Finally, van der Aa et al. (2017) use hidden Markov models to transform unstructured natural language descriptions into measurable PPIs.

Lastly, a set of researches have focused on developing graphical approaches for the definition of PPIs. Korherr and List (2007) extend two graphical notations for business process modelling (BPMN and EPC) to define business process and performance measures related to cost, quality, and cycle time. Friedenstab et al. (2012) extend BPMN for business activity monitoring by proposing a metamodel and a set of graphical symbols for the definition of PPIs, actions to be taken after their evaluation, and dashboards. del Río-Ortega et al. (2017b) present a graphical notation and editor to model PPIs together with business processes built on a set of principles for obtaining cognitively effective visual notations. The proposed notation is based on the PPINOT

metamodel and allows the automated computation of the PPI definitions.

PPI Analysis and Visualization Techniques

Concerning the visualization of process performance, researchers have focused on developing process-specific visual components that complement the use of general-purpose type of graphs such as bar graphs, bullet graphs, sparklines, or scatter plots in order to compare different cohorts of business process instances in order to spot process performance variations. Some of these visualizations include arranging and connecting pieces of information following the process model structure. For instance, in Wynn et al. (2017), a three-dimensional visualization of the process model enriched with a variety of performance metrics is used to identify differences between cohorts. Other visualizations adapt general-purpose graphs to visualize elements relevant to processes. Low et al. (2017) adapt social network graphs and timeline visualization approaches such as Gantt charts to highlight resource and timing changes; Claes et al. (2015) adapt dotted charts to represent the occurrence of events in time, and Richter and Seidl (2017) use a diagram similar to Gantt charts to represent temporal drifts in an event stream.

This last paper is also an example of a technique that analyses the performance data in order to obtain insights about process performance, in this case, temporal drifts. Similarly, other analysis techniques have been proposed such as in Hompes et al. (2017) in which the Granger causality test is used to discover causal factors that explain business process variation. Finally, process cubes can also be used during the analysis. Process cubes are based on the OLAP data cube concept. Each cell in the process cube corresponds to a set of events and can be used to compare and find process performance variation (Aalst 2013).

Examples of Application

Business process performance measurement is commonly applied for business process

control and continuous optimization. Process-oriented organizations use PPM as a tool to quantify issues or weaknesses associated to their business processes, like bottlenecks, and to identify improvement points. Sometimes, these organizations are engaged in initiatives to adopt sets of good practices or frameworks, either general ones, like the aforementioned EFQM, or specific to their domains, like ITIL or SCOR. In these cases, organizations apply the proposed PPM approach, according to the corresponding framework, where a series of performance measures to be defined are frequently proposed. The application of PPM can also be triggered by specific laws, related, for instance, to transparency or audits in the context, for example, of certifications. PPM can also help in deciding the viability of a business after a first short period of existence.

Future Directions for Research

While the definition of PPIs in the context of different performance measurement models has been widely analyzed and has produced a number of well-established approaches, it is recognized that they are suitable for structured business processes whose expected behavior is known *a priori*. Their direct application is, however, limited in the context of processes with a high level of variability or knowledge-intensive processes (KIPs), which are frequently non-repeatable, collaboration-oriented, unpredictable, and, in many cases, driven by implicit knowledge from participants, derived from their capabilities and previous experiences. In that context, new proposals pursue the incorporation of the new concepts involved in this type of processes, like the explicit knowledge used in process activities, into the definition of performance measures and indicators. Other research approaches focus on measuring the productivity of knowledge workers or their interaction and communication in KIPs. Nevertheless, a general proposal for the definition of performance measures in KIPs that can be used independently of the context and that addresses their particularities described above is missing.

A research area that is being recently explored is the development of techniques to enable evidence-driven performance diagnosis and improvement. Traditionally, they have been done based on the experience and intuition of process owners. However, nowadays, the amount and nature of available data produced by the information systems supporting business processes (e.g. event logs) make it possible for the application of different statistical and machine learning techniques for that purpose. Some preliminary approaches include a method for the identification of proper thresholds for a lead PPI in order to support the achievement of an associated lag PPI (del Río-Ortega et al. 2017a) or the use of statistical hypothesis testing to find root causes or performance drifts (Hompes et al. 2017).

Definitions

Business process querying studies methods for managing, e.g., filtering and/or manipulating, repositories of models that describe observed

and/or envisioned business processes and relationships between the business processes.

A *process querying method* is a technique that given a process repository and a process query systematically implements the query in the repository, where a *process query* is a (formal) instruction to manage a process repository.

Overview

This encyclopedia entry summarizes the state-of-the-art methods for (business) process querying proposed in the publications included in the literature reviews reported in Wang et al. (2014); Polyvyanyy et al. (2017b) and the related works discussed in the reviewed publications. The scope of this entry is limited to the methods for process querying that are based on special-purpose (programming) languages for capturing process querying instructions and were developed in the areas of process mining (van der Aalst 2016) and business process management (Weske 2012; Dumas et al. 2013).

Next, this section lists basic concepts in process querying. Let \mathcal{U}_{an} and \mathcal{U}_{av} be the universe of *attribute names* and *attribute values*, respectively.

Event. An *event* e is a relation between some attribute names and attribute values with the property that each attribute name is related to exactly one attribute value, i.e., it is a partial function $e : \mathcal{U}_{an} \rightarrow \mathcal{U}_{av}$.

Process. A *process* is a partially ordered set $\pi := (E, \leq)$, where E is a set of events and \leq is a partial order over E .

Trace. A *trace* is a process $\pi := (E, <)$, where $<$ is a total order over E .

Behavior. A *behavior* is a multiset of processes.

Behavior model. A *behavior model* is a simplified representation of real-world or envisioned behaviors and relationships between the behaviors that serves a particular purpose for a target audience.

Process repository. A *process repository* is an organized collection of behavior models.

Process query. A *process query* is an instruction to filter or manipulate a process repository.

Let \mathcal{U}_{pr} and \mathcal{U}_{pq} be the universe of *process repositories* and the universe of *process queries*, respectively.

Process querying method. A *process querying method* m is a relation between ordered pairs, in which the first entries are process repositories and the second entries are process queries, and process repositories with the property that each pair is related to exactly one process repository, i.e., it is a function $m : \mathcal{U}_{pr} \times \mathcal{U}_{pq} \rightarrow \mathcal{U}_{pr}$.

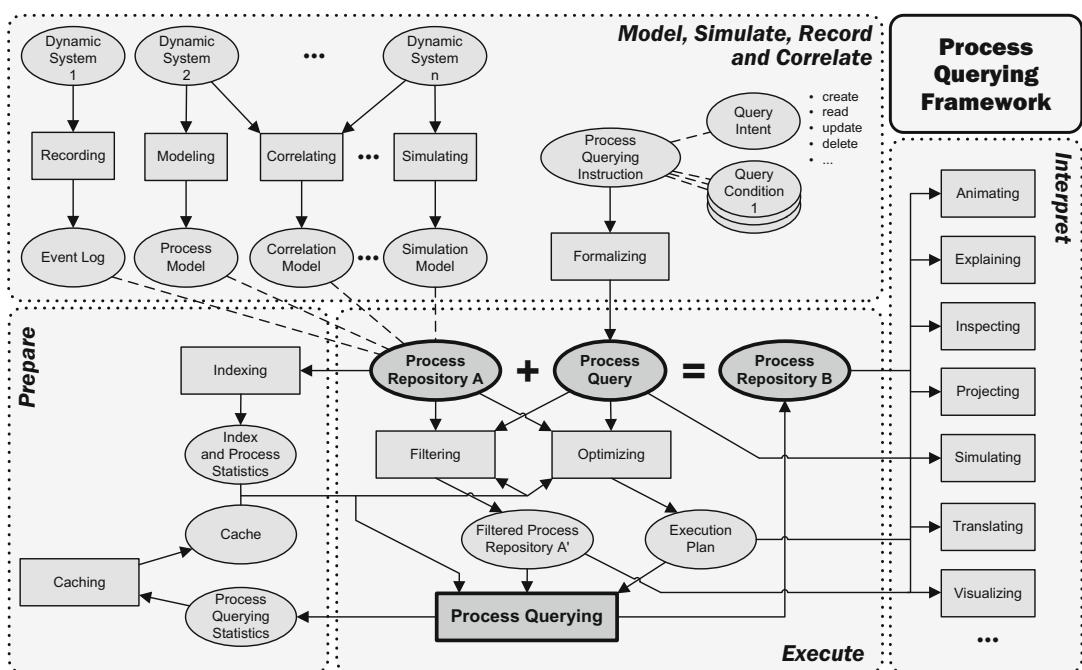

Framework

In Polyvyanyy et al. (2017b), a *process querying framework* is proposed. A schematic visualization of the framework is shown in Fig. 1.

The framework is an abstract system of components that provide generic functionality and can be selectively replaced to result in a

new process querying method. In the figure, rectangles and ovals denote *active components* and *passive components*, respectively. Active components represent actions performed by the process querying methods. Passive components stand for (collections of) data objects. The framework is composed of four parts. These parts are responsible for (i) designing process repositories and process queries, (ii) preparing and (iii) executing process queries, and (iv) interpreting results of the process querying methods; refer to Polyvyanyy et al. (2017b) for details.

The framework proposes four types of behavior models: event logs, process models, simulation models, and correlation models. An *event log* is a finite collection of traces, where each trace is a finite sequence of events observed and recorded in the real world. A process model is a conceptual model that describes behaviors. A simulation model is a process model with a part of its behavior. Finally, a correlation model is a model that describes relations between two behaviors. All the reported below process querying methods operate over event logs and process models.

Business Process Querying, Fig. 1 A schematic view of the process querying framework from (Polyvyanyy et al. 2017b)

Techniques

This section lists techniques that are often used as a basis for implementing process querying methods.

Model Analysis. Behavior models are often formalized as graphs. Several methods for process querying are grounded in the analysis of structural properties of graphs that encode behavior models, e.g., BP-QL, DMQL, GMQL, and VMQL. Examples of graph analysis tasks employed for process querying include the existence of a path problem and subgraph isomorphism problem.

SPARQL Protocol and RDF Query Language (SPARQL). SPARQL is a semantic query language for retrieving and manipulating data captured in Resource Description Framework (RDF) format (Hebeler et al. 2009). SPARQL allows users to write queries against data stored in the form of a set of “subject-predicate-object” triples.

Several methods for process querying are based on SPARQL, e.g., BPMN VQL and FPSPARQL. These methods encode process repositories as RDF data and implement process querying by first transforming process queries into SPARQL queries and then executing SPARQL queries over the RDF data.

Given a model of a finite-state system, for example, a behavior model, and a formal property, *model checking* techniques verify whether the property holds for the system (Baier and Katoen 2008).

Temporal Logic. A temporal logic is a formal system for encoding and reasoning about propositions qualified in terms of time (Øhrstrøm and Hasle 2007). Several methods for process querying are grounded in model checking temporal logic properties, e.g., BPMN-Q, BPSL, CRL, and PPSL. Given a process repository and process query, these methods proceed by translating the process query into a temporal logic expression, e.g., linear temporal logic (LTL), computation tree logic (CTL), and metrical temporal logic

(MTL). Then, each behavior model from the repository gets translated into a finite-state system and verified against the formula. Finally, behavior models that translate into systems for which the property captured in the formula holds constitute the result of the method.

First-Order Logic. First-order logic (FOL) is a formal logic that extends propositional logic which operates over declarative propositions with the use of predicates and quantifiers (Smullyan 1995). Several methods for process querying are grounded in model checking FOL properties, e.g., CRG and QuBPAL. These methods encode process repositories as formal FOL theories and implement process querying by verifying properties (encoded in process queries) of these systems.

Behavior Analysis. Several methods for process querying are grounded in the analysis of properties of behaviors encoded in models, e.g., APQL, BQL, and PQL. These methods support process queries that specify conditions over all the processes (of which there can be potentially infinitely many) encoded in the behaviors of models stored in a process repository.

Methods

This section discusses the state-of-the-art methods for process querying. The methods can be seen as instantiations of the process querying framework, refer to Fig. 1, with various concrete components. In what follows, the methods are grouped based on the types of behavior models that they can take as input in process repositories and are referred to by the names of the corresponding languages for specifying process queries.

Log Querying

Process querying methods proposed in this section operate over event logs.

CRG&eCRG. Compliance Rule Graph (CRG) is a visual language for specifying compliance

rules (Ly et al. 2010). The semantics of CRG is defined based on FOL over event logs. Extended Compliance Rule Graph (eCRG) extends CRG to allow modeling compliance rules over multiple process perspectives (Knuplesch and Reichert 2017). At this stage, eCRG addresses the interaction, time, data, and resource perspectives of process compliance. Similar to CRG, the execution semantics of eCRG is defined based on FOL over event logs.

DAPOQ-Lang. The Data-Aware Process Oriented Query Language (DAPOQ-Lang) allows querying over events in traces of event logs, as well as over related data objects, their versions and data schemas, and temporal properties of all the aforementioned elements (de Murillas et al. 2016).

FPSPARQL. The Folder-Path-enabled extension of SPARQL (FPSPARQL) is a query language founded on the two concepts of folders and paths that allow grouping events and exploring sequences of events recorded in event logs (Beheshti et al. 2011).

FPSPARQL operates over a data model that encodes an event log as a graph. In such a graph, nodes are events from the event log and edges stem from the orderings of events in the traces of the event log. Folders and paths are results of FPSPARQL queries. They constitute abstractions over the event log graphs. A folder abstraction refers to a collection of events, whereas a path abstraction encodes one or several paths in the transitive closure of the graph. Finally, FPSPARQL allows querying logs using standard SPARQL capabilities.

PIQL. Process Instance Query Language (PIQL) is an extension of Decision Model and Notation (DMN) for querying process performance indicators over executed traces (Pérez-Álvarez et al. 2016). DMN is a standard language for describing logic of decisions within organizations. PIQL is a textual language that resembles natural language. It can be used during process execution to define decision logic that

depends on the information kept in the so far executed traces.

Model Querying

This section lists methods for querying collections of process models. These methods can be split into those that operate over process model specifications and those that explore behaviors encoded in process models. Methods that operate over model specifications can be further split into two subclasses. The first subclass includes methods for querying conceptual models that were also reported useful for querying process models. The second subclass consists of dedicated techniques for querying process model collections.

DMQL, GMQL, and VMQL are the methods that belong to the first subclass of methods that operate over process model specifications.

DMQL&GMQL. The Generic Model Query Language (GMQL) is a textual query language designed to query collections of conceptual models created in arbitrary graph-based modeling languages (Delfmann et al. 2015b). GMQL querying is implemented via searching for model subgraphs that correspond to a predefined pattern query. GMQL is proposed to query process models, as well as data models, organizational charts, and other types of models.

The Diagrammed Model Query Language (DMQL) (Delfmann et al. 2015a) extends GMQL with a visual concrete syntax and support for additional requirements, e.g., ability to approximate analysis of the execution semantics of process models in the case of loops.

VMQL. The Visual Model Query Language (VMQL) is a language for querying collections of conceptual models (Störrle 2009, 2011). Among other types of conceptual models, the authors of VMQL demonstrated its use over collections of process models, e.g., Unified Modeling Language (UML) Activity Diagrams and Business Process Model and Notation (BPMN) models. VMQL is based on the concept of a host language. For example, VMQL for querying BPMN models subsumes the syntax and notation of BPMN. This approach allows decreasing the user effort

for reading and writing VMQL queries. VMQL queries can also specify constraints that go beyond the syntax of the host language.

For querying purposes, process models and VMQL queries are encoded in a Prolog database. Executing a VMQL query with respect to a given model requires finding parts of the model that resemble the structure and properties of the query and satisfy the constraints.

Next, we discuss dedicated process querying methods that operate over model specifications.

BPMN-Q. BPMN query language (BPMN-Q) was originally proposed to query business process definitions, i.e., (Awad 2007) the flow between activities, branching and joining structures, and data flow. BPMN-Q extends the abstract and concrete syntax of BPMN. Hence, BPMN-Q is a visual language. Later, BPMN-Q was extended to serve as a visual interface to temporal logics, e.g., LTL (Awad et al. 2008) and CTL (Awad et al. 2011).

BPMN VQL. BPMN Visual Query Language (BPMN VQL) is a visual query language (Francescomarino and Tonella 2008). The syntax and semantics of BPMN VQL are grounded in BPMN and SPARQL, respectively. The SPARQL translation of BPMN VQL queries is based on a formalization of the BPMN meta-model as an ontology. BPMN VQL queries consist of two parts. The matching part of a query specifies a structural condition to match in process models, whereas the selection part specifies parts of models to retrieve as query result.

BPSL. The Business Property Specification Language (BPSL) is a visual language that aims to facilitate the reasoning over business process models (Liu et al. 2007). The authors proposed direct translations of BPSL queries in both LTL and CTL to simplify the integration of BPSL with the existing formal verification tools. The language proposes dedicated operators for the recurring patterns in regulatory process compliance and specifies extension points for the definition and reuse of domain-specific temporal properties.

CRL. Compliance Request Language (CRL) is a visual language that is grounded in temporal logic and encompasses a range of compliance patterns (Elgammal et al. 2016). At this stage, CRL supports compliance patterns that address control flow, resource, and temporal aspects of business processes. During execution, control flow and resource patterns get mapped to LTL, whereas temporal patterns are translated into MTL formulas. MTL extends LTL and is interpreted over a discrete time domain using the digital clock model.

Descriptive PQL. Descriptive Process Query Language (Descriptive PQL) is a textual query language for retrieving process models, specifying abstractions on process models, and defining process model changes (Kammerer et al. 2015). The aforementioned operations are grounded in manipulations with single-entry-single-exit subgraphs (Polyvyanyy et al. 2010) of the process models.

IPM-PQL. Integrated Process Management-Process Query Language (IPM-PQL) is an XML-based language to query process model collections based on structure matching (Choi et al. 2007). IPM-PQL queries follow the structure of SQL queries and support four types of query conditions: process-has-attribute, process-has-activity, process-has-subprocess, and process-has-transition. When executed, IPM-PQL queries are transformed into XML Query (XQuery) expressions.

PPSL. The Process Pattern Specification Language (PPSL) is a lightweight extension of the language for capturing UML activity diagrams that allows users to model process constraints, e.g., those related to quality management (Förster et al. 2005). The semantics of the language is given as translations of PPSL queries into temporal logic, viz., LTL formulas (Förster et al. 2007).

Finally, we summarize process querying methods that operate over behaviors encoded in models.

APQL. A Process-model Query Language (APQL) is a query language based on semantic relations between occurrences of tasks specified in process models (ter Hofstede et al. 2013). The language allows composing the relations between tasks to obtain complex queries. APQL is precise, i.e., its semantics is defined over all possible execution traces of process models. The language is independent of any particular notation used to specify process models.

BQL. Business Query Language (BQL) is a textual query language based on semantic relations between occurrences of tasks specified in process models (Jin et al. 2011). Given a repository of process models, BQL can be used to retrieve the models satisfying the requirements based on the behavior encoded in the models. To compute the relations, BQL relies on the technology of complete prefix unfolding (McMillan 1995).

QuBPAL. Querying Business Process Abstract modeling Language (QuBPAL) is an ontology-based language for the retrieval of process fragments to be reused in the composition of new business processes (Smith et al. 2010). Using QuBPAL, the user can query over three process perspectives: the structure of process specifications, the behavioral semantics of process specifications, and the pre-modeled domain knowledge about the business scenario encoded in models. QuBPAL queries are evaluated over Business Process Knowledge Base—a collection of FOL theories that formalize the process repository of semantically enriched process models.

PQL. Process Query Language (PQL) is a textual query language based on semantic relations between tasks in process models (Polyvyanyy et al. 2015). PQL extends the abstract syntax of APQL and has an SQL-like concrete syntax. The semantic relations between tasks are computed as aggregations over all the possible occurrences of these tasks, as specified in the behavior of the corresponding process model.

PQL is based on the semantic relations of the 4C spectrum (Polyvyanyy et al. 2014) – a sys-

tematic collection of the co-occurrence, conflict, causality, and concurrency relations. In addition to filtering capabilities, PQL addresses manipulation of process models. For example, PQL queries can specify instructions to insert traces into process models, i.e., to augment process models to additionally describe fresh traces. PQL implements instructions to insert new traces into process models as solutions to the process model repair problem (Polyvyanyy et al. 2017a).

Log and Model Querying

Methods listed below were proposed to query over collections that may include process models and/or event logs.

BPQL. Business Process Query Language (BPQL) is a textual language for querying over process models and event logs (Momotko and Subieta 2004). The language is defined as an extension of the Stack-Based Query Language (SBQL) (Subieta 2009). The semantics of the language is defined over the proposed abstract model for capturing process specifications and execution traces. The authors of BPQL proposed BPQL templates to use for monitoring process execution and integrated the language with the XML Process Definition Language (XPDL).

BP-QL. Business Process Query Language (BPQL) is a visual language that allows retrieving paths in process specifications (Beeri et al. 2006). BPQL operates over a dedicated abstract model for representing collections of processes. This model is used to distinguish queries that can be efficiently computed, queries that have high computation costs, and queries that cannot be computed at all. When a BPQL query is evaluated, its structural patterns are matched against process specifications. BPQL uses the proposed abstract model to support queries that can be answered in time polynomial in the size of a process specification. This is achieved at a price of precision of query answers. BPQL supports mechanisms for constructing concise finite representations of the (possibly infinite) query results. BP-Mon and BP-Ex are the two extensions of BPQL to support process

monitoring and querying of executed traces, respectively.

Applications

Due to their generic purpose, i.e., manipulation and filtering of process repositories, process querying methods have broad application in process mining and business process management. The aforementioned process querying methods were proposed and/or successfully applied to solve various problems in these fields. Some examples of the addressed problems include: business process compliance management, business process weakness detection, process variance management, process model translation, syntactical correctness checking, process model comparison, infrequent behavior detection, process instance migration, process monitoring, process reuse, and process standardization.

Future Directions for Research

Future work on process querying will contribute to achieving *process querying compromise* (Polyvyanyy et al. 2017b), i.e., will propose new and improve the existing process querying methods with the support of efficiently computable and practically relevant process queries. As of today, the existing works on process querying constitute non-coordinated efforts. Future work will contribute to the consolidation of various process querying methods leading to the definition of a standard meta-model for behavior models and behaviors that these models describe and a standard language for capturing process queries.

Most existing methods for process querying operate over specifications of behavior models. Future work will lead to new methods for querying based on behaviors encoded in models and study their practical implications.

While there is a plethora of methods and languages for capturing instructions for filtering process repositories, methods for manipulating process repositories are still in their infancy.

Caching for SQL-on-Hadoop

Gene Pang and Haoyuan Li
Alluxio Inc., San Mateo, CA, USA

Definitions

Caching for SQL-on-Hadoop are techniques and systems which store data to provide faster access to that data, for Structured Query Language (SQL) engines running on the Apache Hadoop ecosystem.

Overview

The Apache Hadoop software project (Apache Hadoop 2018) has grown in popularity for distributed computing and big data. The Hadoop stack is widely used for storing large amounts of data, and for large-scale, distributed, and fault-tolerant data processing of that data. The Hadoop ecosystem has been important for organizations to extract actionable insight from the large volumes of collected data, which is difficult or infeasible for traditional data processing methods.

The main storage system for Hadoop is the Hadoop Distributed File System (HDFS). It is a distributed storage system which provides fault-tolerant and scalable storage. The main data processing framework for Hadoop is MapReduce, which is based on the Google MapReduce project

(Dean and Ghemawat 2008). MapReduce is a programming model and distributed batch processing framework for reliably processing large volumes of data, typically from HDFS. However, the distinct programming model for MapReduce can be a barrier for nondevelopers, such as data analysts or business intelligence (BI) tools.

Because of this barrier to entry, new tools and frameworks have emerged for the Hadoop ecosystem. Primarily, new Structured Query Language (SQL) frameworks have gained popularity for the Hadoop software stack. SQL is a domain-specific declarative language to describe retrieving and manipulating data, typically from relational database management systems (RDBMS). These SQL engines for Hadoop have been effective for empowering more users who are familiar with existing tools and the SQL language for managing data. These frameworks typically read data from HDFS, process the data in a distributed way, and return to the user the desired answer. Many SQL engines are available for Hadoop, which include Apache Hive (2018), Apache Spark SQL (2018), Apache Impala (2018), Presto (Facebook 2018), and Apache Drill (2018).

These SQL on Hadoop engines have combined the convenience of data query with SQL and the power of distributed processing of data with Hadoop. However, these engines are commonly not tightly integrated into the Hadoop ecosystem. There can be advantages of separating the computation engine from the storage system, such as cost effectiveness and operational flexibility.

However, one potential weakness is that the performance of accessing data may decline. Since RDBMS typically have tight integration and control of the entire stack from the computation to the storage, performance may be faster and more predictable. For comparable experiences with traditional SQL processing in RDBMS, distributed SQL engines on Hadoop turn to caching to achieve the desired performance.

There are several different ways SQL engines on Hadoop can take advantage of caching to improve performance. The primary methods are as follows:

- Internal caching within the SQL engine
- Utilizing external storage systems for caching

SQL Engine Internal Caching

A common way a SQL engine uses caching is to implement its own internal caching. This provides the most control for each SQL engine as to what data to cache and how to represent the cached data. This internal cache is also most likely the fastest to access, since it is located closest to the computation being performed (same memory address space or local storage), in the desired format. However, the SQL engine internal caching may not be shareable between different users and queries, which is beneficial in a multi-tenant environment. Also, not all SQL processing frameworks have implemented an internal cache, which prevents using cached data for queries.

Apache Spark SQL

Apache Spark SQL is a SQL query engine built on top of Apache Spark, a distributed data processing framework. Spark SQL exposes a concept called a DataFrame, which represents a distributed collection of structured data, similar to a table in an RDBMS. Caching in Spark SQL utilizes the caching in the Spark computation engine. A user can choose to cache a DataFrame in Spark SQL by explicitly invoking a cache command (Spark SQL 2018). When the command is invoked, Spark SQL engine will cache the DataFrame internal to the Spark engine.

There are several user-configurable ways the data can be cached, including MEMORY_ONLY, MEMORY_AND_DISK, DISK_ONLY, and others (Spark RDD 2018). An explicit command must be invoked to remove the DataFrame from the cache.

Apache Hive and LLAP

Apache Hive is a SQL data warehouse for Hadoop, which utilizes an existing distributed computation engine for the data processing. The options of computation engines for Hive to use are MapReduce, Spark, or Tez. Hive uses Live Long And Process (LLAP) (Apache Hive LLAP 2018) for caching data for SQL processing. Currently, only Tez will take advantage of the caching available via LLAP.

LLAP is a long-lived daemon which runs alongside Hadoop components in order to provide caching and data pre-fetching benefits. Since Tez takes advantage of LLAP, when Hive uses Tez as the computation engine, data access will go to the LLAP daemons, instead of the HDFS DataNodes. With this access pattern and architecture, LLAP daemons can cache data for Hive queries.

External Storage Systems for Caching

Another major technique for caching for SQL engines on Hadoop is to utilize an external storage system for caching data. Using a separate system can have several benefits. An external system may be able to manage the cache more effectively and provide additional cache-related features. Also, an external system can be deployed independently from the other components of the ecosystem, which can provide operational flexibility. Additionally, sharing cached data can be enabled or made simpler with a separate system for caching. By using a separate system for handling the caching of data, SQL engines can take advantage by reading the data from the cache, instead of the originating data source. This can greatly improve performance, especially when frequently accessed files are cached. Below

are some of the main systems which can provide caching in Hadoop ecosystems.

Alluxio

Alluxio (2018) is a memory speed virtual distributed storage system. Alluxio provides a unified namespace across multiple disparate storage systems. Alluxio enables users to “mount” any existing storage system like HDFS, Amazon S3, or a storage appliance, and presents a single, unified namespace encompassing all the data. When a mount is established, applications simply interact with the Alluxio namespace, and the data will be transparently accessed from the mounted storage and cached in Alluxio. Since there is no limit to how many mounts are possible, Alluxio enables accessing all data from a single namespace and interface, and allows queries to span multiple different data sources seamlessly. Figure 1 shows how Alluxio can mount multiple storage systems for multiple computation frameworks.

Alluxio enables caching for SQL engines by providing memory speed access to data via its memory centric architecture. Alluxio stores data on different tiers, which include memory, solid-state drive (SSD), and disk. With the memory tier and the tiered storage architecture, Alluxio can store the important and most frequently accessed

data in the fastest memory tier, and store less accessed data in slower tiers with more capacity.

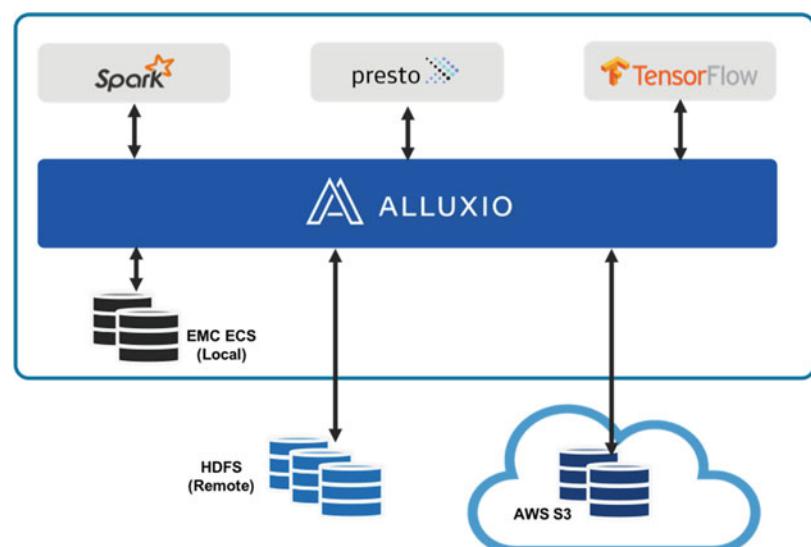

SQL engines can access any data via the Alluxio unified namespace, and the data will be either fetched from the configured mounted storages, or served from Alluxio-managed storage (memory, SSD, and disk), which can greatly improve performance. When Alluxio is deployed colocated with the computation cluster, the Alluxio memory storage can behave similar to the internal caches of SQL engines. Alluxio is able to transparently cache data from various other storage systems, like HDFS. Additionally, since the Alluxio storage is independent from the SQL engines, the cached data can easily be shared between different computation frameworks, thus allowing greater flexibility for deployments.

Apache Ignite HDFS Cache

Apache Ignite (2018) is a distributed platform for in-memory storage and computation. Apache Ignite is a full stack of components which includes a key/value store, a SQL processing engine, and a distributed computation framework, but can be used to cache data for HDFS and SQL engines on Hadoop.

Apache Ignite provides a caching layer for HDFS via the Ignite File System (IGFS). All clients and applications interact with IGFS for data, and IGFS handles reading and writing the

Caching for SQL-on-Hadoop, Fig. 1
Alluxio mounting various storage systems

data to memory on the nodes. When using IGFS as a cache, users can optionally configure a secondary file system for IGFS, which allows transparent read-through and write-through behavior. Users can configure HDFS for the secondary file system, so when the data is synced to IGFS, the data in Ignite is cached in memory.

Using Apache Ignite, SQL engines can access their HDFS data via IGFS, and the data can be cached in the Ignite memory storage. Any SQL engine can take advantage of this cached data for greater performance for queries. When using IGFS, the SQL engine internal caching does not need to be used, which will also enable sharing of the cached data. However, IGFS only allows a single secondary HDFS-compatible file system, if SQL queries need to access varied sources, IGFS would not be able to cache the data.

HDFS Centralized Cache Management

Another external caching option is for the cache to be implemented in the Hadoop storage system, HDFS. Depending on the operating system (OS) buffer cache is one way to take advantage of caching in HDFS. However, there is no user control over the OS buffer cache. Instead, HDFS has a centralized cache management feature (Apache Hadoop HDFS 2018), which enables users to explicitly specify files or directories which should be cached in memory. Once a user specifies a path to cache in HDFS, the HDFS DataNodes will be notified, and will cache the data in off-heap memory. In order to remove a file or directory from the cache, a separate command must be invoked. HDFS caching can help accelerate access to the data, since the data can be stored in memory, instead of disk.

By enabling the HDFS centralized cache, the data of specified files will reside on memory on the HDFS DataNodes, so any SQL engines or applications accessing those files will be able to read the data from memory. Increasing the data access performance of HDFS will help any queries accessing the cached files. Apache Impala has additional support for utilizing the HDFS centralized caching feature for Impala tables

which are read from HDFS. With Apache Impala, users can specify tables or partitions of tables to be cached via HDFS centralized caching. IBM Big SQL (Floratou et al. 2016) also uses the HDFS cache for accelerating access to data and utilizes new caching algorithms Adaptive SLRU-K and Adaptive EXD to improve the cache hit rates for better performance.

Since the centralized caching is an HDFS feature, it can help improve performance for any HDFS data access. However, for disaggregated clusters, where the HDFS cluster is separate from the SQL engine cluster, the HDFS caching may not be able to help much. Separating computation and storage clusters is becoming popular for its scalability, flexibility, and cost effectiveness. In these environments, when the computation cluster requires data, the data must be accessed across the network, so even if the data resides in the memory cache on the HDFS DataNodes, the network transfer may be the performance bottleneck. Therefore, further improving performance via caching requires either SQL engine internal caching or a separate caching system. Also, since the caching system is tightly integrated with HDFS, the deployment is not as flexible as other external caching systems.

Conclusion

Caching can significantly improve query performance for SQL engines on Hadoop. There are several different techniques for caching data for SQL frameworks. SQL engine internal caching has the potential for the greatest performance, but each framework must implement a cache, and the cached data is not always shareable by other applications or queries. Another option is to use the HDFS centralized caching feature to store files in memory on the HDFS DataNodes. This server-side cache is useful to speed up local access to data, but if SQL engines are not colocated with HDFS, or the data is not stored in HDFS, the network may become the performance bottleneck. Finally, external systems can cache data for SQL frameworks on Hadoop. When colocated with the computation cluster, external systems can store

data in memory similar to an internal cache, but provide the flexibility to share the data effectively between different applications or queries.

Cheap Data Analytics on Cold Storage

Raja Appuswamy

Data Science Department, EURECOM, Biot, France

Definitions

Driven by the desire to extract insights out of data, businesses have started aggregating vast amounts of data from diverse data sources. However, recent analyst reports claim that only 10–20% of data stored is actively accessed with the remaining 80% being *cold* or infrequently accessed. Cold data has also been identified as the fastest-growing storage segment, with a 60% cumulative annual growth rate (Mendoza 2013; Moore 2015; Nandkarni 2014).

As the amount of cold data increases, enterprise customers are increasingly looking for more cost-efficient ways to store this data. A recent report from IDC emphasized the need for such low-cost storage by stating that only 0.5% of potential Big Data is being analyzed, and in order to benefit from unrealized value extraction, infrastructure support is needed to store large volumes of data, over long time duration, at extremely low cost

(Nandkarni 2014). Thus, the topic of managing cold data has received a lot of attention from both industry and academia over the past few years. Systems that are purpose-built to provide cost-efficient storage and analysis of cold data are referred to as *cold storage* systems.

Background and Overview

Enterprise databases have long used storage tiering for reducing capital and operational expenses. Traditionally, databases used a two-tier storage hierarchy. An *online* tier based on enterprise *hard disk drives (HDD)* provided low-latency (ms) access to data. The *backup* tier based on offline tape cartridges or optical drives, in contrast, provided low-cost, high-latency (hours or days) storage for storing backups to be restored only during rare failures.

As databases grew in popularity, the necessity to reduce recovery time after failure became important. Further, as regulatory compliance requirements forced enterprises to maintain long-term data archives, the offline nature of the backup tier proved too slow for both storing and retrieving infrequently accessed archival data. This led to the emergence of a new *archival* tier based on nearline storage devices, like virtual tape libraries (VTL), which could store and retrieve data automatically without human intervention in minutes.

Cheap Data Analytics on Cold Storage, Fig. 1

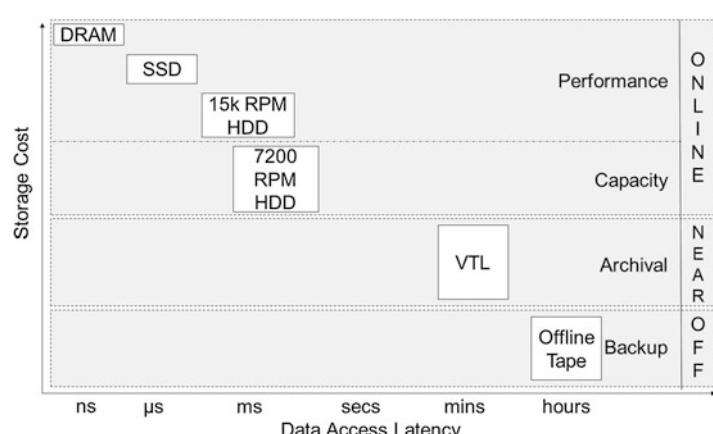

Storage tiering for enterprise databases

Over the past decade, the emergence of flash-based solid-state storage, declining price of DRAM, and demand for low-latency, real-time data analytics have resulted in the traditional online tier being bifurcated into two subtiers, namely, a *performance* tier based on RAM/SSD and a *capacity* tier based on HDD. Thus, most modern enterprises today use a four-tier storage hierarchy (performance, capacity, archival, backup) implemented using three storage types (online, nearline, and offline) as shown in Fig. 1.

Given the proliferation of cold data over the past few years, the obvious question that arises is where should such cold data be stored. Given that databases already have a tiered storage infrastructure in place, an obvious low-cost solution to deal with this problem is to store cold data in either the capacity tier or the archival tier. Unfortunately, both these options are not ideal given recent trends in the high-density storage hardware landscape.

HDD-Based High-Density Storage

Traditionally, 7,200 RPM HDDs have been the primary storage media used for provisioning the capacity tier. For several years, areal density improvements enabled HDDs to increase capacity at Kryder's rate (40% per year), outstripping the 18-month doubling of transistor count predicted by Moore's law. However, over the past few years, HDD vendors have hit walls in scaling areal density with conventional perpendicular magnetic recording (PMR) techniques (Fontana and Decad

2015). As a result, HDD vendors have started working on several techniques to improve areal density, like using helium-bearing instead of air-bearing for the disk head to pack more platters tightly or using shingled magnetic recording (SMR) techniques that pack more data by overlapping adjacent disk tracks, to further increase areal density. Despite such attempts from HDD vendors, HDD areal density is improving only at an annual rate of 16% instead of 40% (Fontana and Decad 2015; Moore 2016).

HDDs also present another problem when used as the storage medium of choice for storing cold data, namely, high idle power consumption. Unlike tape drives, which consume no power once unmounted, HDDs consume a substantial amount of power even while idle (Colarelli and Grunwald 2002). Such power consumption translates to a proportional increase in operational expenses. Thus, the capacity tier, with its always-on HDD-based storage, is not an ideal option for storing infrequently accessed cold data.

Tape-Based High-Density Storage

Unlike HDDs, the areal density of tapes has been increasing steadily at a rate of 33% per year, and the *Linear Tape Organization (LTO)* roadmap (LTO Ultrium 2015) projects continued increase in density for the foreseeable future. Today, a single LTO-7 cartridge is capable of matching or even outperforming a HDD, with respect to sequential data access bandwidth. As modern tape libraries use multiple drives, the cumulative bandwidth achievable using even low-end tape libraries is 1–2 GB/s. However, the random access latency of tape libraries is still 10,000× higher than HDDs (minutes versus ms) due to the fact that tape libraries need to mechanically load tape cartridges before data can be accessed. Thus, tape-based archival tier is used to store only rarely accessed compliance and backup data. As the expected workload in such cases is dominated by sequential writes with a few rare reads, the high access latency of tape drives is tolerable.

Using the archival tier to store cold data, however, changes the application workload, as analytical queries need to be issued over cold data

to extract insightful results (EMC 2014). As a nearline storage device with access latency that is five orders of magnitude larger than HDD, tape will impose a significant performance penalty for even latency-insensitive batch analytic workloads (Kathpal and Yasa 2014). Thus, today, enterprises are faced with a trade-off, as they can store cold data in tape-based archival tier at the expense of performance or in the HDD-based capacity tier and trade-off cost.

C

Key Research Findings

Over the past few years, storage hardware vendors and researchers have become cognizant of the gap between the HDD-based capacity tier and the tape-based archival tier. This has led to the emergence of a new class of nearline storage devices explicitly targeted at cold data workloads. These devices, also referred as *cold storage devices (CSD)*, have two salient properties that distinguish them from the tape-based archival tier. First, they use archival-grade, high-density, shingled magnetic recording-based HDD as the storage media instead of tapes. Second, they explicitly trade off performance for power consumption by organizing hundreds of disks in a massive array of idle disk (MAID) configuration that keeps only a fraction of HDD powered up at any given time (Colarelli and Grunwald 2002).

CSD differ dramatically with respect to price, performance, and peak power consumption characteristics. Some CSD enforce a strict upper limit on the number of HDD that can be spun up at any given point to limit peak power draw. By doing so, they right-provision hardware resources, like in-rack cooling and power management, to cater to the subset of disks that are spun up, reducing operational expenses further. For instance, Pelican (Balakrishnan et al. 2014) packs 1,152 SMR disks in a 52U rack for a total capacity of 5 PB. However, only 8% of disks are spun up at any given time due to restrictions enforced by in-rack cooling and power budget. Similarly, each OpenVault Knox (Yan 2013) CSD stores 30 SMR HDDs in a 2U chassis of which only one can be spun up to minimize the sensitivity

of disks to vibration. Other CSD, like Spectra ArcticBlue Spectra Logic (2013), provide more performance flexibility at the expense of cost, similar to traditional MAID arrays, by only spinning down idle disks while permitting a much larger subset of disks to be active simultaneously.

The net effect of these limitations is that the latency to access data stored in the CSD depends on whether the data resides in a disk that is spun up or down. Access to data in any of the spun-up disks can be done with latency and bandwidth comparable to that of the traditional capacity tier. For instance, Pelican, OpenVault Knox, and ArcticBlue are all capable of saturating a 10 Gb Ethernet link as they provide between 1 and 2 GB/s of throughput with an access latency of 5–10 milliseconds for reading data from spun-up disks. However, accessing data on a spun-down disk takes 5–10 s, as the target disk needs to be spun up before data can be accessed.

CSD form a perfect middle ground between HDD and tape. Due to the use of high-density disks and MAID techniques, CSD are touted to offer cost/GB comparable to tape. With worst-case access latencies in seconds, CSD are closer to HDD than tape with respect to performance. However, CSD are not a drop-in replacement for HDD (Borovica-Gajic et al. 2016). In order to effectively exploit CSD for reducing the cost of cold data storage and analytics, cold storage infrastructures need to design three components of both CSD and analytic engines to work in concert with the shared goal of minimizing the number of disk spin-ups, namely, the CSD storage manager, the CSD I/O scheduler, and the analytic engine's query executor.

CSD Storage Manager

The CSD storage manager is responsible for implementing the storage layout that maps data to disks. Designing an optimal data layout for CSD is a complex problem, as one has to balance performance, reliability, and availability simultaneously. From performance point of view, data that is accessed together should be stored on a set of disks that can spin up together so that requests for such data can be serviced concurrently without any group switches. From the reliability

aspect, the disk chosen for storing data should span multiple failure domains, like different trays in the rack, so that a failure in any single domain does not result in total data loss. With respect to availability, data layout should ensure that recovery from a disk failure is seamless and quick, as disk failures will be a norm rather than an exception in CSD.

In CSD like Pelican (Balakrishnan et al. 2014), where the power and cooling infrastructure of the CSD enforces a strict limit on which set of disks can be spun up at any given time, the choice of data layout is a direct consequence of these restrictions. Pelican (Balakrishnan et al. 2014) assembles disks into groups such that disks within each group belong to different failure domains and can be spun up simultaneously. Each data object stored by Pelican is striped across disks within a single group, using erasure coding to protect data in case of disk failures. By using disks that can be active at the same time, Pelican meets the performance requirement, as multiple object requests can be served concurrently due to striping. Erasure coding helps in improving availability, as recovery after disk failures can be done within a group without any spin-ups and several disks can participate in data restoration.

A storage layout that uses historic data access patterns as a hint for future accesses could further improve performance by packing multiple objects that are always accessed together into a few disk groups. The task of identifying an optimal mapping of objects to disks given a history of accesses can be modeled as an optimization problem (Reddy et al. 2015). However, given the large number of objects stored in CSD, it can be quite complicated to handle each object individually in the optimization algorithm. Thus, the problem of choosing a data layout is decomposed into two subproblems: (i) identifying clusters of objects that are accessed together from the trace and (ii) identifying an optimal mapping of objects to disks. The goal of the first step is to transform individual object access patterns into group access patterns by clustering objects that are accessed together. The optimization algorithm can then map clusters to disks. It has been shown that such an access-driven data layout approach can save

up to 78% power over random placement (Reddy et al. 2015).

CSD I/O Scheduler

The goal of the CSD's I/O scheduler is to service object requests from different clients in a way that minimizes the number of group switches while at the same time ensuring fairness across clients. The CSD group scheduling problem can be reduced to the single-head tape scheduling problem in traditional tertiary storage systems, where it has been shown that an algorithm that picks the tape with the largest number of pending requests as the target to be loaded next performs within 2% of the theoretically optimal algorithm (Prabhakar et al. 2003). If efficiency was the only goal, we could apply such an algorithm, which we henceforth refer to as *Max-Requests*, to the CSD case by picking the disk group with the maximum number of requests. However, the algorithm would not provide fairness, as a continuous stream of requests for a few popular disks can starve out requests for less popular ones.

Pelican CSD solves this problem by scheduling object requests in a *first-come first-serve (FCFS)* order to provide fairness with some parameterized slack that occasionally violates the strict FCFS ordering by reordering and grouping requests to the same disk group to improve performance (Balakrishnan et al. 2014). However, by building on FCFS, Pelican's algorithm trades off efficiency for fairness. The Skipper framework (Borovica-Gajic et al. 2016) introduces a new algorithm that strikes a balance between FCFS and Max-Requests by associating a rank with each group that is computed by considering both the number of requests that need to be serviced for that disk group, and the average time spent by requests waiting for that disk group to spin up. The scheduler always picks the group with the highest rank as the target to be spun up next. By using the number of requests in computing the rank, the scheduler behaves efficiently similar to the Max-Requests algorithm. By including the average waiting time, the scheduler ensures that a request to a less popular group that has been not been serviced for a while will get prioritized over other requests to more popular groups.

Database Query Executor

When a CSD is used as the storage back end for an analytical database engine, query execution will result in the database reading data objects directly from the CSD. In the best case, these database read requests are always serviced from a disk group that is spun up. In such a case, there would be no performance difference between using a CSD and the traditional HDD-based capacity tier. However, in the pathological case, every data access request issued by the database would incur a spin-up delay and cripple performance. Unfortunately, the average case is more likely to be similar to the pathological case due to two assumptions made by traditional databases: (1) storage subsystem has exclusive control over data allocation, and (2) the underlying storage media support random accesses with uniform access latency.

Today, most enterprise databases run in a virtualized setting in a private cloud hosted on premise or in the public cloud. In such a virtualized environment, a CSD will store data corresponding to several databases by virtualizing available storage behind an object interface, similar to OpenStack Swift (Oracle 2015) or Amazon S3 (Amazon 2015). As each database reads objects from the CSD, it has no control over the CSD data layout which is performed by the CSD storage manager. The lack of control over data layout implies that the latency to access a set of relations depends on the way they are laid out across disk groups.

Moreover, the CSD services requests from multiple databases simultaneously. Thus, even if all data corresponding to a single database is located in a single group, the execution time of a single query is not guaranteed to be free of disk spin-ups. This is because the access latency of any database request depends on the currently loaded group, which depends on the set of requests from other databases being serviced at any given time. Thus, in a virtualized enterprise data center that uses CSD as a shared service, both assumptions made by analytical database engines are invalidated leading to suboptimal query execution (Borovica-Gajic et al. 2016).

Exploiting the cost benefits of CSD while minimizing the associated performance trade-off requires eliminating unnecessary disk spin-ups. The only way of achieving such an optimal data access pattern is to have the database issue requests for all necessary data upfront so that the CSD can return data back in an order that minimizes the number of disk spin-ups. Thus, the order in which database receives data, and hence the order in which query execution happens, should be determined by the CSD to minimize the performance impact of group switches.

Unfortunately, current databases are not designed to work with such a CSD-driven query execution approach. Traditionally, databases have used a strict optimize-then-execute model to evaluate queries. The database query optimizer uses cost models and statistics gathered to determine the optimal query plan. Once the query plan has been generated, the execution engine then invokes various relational operators strictly based on the generated query plan with no run-time decision-making. This results in pull-based query execution where the database explicitly requests data in an order determined by the query plan. This pull-based execution approach is incompatible with the CSD-driven approach, as the optimal order chosen by the CSD for minimizing group switches is different from the ordering specified by the query optimizer.

In order to enable CSD-driven query execution, analytical database engines should adopt push-based query execution instead of a pull-based one. There are two approaches that can be used to perform push-based query execution. The first approach is to tightly couple query execution with I/O scheduling in such a way that the scheduler knows and delivers only objects that are required for the query executor to make progress. For instance, in a two-table hash join, the scheduler would deliver objects corresponding to the build relation over which the hash table is built before delivering the probe relation. Such an approach was used by tertiary database engines (Sarawagi and Stonebraker 1996) and makes two assumptions: (i) the database has exclusive access to the storage device, and (ii) the I/O scheduler on the storage device is aware

of database query execution. Unfortunately, both assumptions are not true today with CSD, as CSD storage is exposed behind an object interface and shared among multiple databases.

The second approach, exemplified by the Skipper framework (Borovica-Gajic et al. 2016), is to perform CSD-driven, push-based, out-of-order execution of queries by building on work done in *adaptive query processing (AQP)* (Deshpande et al. 2007). *Multiway join (MJoin)* (Viglas et al. 2003) is one such AQP technique that enables out-of-order execution by using an n-ary join and symmetric hashing to probe tuples as data arrives, instead of using blocking binary joins whose ordering is predetermined by the query optimizer. However, the incremental nature of symmetric hashing in traditional MJoin requires buffering all input data, as tuples that are yet to arrive could join with any of the already received tuples. Thus, in the worst-case scenario of a query that involves all relations in the dataset, the MJoin cache must be large enough to hold the entire dataset. This requirement makes traditional MJoin inappropriate for the CSD use case as having a buffer cache as large as the entire dataset defeats the purpose of storing data on the CSD. Skipper solves this problem by redesigning both MJoin and database buffer caching algorithms to work in concert such that MJoin can perform query execution even with limited cache capacity (Borovica-Gajic et al. 2016).

Examples of Application

With the right combination of layout, I/O scheduling, and query execution, cold data analytic engines like Skipper have demonstrated that it is possible to mask the long access latency of CSD for latency-insensitive batch analytic workloads. Thus, the obvious application for CSD is as the medium of choice for storing cold data, and a natural way of integrating CSD in the four-tier storage hierarchy shown in Fig. 1 is to use it for building a new cold storage tier that stores only cold data.

However, CSD could potentially have a much larger impact on the storage hierarchy based

on two observations. First, with latency-critical workloads running in the performance tier, the HDD-based capacity tier is already limited to batch analytic workloads today. Second, due to the use of high-density SMR disks and MAID techniques, CSD can offer cost and capacity comparable to the tape-based archival tier. Given these two observations, it might be feasible to get rid of the capacity and archival tiers by using a single consolidated cold storage tier. Such an approach would result in the four-tier hierarchy shown in Fig. 1 being reduced to a three-tier hierarchy with DRAM or SSD in the performance tier, CSD in the cold storage tier, and tape in the backup tier. Recent studies report that enterprises can lower their total cost of ownership (TCO) between 40% and 60% by using such storage consolidation (Borovica-Gajic et al. 2016). In terms of absolute savings, these values translate to hundreds of thousands of dollars for a 100TB database and tens of millions of dollars for larger PB-sized databases.

The implications and benefits of using CSD are also applicable to cloud service providers. For instance, cloud providers have already started deploying custom-built CSD for storing cold data (Bandaru and Patiejunas 2015; Bhat 2016; Google 2017). An interesting area of future work involves exploring implementation and pricing aspects of cloud-hosted “cheap-analytics-over-CSD-as-a-service” solutions. Such services would benefit both customers and providers alike, as providers can increase revenue by expanding their storage-as-a-service offering to include cheap analytic services and customers can reduce the TCO by running latency-insensitive analytic workloads on data stored in CSD.

Future Directions for Research

Systems like Pelican (Balakrishnan et al. 2014) and Skipper (Borovica-Gajic et al. 2016) are a first essential step toward broader adoption of cold data analytics, in general, and CSD in particular. There are several avenues of future work with respect to both cold storage hardware and data analytic software.

Over the past few years, several other systems have been built using alternate storage media to reduce the cost of storing cold data. For instance, DTStore (Lee et al. 2016) uses LTFS tape archive for reducing the TCO of online multimedia streaming services by classifying data based on access pattern and storing cold data in tape drives. ROS (Yan et al. 2017) is a rack-scale optical disk library that provides PB-sized storage with in-line accessibility for cold data using thousands of optical disks packed in a single 42U rack. Nakshatra (Kathpal and Yasa 2014) enables Hadoop-based batch analytic workloads to run directly over data stored in tape archives. Similar to Skipper, Nakshatra also modifies both the tape archive’s I/O scheduler and the MapReduce run time to perform push-based execution to hide the long access latency of tape drives.

Today, it is unclear as to how these alternative storage options fare with respect to SMR-HDD-based CSD as the storage media of choice for storing cold data. Some storage media, like optical disks, have the shortcoming that their sequential access bandwidth is substantially lower than HDD or tape. Tape and optical media also have very high access latency compared to CSD. However, an interesting artifact of using push-based engines like Skipper is that query execution becomes much less sensitive to the long access latency of storage devices. Similarly, optical disks are traditionally known to have longer life span compared to HDD and tape. However, it is possible to deal with even frequent media failures by trading off some storage capacity for improved reliability by using erasure coding and data replication techniques in software. Thus, further research is required to understand the implications of storing cold data on these storage devices by running realistic cold data analytic workloads and performing a comparative study of performance and reliability.

On the software side, current systems like Skipper and Nakshatra only target a simplified subset of SQL or MapReduce-based analytic workloads. They do not support complex business intelligence workloads that require operators like data cube (Gray et al. 1997), data mining workloads like clustering and

classification, or iterative machine learning workloads. They also do not consider the availability of additional layers of persistent storage that could be used as caches or prefetch buffers for data stored in CSD or as an extended memory that can be used to swap out intermediate data structures generated by operators like MJoin. Further research is also required to understand how push-based execution can be extended to these workloads.

Clojure

Nicolas Modrzyk
Karabiner Software, Tokyo, Japan

It's easy to get sidetracked with technology, and that is the danger, but ultimately you have to see what works with the music and what doesn't. In a lot of cases, less is more. In most cases, less is more.

Herbie Hancock

Definitions

How to use some best features of Clojure, a LISP like functional programming language, to target big data analysis.

Introduction

Rich Hickey's Clojure language is not in the new section of hyped languages anymore, which is great news for everybody interested in Clojure. The language has just reached [version 1.9](#), and the amount of strong and precise development that went into this new version deserved an ova-

tional praise. But why would you use Clojure nowadays? What can it do for you that the available trillions of other languages available on the market cannot do, or not as efficiently, with programming in Java 1.9, Python, or NodeJS getting all the hype and the tooling nowadays, with even big consulting firms entering the NodeJS market. Clojure being a LISP has a fantastic minimal core and a very small set of functions and data structures. Of course, you have asynchronous thread-safe parallel queues, of course you have parallel processing of all the data structures, and it is also a breeze to go for test-driven development, but what's more is that Clojure changes the way you think about programming and write programs in general. It makes you think in small, versatile, reusable building block. Eventually the users of Clojure, the people writing code with it, do not really think about it anymore; it just becomes the way they naturally code, whatever the language. Clojure also makes your code smaller, easier to debug, maintain, and push to production with less fear of being woken up at 3 AM for issues. Your program is consistent and reliable. Let's review some of the Clojure features and ecosystem that makes Clojure a language of choice for handling big data.

Clojure for Instant Prototyping, with a REPL

Many languages have a REPL nowadays, a Read-Eval-Print-Loop, like a shell prompt, where you can write and execute code block by block. Clojure is not the only language armed with a REPL, but it is one of the most convenient because many functions consist of a simple code block that usually holds on one line.

Take the Fibonacci sequence, for example, it does hold as a one liner

```
(def fib-seq
  ((fn rfib [a b]
    (lazy-seq
      (cons a
        (rfib b (+ a b))))))
  0 1))
```

and is still easily readable.

You usually start a REPL with Leiningen (or boot), the two most famous build tools that actually install Clojure at the same time and make you in command of a build environment at the same time.

Starting a REPL with:

```
lein repl
```

or

```
boot repl
```

And you can copy paste the code above and retrieve the first n elements of the Fibonacci sequence, with the result printed below.

```
(take 10 fib-seq)
;(0 1 1 2 3 5 8 13 21 34)
```

When working with Clojure, programmers would usually always have a REPL running to try ideas on the run or in a business meeting.

Clojure for Code as Data

Beyond having a REPL, Clojure being a LISP has its syntax and its code execution commands virtually identical. Clojure code is made of successive lists of lists of symbols.

What does that mean?

At the REPL, since you have it open, if you want to perform the simple Math of adding 1 to 1, you would write: (remember the LISP prefix notation ...)

```
(+ 1 1)
; that returns 2
```

The code is made of a single sequence, surrounded by parenthesis, and the sequence itself is made of 3 characters, +, 1, and 1.

What the REPL does is converting the string you have written into a sequence and then evaluating its content. To perform the same thing the REPL is doing, you can use the function read-string, where read-string takes a string and converts it to a sequence of symbols, similar to an abstract syntax tree.

```
(read-string "(+ 1 1)")
; (+ 1 1)
```

To evaluate the list, you call eval on the list, which executes the code and returns 2 again.

```
(eval
  (read-string "(+ 1 1")))
; 2
```

To run eval on a sequence directly, people usually use the ‘ (quote) symbol, where the quote means this is already a set of symbols as a sequence, no need to read it.

```
(eval '(+ 1 1))
; 2
```

Why is this nice? It makes it really easy to tweak the compilation step found in coding. To achieve that, Clojure provides macros, which are evaluated during the pre-processing phase, transforming the lists of lists of sequence before they are executed. See the plus-one macro below, which adds one to the variable x.

```
(defmacro plus-one [x]
  '(+ 1 ~x))
```

When performing the compiling step of eval, this macro will rewrite the list as a list of 3 symbols, as seen above, and as expanded below:

```
(clojure pprint/print
  (macroexpand '(plus-one 1)))
; (clojure.core/+ 1 1)
```

This is different than writing a simple function, plus-one-fn:

```
(defn plus-one-fn [x] (+ 1 x))
```

In the sense, that the block code is written, and evaluated as is, not rewritten then evaluated. Which takes us to ...

Clojure Threading Macros

Clojure Macros have the ability to rewrite the sequence of lists of lists before they are executed. Two of the most used macros are `->` and `->>`. The first macro, `->`, takes a list of forms and rewrite in a different order. The new order is such that the previous step block comes as the first parameter, and so the second element of the list in the next step. With the simple `(+ 1 1)` example, again this gives:

```
(-> 1
    (+ 1))
; 2
```

The rewritten code can be expanded and seen using Clojure's macroexpand:

```
(macroexpand `(-> 1 (+ 1)))
; (clojure.core/+ 1 1)
```

Those two macros come very handy when handling data. Let's take a new example with `->>`, the macro that rewrites code with the previous code block becoming the last element of next steps list. Say you want to count the sum of all the integers from 1 to 100000, with the `->>` macro, this would be written:

```
(->> 100000
      (range)
      (apply +))
```

or as a one liner:

```
(->> 100000 (range) (apply +))
```

Again, using macroexpand, you would notice this expands to:

```
(apply + (range 100000))
```

But was much more readable. An example of a more complex operation, where:

- a sequence from 0 up to 100000 is created,
- then each element of the sequence is incremented,
- then each element of the sequence is incremented,
- and finally create a vector of the result

The above processing could be written like this:

```
(into []
  (filter
    even?
    (map inc (range 100000))))
```

Or the definitely more readable:

```
(->>
  100000
  (range)
  (map inc)
  (filter even?)
  (into []))
```

Those Clojure threading macros tend to effectively be usable in many places. For example, in the Origami library, which is a Clojure wrapper around OpenCV, transformations can be applied to images in a sequence also using the `->` macro, as shown below:

```
(->
  (imread "doc/cat_in_bowl.jpeg")
  (cvt-color! COLOR_RGB2GRAY)
  (canny! 300.0 100.0 3 true)
  (bitwise-not!)
  (u/resize-by 0.5)
  (imwrite "doc/canny-cat.jpg"))
```

The result of the transformation shown in the pictures below (Figs. 1 and 2).

Clojure Laziness and Reducers

Usually Clojure tries to do the least amount of work as possible. Meaning, lists of lists are lazily evaluated, effectively evaluated only when really required. Laziness is a core feature of Clojure and

Clojure, Fig. 1 Cat in a bowl

Clojure, Fig. 2 Cat in a bowl

of many programmers. In the example below, a binding named lazy-var is created.

```
(def lazy-var (plus-one-fn 3))
```

The binding was created, but it was not really used yet. It will only be used when, for example, it is required to be printed.

```
(println lazy-var);  
4
```

Laziness is used in many functions of Clojure core, so those functions keep a good balance between efficiency and laziness. (Isn't that what we are all trying to achieve anyway?) Reducers, or reducing functions, on the contrary know they will be combined to be applied on collections that will finally turn into a realized result, realized taken in the sense of not-lazy.

And so, knowing this, reducers can efficiently work in parallel across all the elements of collections they are being applied to. Here is the simple threading example again, this time using reducers.

```
(require  
'[clojure.core.reducers :as r])  
  
(->>  
100000  
(range)  
(r/map inc)  
(r/filter even?)  
(into []))
```

It looks pretty much the same on paper, apart from the r/ prefixes added to the map and filter functions. What does not show on paper is the

fact that the r/map and r/filter functions have been running in parallel and, on sizeable collections, the time required to evaluate all the forms is substantially faster.

The [claypool library](#), while not an official Clojure library, is quite convenient to specify the size of the different thread pools used to do parallel processing on collections.

In Clojure, there is an infamous function named pmap that has been known to make great use of all the cores available to the runtime. (And take down clusters by using all the possible resources available.)

In Clojure, to create a sequence of five elements from 0 to 4 and increase all the elements sequentially, map is usually used.

```
(->>  
5  
(range)  
(map inc))
```

To perform the same processing using as many cores as possible, its parallel version named pmap is usually used.

```
(->>  
5  
(range)  
(pmap inc))
```

And to perform the same parallel work again, but using only four cores, the claypoole library version of pmap could be used, this time specifying the thread pool size.

```
(require  
'[com.climate.claypoole :as cp])  
  
(->>  
5  
(range)  
(cp/pmap 4 inc))
```

Clojure for Multi-threading

Reducers and the different versions of pmap are perfect to apply computations in parallel. To perform asynchronous message handling between different blocks of code, Clojure comes with a core library named core.async, available on [github](#).

To present this, a small example made of two asynchronous blocks of code, exchanging messages through a channel will be used.

One asynchronous block will send messages to the channel, while the other will read messages from that same channel and print them out.

This very first example creates a thread and prints message asynchronously by itself.

```
(require
  '[clojure.core.async
    :refer :all])

(thread
  (dotimes [n 10]
    (Thread/sleep 100)
    (println "hello:" n)))
```

If executed at the REPL, as soon as the block of code is evaluated, evaluation does not block and returns a reference to the executing async thread.

In the meantime, the thread goes on with his happy life and starts printing hello messages every 100 ms.

This second example creates two threads. A thread will update an atom, a variable ready for asynchronous updates, by safely increasing its value by one. A second thread safely reads the value of the atom, while it's being updated by the first thread.

```
(def my-value (atom 0))

(thread
  (dotimes [n 10]
    (Thread/sleep 1000)
    (swap! my-value inc)))

(thread
  (dotimes [_ 5]
    (Thread/sleep 1000)
    (println
      "Counter is now:"
      @my-value)))
```

The number of threads can be increased, and in action, no deadlock occurs. Updates to the atom are done using the STM transaction model that prevents deadlock to occur using transaction to perform updates on atoms.

The third asynchronous example removes the use of the intermediate atom, by directly acting on messages sent via a channel.

The first thread still creates messages, but this time sends them to the newly created hi-chan channel, while the second thread reads the value coming through the channel and prints them out.

```
(def hi-chan (chan))

(thread
  (dotimes [n 10]
    (Thread/sleep 1000)
    (>!! hi-chan
      (str "hello:" n)))

(thread
  (dotimes [_ 10]
    (Thread/sleep 1000)
    (println
      "Channel value:"
      (<!! hi-chan))))
```

Here again, both thread code blocks return immediately without blocking the execution of the main thread, making all this feasible to execute at the REPL.

Core.async can also run in the browser via ClojureScript and is a very compelling strategy to create a back buffer for onscreen user events and other asynchronous data requests.

Clojure for the Backend

Many frameworks exist for server and api development in Clojure, but most of them seem to be inspired or paying close attention to the efforts that were put into the ring and compojure mini-frameworks.

Ring itself is an abstraction over HTTP, while Compojure is a routing library that can, and mostly does, run on top of ring.

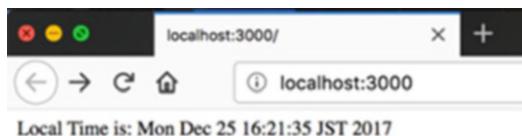

If you have Leiningen installed, getting started with Compojure is as easy as using the compojure project template.

```
lein new compojure intro
```

This creates a prod-ready but also development-ready environment to start writing code.

From the newly created intro folder, a ring development server can be started using the following command.

```
lein ring server
```

Clojure, Fig. 3 Ring HTTP get

This will set up everything needed, apart from your favorite text editor. The main core.clj file in the created project looks deceptively simple, with a single route defined for a GET request on the root context, anything else returning a simple Not Found string.

```
(defroutes app-routes
  (GET "/" [] "Hello World")
  (route/not-found "Not Found"))

(def app
  (wrap-defaults
    app-routes
    site-defaults))
```

The main route can be updated by adding time via a Java date object, using basic Clojure/Java Interop.

```
(defroutes app-routes
  (GET "/" []
    (str
      "Server Time is: "
      (java.util.Date())))
  (route/not-found "Not Found"))
```

This is of course nowhere near a production-ready app, but the point here is that this creates a fully ready development environment in a few minutes, thus bringing server-side prototyping setup down to pretty much zero (Fig. 3).

To get further into the backend programming in Clojure, there is a nice introduction in the blog post below, when you want to quickly grasp all the ring/compojure concepts:

[sinatra-docs-in-clojure](#)

Clojure for the Front End

ClojureScript is Clojure ported to javascript runtime, and why and how to use it is extensively covered in the Reactive with ClojureScript apress book.

The sheer happiness that results from using ClojureScript for the frontend is that this makes your full application code to be written all in Clojure:

- the backend,
- the frontend, and
- the data exchanged between both the backend and the frontend can also be in the Extensible Data Notation, a subset of Clojure.

Clojure's Reagent is a library that acts as a thin wrapper around React, the frontend framework created by Facebook. It removes the extra javascript boiler-plate to make the code very compact, easier to read, write, and maintain.

Reagent can be combined with, among many others, core.async so to get asynchronous looking code (remember only JavaScript thread in the browser) without sacrificing readability.

As for Clojure on the backend, here again there is a Leiningen project template for the reagent framework that can be created with the command below.

```
lein new reagent reagent-intro
```

To get started with the reagent setup, this Leiningen needs two commands to be started, one for the backend and one for the frontend.

Here is the command to start the server development environment:

```
lein ring server
```

Here is the command to start the client development environment:

```
lein figwheel
```

The setup in place, it is now possible to start editing the core.cljs file in the created project.

```
(defn some-component []
  [:div
   [:h3 "I am a component!"]
   [:p.someclass
    "I have " [:strong "bold"]
    [:span {:style {:color "#cc77cc"}}
     " and red"] " text ."]])
```

```
(defn mount-root []
  (reagent/render
    [some-component]))
```

```
(.getElementById js /document
  "app"))

(defn init []
  (mount-root))
```

The code above renders to HTML and is returned to the client as shown in the figure below (Fig. 4).

`init!` is defined and called only once in development mode; thus the `mount-root`, which can be rewritten, is kept separate.

The function `mount-root` itself takes a reagent component and a mount point in the current HTML dom, here `< div id = app >< /div >`, and puts the component at that place.

A component is defined as a standard Clojure function, whose return value is a special kind of markup specific to Clojure, named hiccup.

Hiccup is eventually taken and transformed from a list of Clojure vectors to valid HTML.

Here the component `some-component` output some basic HTML elements like `div`, `h3`, `p`, and `span` elements.

Components can be combined together, so it is possible to create a component from two smaller components, thus being completely in line with Clojure big philosophy of building blocks.

The code below creates a simple Reagent component `top-component`, made of two components of type `some-component`.

```
(defn top-component []
  [:div
   [some-component]
   [some-component]])
```

Note here that even though `some-component` is created using a single common definition, the two mounted `some-component` are different instances.

I am a component!

I have bold and red text.

Also, if not obvious, it is not required to have Clojure on the backend to be able to use ClojureScript and Reagent.

Many now in production projects did a rewrite of their frontend from JavaScript to ClojureScript first, to improve maintainability, without updating the server-side code.

Clojure for Big Data

Sparkling and Flambo are two among the Clojure offers to handle spark data and spark clusters.

Flambo is slightly easier and more importantly makes use of the previously introduced threading macros, `->` and `->>`.

A simple bang-in example of using Flambo is shown below. The example counts the total number of characters of each line, line by line, and then reduces to a single value of the overall total over all the lines.

```
(->
 (f/text-file sc "data.txt")
 ;; returns an unrealized
 ;; lazy dataset
 (f/map (f/fn [s] (count s)))
 ;; returns RDD array
 ;; of length of lines
 (f/reduce (f/fn [x y] (+ x y))))
 ;; use an inline anonymous
 ;; function for reduction
```

Here, `sc` is a Spark Context, which can target a local in-memory cluster, a stand-alone spark cluster, or a mesos cluster.

```
(def c
 (-> (conf/spark-conf)
       (conf/master "local")
       (conf/app-name "infinity")))
 (def sc (f/spark-context c))
```

To perform a spark job, a spark resilient distributed dataset is used, and in the first example presented, the dataset was created by reading from a text file from the local file system.

Creating a Spark RDD can also be done in a few other different ways, like a RDD made from blobs of files stored in HDFS.

```
(def data
 (f/text-file
   sc
   (str
```

```
"hdfs://hostname:port"
"/home/data"
"/*/*.bz2")
```

Of course, using regular Java Interop, it is also possible to target other RDD sources like Cassandra, HBase, and any other storage supported by hadoop.

Flambo itself allows to create valid Spark job that can be deployed and run as any other jobs, but one main limitation it has is that it does not do allow to write and run new job at the REPL without using AOT.

AOT is ahead-of-time compilation meaning you need to statically compile all your code before running, which does prevent it from being created and run at the REPL.

This limitation sparked, pun intended, a new project worth considering named [powderkeg](#), whose goal is to overcome that very limitation.

Clojure for Machine Learning

To go beyond simple big data, and as a recent and strong contender to the TensorFlow framework, Cortex has recently joined the Clojure ecosystem for machine learning.

Some starters and favorites examples to look at to fully understand how Cortex works are: [The cats and dogs sorting example](#) or [the fruits classification example](#).

In this short entry, we will present briefly training a network for xor operations, as it has recently been included in the cortex examples section and is very simple to go over.

As known, xor operations take two values in input and one value in output. This is represented here by creating a dataset to train the network, made of a vector of elements, where each element is a map with an input, :x, and an output, :y, value.

```
(def xor-dataset
  [{:x [0.0 0.0] :y [0.0]}
   {:x [0.0 1.0] :y [1.0]}
   {:x [1.0 0.0] :y [1.0]}
   {:x [1.0 1.0] :y [0.0]}])
```

The neural network to be created will be a linear network of three layers, where the activation

layer will be the hyperbolic tangent activation function. (See: [tanh function](#))

In the definition of the network, input and output layer each specify how many variables are available, and so below:

- 2 for the input, and
- 1 for the output

The network is then created almost by translating written text to a network definition using the cortex api.

```
(def nn
  (network/linear-network
    [(layers/input 2 1 1 :id :x)
     (layers/linear->tanh 10)
     (layers/linear 1 :id :y)]))
```

Now along with the dataset, let's create a trained version of this neural network.

In machine learning, training a network is usually done using two data sets.

- a training set, to tell the network what is expected and correct
- a testing set, to test the network and check whether how it performs.

The training stage is then achieved by passing those two data sets, but here the same dataset is used.

The number of rounds of training is also specified, here 3000 to get an efficient network.

```
(def trained
  (train/train-n
    nn
    xor-dataset
    xor-dataset
    :batch-size 4
    :epoch-count 3000
    :simple-loss-print? false))
```

Each training step outputs some output of the current state of the trained network, notably whether it performed better or not than its own version in the previous step.

```
Training network:
...
Loss for epoch 1:
  (current) 0.7927149 (best)
Saving network to
  trained-network.nippy
```

Finally, to validate results yet another dataset is created, of usually new values, and of course only input values.

```
(def new-dataset
  [{:x [0.0 0.0] }
   {:x [0.0 1.0] }
   {:x [1.0 0.0] }
   {:x [1.0 1.0] }])
```

Then follows running the trained network with this new dataset.

```
(clojure pprint/pprint
  (execute/run
    trained
    new-dataset))
```

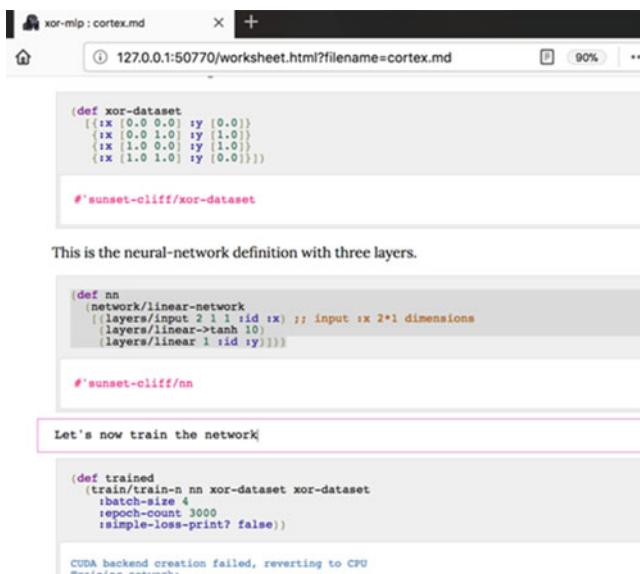

The result is, not surprisingly, very accurate, as shown from a screenshot of the network executed at the REPL.

```
[{:y [0.4397728145122528]}
{:y [0.3689133822917938]}
{:y [0.37379032373428345]}
{:y [0.4282912313938141]}]
```

Clojure for Teaching

Another small in size but very important contribution to the Clojure ecosystem is named Gorilla.

Clojure, Fig. 5 Gorilla

Simply said, Gorilla is a web-based REPL, which allows to create annotated NoteBooks, along ready to be executed code blocks, all in the browser.

It is made of a server-side part that runs a background repl and a simple compojure-based API ready to receive Clojure code as string.

The second part is a Clojure frontend, running a websocket sending Clojure code to the REPL on the server, and waits for the result of the execution and displays it.

The gorilla framework can be added to any of your project using a Leiningen plugin.

This plugin is added either to the project definition project.clj or the global leiningen profile, profile.clj.

```
[lein-gorilla "0.4.0"]
```

Starting the gorilla environment can now be done using a Leiningen command:

```
lein gorilla
```

Gorilla now makes the library and source code available through a web interface. All the presented Cortex code could be run in the browser, for example, and a possible figure is shown below (Fig. 5).

Beyond

Other key Clojure-based projects that can also be looked into are:

- Riemann is an event aggregator, monitoring system entirely written in Clojure. It can receive and process events from almost anything you can imagine.
- Apache Storm almost entirely written in Clojure, reportedly clocks millions of tuples processed per second per node. This is a framework of choice, and if you have complete decision over the technologies used in your next project, comes as a no brainer.
- Datomic, which is a distributed persistence and query model over an historical set of stored facts.

Conclusion

This short entry presented diverse possibilities on how to put Clojure straight into action to:

- Help developers in writing code using a REPL, thus reducing usual life cycle overhead associated with many programming languages
- Reduce maintenance associated with writing code in other languages, by considerably reducing the lines of code used to work and transform data structure by writing macros and/or using the already available threading macros
- Enable pinpoint custom usage of the cores available to each runtime node of your application. Parallel computations is available to most data structures
- core.async allows message passing between different components of your application. Point of interaction can be defined with atom, or channels, and by being reliably highlighted, reduces the coupling between different parts of the code, making the overall end product resistant to changes.
- Front-to-End Clojure brings commonness and portability of the application code thus helping

avoid usual pitfalls when doing client-server programming, in simple sync-ed HTTP requests or real-time websockets.

- Also, not only the code of the application but the projects metadata used by the build tool Leiningen itself was a DSL written in Clojure.
- Bringing entry points to directly interact with any Spark cluster via the REPL, thus making it easier to debug common and more advanced distributed data problems.
- It is also ready for machine learning, providing a real and powerful alternative to TensorFlow with Cortex.
- Finally, the ability to consume all the above, and present annotated pages of work, ready to be distributed and ready for reuse via Gorilla Notebook-style environment.

Cloud Big Data Benchmarks

► [Virtualized Big Data Benchmarks](#)

Cloud Computing for Big Data Analysis

Fabrizio Marozzo and Loris Belcastro
DIMES, University of Calabria, Rende, Italy

Definitions

Cloud computing is a model that enables convenient, on-demand network access to a shared pool of configurable computing resources (e.g., networks, servers, storage, applications, and services) that can be rapidly provisioned and released with minimal management effort or service provider interaction (Mell and Grance 2011).

Overview

In the last decade, the ability to produce and gather data has increased exponentially. For ex-

ample, huge amounts of digital data are generated by and collected from several sources, such as sensors, web applications, and services. Moreover, thanks to the growth of social networks (e.g., Facebook, Twitter, Pinterest, Instagram, Foursquare, etc.) and the widespread diffusion of mobile phones, every day millions of people share information about their interests and activities. The amount of data generated, the speed at which it is produced, and its heterogeneity in terms of format represent a challenge to the current storage, process, and analysis capabilities. Those data volumes, commonly referred as Big Data, can be exploited to extract useful information and to produce helpful knowledge for science, industry, public services, and in general humankind.

To extract value from such data, novel technologies and architectures have been developed by data scientists for capturing and analyzing complex and/or high velocity data. In general, the process of knowledge discovery from Big Data is not so easy, mainly due to data characteristics, such as size, complexity, and variety, that are required to address several issues. To overcome these problems and get valuable information and knowledge in shorter time, high-performance and scalable computing systems are used in combination with data and knowledge discovery techniques.

In this context, Cloud computing has emerged as an effective platform to face the challenge of extracting knowledge from Big Data repositories in limited time, as well as to provide an effective and efficient data analysis environment for researchers and companies. From a client perspective, the Cloud is an abstraction for remote, infinitely scalable provisioning of computation and storage resources (Talia et al. 2015). From an implementation point of view, Cloud systems are based on large sets of computing resources, located somewhere “in the Cloud,” which are allocated to applications on demand (Barga et al. 2011). Thus, Cloud computing can be defined as a distributed computing paradigm in which all the resources, dynamically scalable and often virtualized, are provided as services over the Internet. As defined by NIST (National Institute of Stan-

dards and Technology) (Mell and Grance 2011), Cloud computing can be described as: “*A model for enabling convenient, on-demand network access to a shared pool of configurable computing resources (e.g., networks, servers, storage, applications, and services) that can be rapidly provisioned and released with minimal management effort or service provider interaction.*” From the NIST definition, we can identify five essential characteristics of Cloud computing systems, which are (i) on-demand self-service, (ii) broad network access, (iii) resource pooling, (iv) rapid elasticity, and (v) measured service.

Cloud computing vendors provide their services according to three main distribution models:

- *Software as a Service (SaaS)*, in which software and data are provided through Internet to customers as ready-to-use services. Specifically, software and associated data are hosted by providers, and customers access them without the need to use any additional hardware or software.
- *Platform as a Service (PaaS)*, in an environment including databases, application servers, development environment for building, testing, and running custom applications. Developers can just focus on deploying of applications since Cloud providers are in charge of maintenance and optimization of the environment and underlying infrastructure.
- *Infrastructure as a Service (IaaS)*, that is an outsourcing model under which customers rent resources like CPUs, disks, or more complex resources like virtualized servers or operating systems to support their operations. Compared to the PaaS approach, the IaaS model has a higher system administration costs for the user; on the other hand, IaaS allows a full customization of the execution environment.

Key Research Findings

Most available data analysis solutions today are based on open-source frameworks, such as

Hadoop (<https://hadoop.apache.org/>) and Spark (<https://spark.apache.org/>), but there are also some proprietary solutions proposed by big companies (e.g., IBM, Kognitio).

Concerning the distribution models of Cloud services, the most common ones for providing Big Data analysis solutions are PaaS and SaaS. Usually, IaaS is not used for high-level data analysis applications but mainly to handle the storage and computing needs of data analysis processes. In fact, IaaS is the more expensive distribution model, because it requires a greater investment of IT resources. On the contrary, PaaS is widely used for Big Data analysis, because it provides data analysts with tools, programming suites, environments, and libraries ready to be built, deployed, and run on the Cloud platform. With the PaaS model, users do not need to care about configuring and scaling the infrastructure (e.g., a distributed and scalable Hadoop system), because the Cloud vendor will do that for them. Finally, the SaaS model is used to offer complete Big Data analysis applications to end users, so that they can execute analysis on large and/or complex datasets by exploiting Cloud scalability in storing and processing data.

As outlined in Li et al. (2010), users can access Cloud computing services using different client devices, Web browsers, and desktop/mobile applications. The business software and user data are executed and stored on servers hosted in Cloud data centers, which provide storage and computing resources. Such resources include thousands of servers and storage devices connected to each other through an intra-Cloud network.

Several technologies and standards are used by the different components of the architecture. For example, users can interact with Cloud services through SOAP-based or RESTful Web services (Richardson and Ruby 2008) and Ajax technologies, which let Cloud services to have look and interactivity equivalent to those provided by desktop applications.

Developing Cloud-based Big Data analysis applications may be a complex task, with specific issues that go beyond those of stand-alone

application programming. For instance, Cloud programming must deal with deployment, scalability, and monitoring aspects that are not easy to handle without the use of ad hoc environments (Talia et al. 2015). In fact, to simplify the development of Cloud applications, specific development environments are often used. Some of the most representative Cloud computing development environments currently in use can be classified into four types:

- *Integrated development environments*, which are used to code, debug, deploy, and monitor Cloud applications that are executed on a Cloud infrastructure, such as Eclipse, Visual Studio, and IntelliJ.
- *Parallel-processing development environments*, which are used to define parallel applications for processing large amount of data that are run on a cluster of virtual machines provided by a Cloud infrastructure (e.g., Hadoop and Spark).
- *Workflow development environments*, which are used to define workflow-based applications that are executed on a Cloud infrastructure, such as Swift and DMCF.
- *Data-analytics development environments*, which are used to define data analysis applications through machine learning and data mining tools provided by a Cloud infrastructure. Some examples are Azure ML and BigML.

The programming model is a key factor to be considered for exploiting the powerful features of Cloud computing. MapReduce (Dean and Ghemawat 2004) is widely recognized as one of the most important programming models for Cloud computing environments, being it supported by Google and other leading Cloud providers such as Amazon, with its Elastic MapReduce service, and Microsoft, with its HDInsight, or on top of private Cloud infrastructures such as OpenNebula, with its Sahara service. Hadoop is the best-known MapReduce implementation, and it is commonly used to develop parallel applications that analyze big amounts of data on Clouds. In fact, Hadoop

ecosystem is undoubtedly one of the most complete solutions for data analysis problem, but at the same time, it is thought for high-skilled users.

On the other hand, many other solutions are designed for low-skilled users or for low-medium organizations that do not want to spend resources in developing and maintaining enterprise data analysis solutions. Two representative examples of such data analysis solutions are Microsoft Azure Machine Learning and Data Mining Cloud Framework.

Microsoft Azure Machine Learning (Azure ML) (<https://azure.microsoft.com/services/machine-learning-studio/>) is a SaaS for the creation of machine learning workflows. It provides a very high level of abstraction, because a programmer can easily design and execute data analytics applications by using simple drag-and-drop web interface and exploiting many built-in tools for data manipulation and machine learning algorithms.

The Data Mining Cloud Framework (DMCF) (Marozzo et al. 2015) is a software system developed at University of Calabria for allowing users to design and execute data analysis workflows on Clouds. DMCF supports a large variety of data analysis processes, including single-task applications, parameter-sweeping applications, and workflow-based applications. A workflow in DMCF can be developed using a visual- or a script-based language. The visual language, called VL4Cloud (Marozzo et al. 2016), is based on a design approach for end users having a limited knowledge of programming paradigms. The script-based language, called JS4Cloud (Marozzo et al. 2015), provides a flexible programming paradigm for skilled users who prefer to code their workflows through scripts.

Other solutions have been created mainly for scientific research purposes, and, for this reason, they are poorly used for developing business applications (e.g., E-Science Central, COMPSs, and Sector/Sphere).

e-Science Central (e-SC) (Hiden et al. 2013) is a Cloud-based system that allows scientists to store, analyze, and share data in the Cloud. It pro-

vides a user interface that allows programming visual workflows in any Web browser.

e-SC is commonly used to provide a data analysis back end to stand-alone desktop or Web applications. To this end, the e-SC API provides a set of workflow control methods and data structures. In the current implementation, all the workflow services within a single invocation of a workflow execute on the same Cloud node.

COMPSs (Lordan et al. 2014) is a programming model and an execution runtime, whose main objective is to ease the development of workflows for distributed environments, including private and public Clouds. With COMPSs, users create a sequential application and specify which methods of the application code will be executed remotely. Providing an annotated interface where these methods are declared with some metadata about them and their parameters does this selection. The runtime intercepts any call to a selected method creating a representative task and finding the data dependencies with all the previous ones that must be considered along the application run.

Sector/Sphere (Gu and Grossman 2009) is an open-source Cloud framework designed to implement data analysis applications involving large, geographically distributed datasets. The framework includes its own storage and compute services, called Sector and Sphere, respectively, which allow to manage large dataset with high performance and reliability.

Examples of Application

Cloud computing has been used in many scientific fields, such as astronomy, meteorology, social computing, and bioinformatics, which are greatly based on scientific analysis on large volume of data. In many cases, developing and configuring Cloud-based applications requires a high level of expertise, which is a common bottleneck in the adoption of such applications by scientists.

Many solutions for Big Data analysis on Clouds have been proposed in bioinformatics, such as Myrna (Langmead et al. 2010), which

is a Cloud system that exploits MapReduce for calculating differential gene expression in large RNA-seq datasets.

Wang et al. (2015) propose a heterogeneous Cloud framework exploiting MapReduce and multiple hardware execution engines on FPGA to accelerate the genome sequencing applications.

Cloud computing has been also used for executing complex Big Data mining applications. Some examples are as follows: Agapito et al. (2013) perform an association rule analysis between genome variations and clinical conditions of a large group of patients; Altomare et al. (2017) propose a Cloud-based methodology to analyze data of vehicles in a wide urban scenario for discovering patterns and rules from trajectory; Kang et al. (2012) present a library for scalable graph mining in the Cloud that allows to find patterns and anomalies in massive, real-world graphs; and Belcastro et al. (2016) propose a model for predicting flight delay according to weather conditions.

Several other works exploited Cloud computing for conducting data analysis on large amount of data gathered from social networks. Some examples are as follows:

You et al. (2014) propose a social sensing data analysis framework in Clouds for smarter cities, especially to support smart mobility applications (e.g., finding crowded areas where more transportation resources need to be allocated); Belcastro et al. (2017) present a Java library, called ParSoDA (Parallel Social Data Analytics), which can be used for developing social data analysis applications.

Future Directions for Research

Some of most important research trends and issues to be addressed in Big Data analysis and Cloud systems for managing and mining large-scale data repositories are:

- *Data-intensive computing.* The design of data-intensive computing platforms is a very significant research challenge with the goal of building computers composed of a large num-

ber of multi-core processors. From a software point of view, these new computing platforms open big issues and challenges for software tools and runtime systems that must be able to manage a high degree of parallelism and data locality. In addition, to provide efficient methods for storing, accessing, and communicating data, intelligent techniques for data analysis and scalable software architectures enabling the scalable extraction of useful information and knowledge from data are needed.

- *Massive social network analysis.* The effective analysis of social network data on a large scale requires new software tools for real-time data extraction and mining, using Cloud services and high-performance computing approaches (Martin et al. 2016). Social data streaming analysis tools represent very useful technologies to understand collective behaviors from social media data. New approaches to data exploration and model visualization are necessary taking into account the size of data and the complexity of the knowledge extracted.
- *Data quality and usability.* Big Data sets are often arranged by gathering data from several heterogeneous and often not well-known sources. This leads to a poor data quality that is a big problem for data analysts. In fact, due to the lack of a common format, inconsistent and useless data can be produced as a result of joining data from heterogeneous sources. Defining some common and widely adopted format would lead to data that are consistent with data from other sources, that means high-quality data.
- *In-memory analysis.* Most of the data analysis tools access data sources on disks, while, differently from those, in-memory analytics access data in main memory (RAM). This approach brings many benefits in terms of query speed up and faster decisions. In-memory databases are, for example, very effective in real-time data analysis, but they require high-performance hardware support and fine-grain parallel algorithms (Tan et al. 2015). New 64-bit operating systems allow to

- address memory up to one terabyte, so making realistic to cache very large amount of data in RAM. This is why this research area has a strategic importance.
- *Scalable software architectures for fine-grain in-memory data access and analysis.* Exascale processors and storage devices must be exploited with fine-grain runtime models. Software solutions for handling many cores and scalable processor-to-processor communications have to be designed to exploit exascale hardware (Mavroidis et al. 2016).

Cloud Databases

► Databases as a Service

Cloud-Based SQL Solutions for Big Data

Marcin Zukowski

Snowflake Computing, San Mateo, CA, USA

Overview

Cloud computing is one of the most important trends in the current software industry. Cloud possesses unique technical and business characteristics, enabling new approaches to software design and new usage models. In this chapter we present the key characteristics of the cloud systems, and discuss opportunities and challenges traditional database systems face when deployed on this new platform. Using a set of existing systems, we demonstrate various approaches to building cloud-based SQL Big Data solutions.

Cloud

Cloud computing is possibly the largest shift in computing since the client-server model became popular. In recent years, we see companies of all sizes embrace it, often for very different reasons. Architecturally, it introduces a lot of previously unavailable features, that provide amazing opportunities to system and application developers. At the same time, careful (re)design of software is needed to take full advantage of them.

The term “Cloud” tends to be used in various contexts:

- An abstract remote location where data is stored, and processing takes place (e.g., “my photos are in the cloud”);
- Infrastructure-as-a-Service (IaaS) solutions, that mostly replace on-premise physical entities like buildings, (virtual) compute and storage resources and networking infrastructure;
- Platform-as-a-Service (PaaS) solutions, extending IaaS with additional services (e.g., database systems, messaging services

etc.) enabling development of end-user applications;

- Software-as-a-Service (SaaS) solutions, encapsulating the complete application functionality in an end-user system;
- Single-vendors cloud systems, e.g., Amazon Web Services (AWS). They typically provide IaaS (e.g., EC2 for AWS) and PaaS (e.g., SQS and Lambda) solutions, and sometimes also end-user SaaS solutions (e.g., AWS Quick-sight). This meaning is used mostly in this article.

Historically, multiple companies made attempts to build cloud platforms. However, the technical complexity and economies of scale led to only a few companies dominating the market (Amazon Web Services (AWS), Microsoft Azure and Google Cloud Platform), with a reasonably small number of other players ([Magic Quadrant for Cloud Infrastructure as a Service, Worldwide](#)).

Cloud Platform Characteristics

Cloud systems provide a new, unique set of features not available previously, which offer exciting opportunities for database systems.

Elastic Compute

On-demand provisioning of computing resources is a defining feature of cloud platforms. It allows quickly (typically in minutes) getting access to (effectively) arbitrarily large amount of compute nodes. Additionally, these resources can be as-needed scaled up and down, resulting in users paying only for the actual usage.

This is dramatically different from traditional on-premise situation, where hardware resources:

- Had to be planned months in advance, leading to high capital expenses (CapEx) and slow project rollouts
- Were provisioned for peak usage (further increasing CapEx and reducing cost efficiency)

- or average utilization (leading to insufficient performance at peak times)
- Required continuous maintenance (high operating expense – OpEx)
- Required additional infrastructure (buildings, power) impacting both CapEx and OpEx

Additional elasticity aspects of cloud compute layers include:

- Instance types, e.g., instances with more RAM VS more storage, or with specialized hardware components like GPUs or FPGAs
- Payment models, e.g., fully on-demand or up-front for a given period
- Availability models, e.g., cheaper spot instances in AWS, that can be taken away anytime, and “reserved” instances that provide a better cost efficiency for highly-utilized systems
- Ability to use various storage layers, see below

An elastic compute layer is present in all cloud systems, e.g., AWS EC2, Google Compute Engine and Azure VMs.

Storage Services

Most cloud systems provide multiple layers of storage systems, differing on a number of

dimensions. The table below lists the most popular storage layers from leading providers and their vendor-specific services. These different services can lead to very different software design choices, depending on the requirements of a given system or application (Table 1).

C

Additional Features and Opportunities

Multi-Tenancy A unique aspect of cloud systems is that each cloud platform serves thousands of different users. On the cloud provider side, this leads to economy-of-scale benefits, savings from sharing resources, and higher predictability of general usage trends. On the user side, it gives access to a huge pool of resources. It also opens the possibility of sharing access to the same data, if its stored in a shared layer (like S3). As a result, sharing of data is possible without a physical data movement task (e.g., transferring files) and becomes to a logical operation (e.g., granting access). This allows completely new classes of applications and systems.

Geographical distribution Most cloud systems are internally distributed across multiple (typically 3) physical data centers. As a results many (but not all) services provide resiliency not only to single-machine or single-rack failures, but to the entire data center failures. This provides the

Cloud-Based SQL Solutions for Big Data, Table 1 Example storage services present in various cloud platforms

	Cost	Size	Latency	Bandwidth	Persistency	Access	AWS (Amazon EC2: Storage)	Azure (Introduction to Microsoft Azure Storage)	Google (Google Cloud Platform: Storage Options)
Local instance storage	Free (included)	Limited, fixed	Very low	Very high	Ephemeral	Single instance	Available (not all types)	Available	Available (not all types)
Distributed block storage	Medium	Limited, elastic	Low	High	Persistent	Single instance (at a time)	EBS	General purpose storage	Persistent disks
Distributed file system	High	Unlimited	Medium	Medium	Persistent	Shared	EFS	Azure files	Not available
Object (blob) store	Very low	Unlimited	High	Low	Persistent	Shared	S3	Azure blob storage	Cloud storage

level of availability previously only available to the largest companies.

Security Cloud systems offer improvements to system security at various levels: physical security (state of the art systems deployed at scale); network security (e.g., Virtual Private Cloud in AWS); encryption (automatic storage encryption; encryption key management); authentication and identity management (IAM in AWS); auditing and more. As a result, building secure systems in a cloud is often easier than providing a similar (externally facing) system on-premise.

Additional services Cloud vendors offer dozens of additional managed services, in areas like (examples for AWS): messaging systems (e.g., SMS, SQS), databases (e.g., RDS, DynamoDB), serverless computing (e.g., Elastic Beanstalk, Lambda), management (e.g., CloudTrail, CloudWatch) and more. These powerful tools make creating applications much easier in the cloud environment.

SaaS While IaaS provides flexibility and cost benefits to organizations, a good software-as-a-service product can lead also to a higher productivity, better user satisfaction, and personnel cost reduction. As a result, cloud systems often focus on providing a low-maintenance, mostly automated and easy-to use experience. For example, aspects like friendly user interfaces, automatic software update management, high-availability, built-in monitoring etc are all now expected by most users of cloud systems.

Cloud System Challenges

While providing a lot of great features, cloud system introduce challenges which application designers need to incorporate into their architecture. This section lists some of them.

Unpredictability of single-instance performance Since resources in the cloud are typically shared and virtualized, it is possible for one tenant of the same physical resource to have a negative impact on other users. Modern

virtualization technologies prevent that to a large extent, but the problem is not completely gone.

Increased failure rates similarly, it is more common for instances in the compute layer to die without a warning, due to hardware or software corruption, often caused by activity unrelated to a given user.

Non-transparent system topology For the end-user, the mapping of virtual compute instances onto physical entities is not visible. As a result, one cant say if two nodes might influence each others behavior, or predict the cost of the network communication.

Unpredictability of services stability and performance While cloud services typically offer very high availability, some of them behave inconsistently. For example, it is known that a simple read request to AWS S3, while usually taking a fraction of a second, occasionally can take multiple seconds.

Limited hardware choice Many on premise systems use carefully tuned hardware units, with balanced CPU/RAM/disk and network. While cloud offers multiple instance types, it is often not possible to get the exact hardware configuration that would be optimal for a given application.

Cloud and Database Systems

The previously described properties of the cloud clearly demonstrate these systems are significantly different from on-premise infrastructure available to most companies.

It is perfectly possible to deploy existing software in a cloud environment, and a lot of database systems in fact are deployed this way. However, such strategy often does not allow benefiting from the unique cloud opportunities, and might not handle cloud-specific problems well.

Let us look at a list of various challenges that database system designers face when designing for the cloud

Elasticity Most popular design for on-premise large scale database systems is “shared nothing” (Stonebraker 1985). This is a great architecture for fixed-topology systems, but presents a lot of problems when highly elastic behavior is desired. As a result, other approaches have been proposed.

Scalability Combination of elastic compute resources and pay-for-use billing model, leads to customers demanding higher peak compute power (for a shorter time). As a result, distributed database systems need to be designed to efficiently scale to larger sizes.

Infrastructure reliability In traditional systems, an infrastructure failure (failed disk, network partitioning etc) and performance degradations were often considered exceptional events. In the cloud, they are more likely and systems need to be designed for them.

Performance consistency The performance differences between various nodes participating in query processing can be much higher in a shared environment. As a result, features like load balancing and skew handling are significantly more important in the cloud.

System topology With most of the cloud infrastructure virtualized, the placement of logical entities on physical hardware is often unknown. This causes problems for aspects like fault tolerance, where a single machine failure can potentially influence multiple logical instances, making it much harder to provide system failure guarantees.

Network efficiency Many high-performance distributed database systems are designed for high-performance networking interfaces like InfiniBand – when suddenly faced with e.g., a 1 gigabit Ethernet connection, their performance

can degrade quickly. This influences aspects like distributed algorithms, data exchange formats etc.

Security While being typically deployed in isolated, private environments, databases did not have to worry about many aspects of security present in the cloud environments. For example, for many users, having all data encrypted in-flight is legally required in a shared environment.

Extensibility Many database systems allow using custom software to enhance various features of the system (for example, C or C++ user defined functions). Shared systems need to devise mechanisms protecting against malicious code provided through these mechanisms.

Monitoring On-premise databases could assume the users had system-level access to the instances, giving them insight into aspects like memory or disk utilization. With databases provided as a service, they often do not have this access, and additional levels of monitoring needs to be exposed via separate interfaces.

Client connectivity Databases traditionally assumed the user maintained a network connection throughout their session. However, with web user interfaces and users being more mobile, the need for clients that do not depend on continuous connection arises.

External data Traditional data warehouses could assume they managed all (or most) of the data they needed to access. With the recent data explosion, many organizations keep a lot of data in low-cost services like S3. Ability to efficiently access these becomes highly desired, especially with that data being easily accessible within a given cloud system.

Simplicity Another area where databases do not match the SaaS world perfectly is the system usability. Databases are famous for the complexity of their management, with activities like tuning,

backups, monitoring consume a lot of precious personnel time.

Pricing Traditional database license was reasonably simple, with the user typically paying for the volume of data or the amount of used hardware resources. With the clouds elasticity, new payment models had to be invented, typically focused on actual system usage.

Multi-tenancy Cloud database systems that choose to provide multi-tenant services face additional challenges. For example, workload of one user might adversely influence other users. Additionally, any layers of the system that are shared require strong access control mechanisms. Finally, multi-tenancy can cause scalability challenges for the shared system components.

Example Systems

In this section we discuss a few representative examples of database systems provided as cloud services. While they obviously differ in many database-specific areas, like SQL support, performance etc, we focus on their very different approaches to building a cloud data warehousing system.

Amazon Redshift

Amazon Redshift ([Amazon Redshift](#)) was the first widely available cloud data warehousing system and is still the market leader. It is derived from the on-premise Paraccel database, which followed the traditional shared nothing model (Chen et al. 2009). It uses user-sized EC2 clusters for both processing and storage.

While originally keeping the major design decisions unchanged, Redshift did introduce a number of cloud-focused improvements and extensions (Gupta et al. 2015), mainly:

- Ability to scale up/down and pause/resume, providing much better elasticity than in the on-premise systems

- Integration with S3, simplifying data backups
- Rich user interface for managing and monitoring

Additionally, in 2017 Amazon introduced a major architectural extension for Redshift called Spectrum ([Amazon Redshift Spectrum](#)). It is a sub-system focused on scanning data in S3, where a part of the Redshift query can be pushed to a separate system, which uses highly parallel compute infrastructure for operations like scans, filters and aggregations.

Microsoft Azure SQL Data Warehouse

Azure SQL Data Warehouse (SQLDW) ([Microsoft Azure SQL Data Warehouse](#)) is a cloud-focused evolution of the SQL Server Parallel Data Warehouse ([Parallel Data Warehouse overview](#)), which in turn extended SQL Server with shared-nothing architecture derived from DATAAllegro ([DATAAllegro](#)).

Azure SQLDW uses compute nodes accessing data stored in a distributed block store. All the data is up-front partitioned in the storage layer into a limited (60) set of partitions. Each compute node owns a subset of them, and inter-node data transfer is required to access data owned by other nodes. As such, the data assignment approach and processing layer of Azure SQLDW are similar to shared nothing systems. Still, using a separate storage layer provides some benefits of the shared filesystem approaches. For example redistributing the data between nodes is a logical operations (no data copying is needed) and is relatively fast.

Google BigQuery

Google BigQuery ([Google BigQuery](#)) has a very different lineage than Redshift and Azure SQLDW. It is based on internal Google products ([BigQuery under the hood](#)), mainly Dremel (Melnik et al. 2010) for data processing and Colossus distributed file system ([Fikes](#)) for data storage, following the shared-storage architecture.

Originally Dremel was a reasonably simple internal query processing system with limited functionality (e.g., no real distributed joins;

append-only), with a limited, SQL-like language. After releasing it publicly as BigQuery in 2011, Google has implemented a number of significant improvements bringing it much closer to traditional database systems, including a more-standard SQL support and update capability.

BigQuery is unique in the discussed set of products with its usage model – the user issues a query and only pays for the amount of data that query processes. This is the closest to the pure SaaS approach, with users not having to manage anything related to resource allocation. With this approach, it is also possible for a single query to use tens or even hundreds of machines, depending on what is currently available, with the users cost staying the same.

BigQuery provides a demonstration of how highly distributed compute layer combined with an efficient distributed storage can provide exceptional query performance without any up-front investment.

Snowflake Elastic Data Warehouse

Snowflake ([Introducing Snowflake](#)) is a rare example of a SQL data warehousing system designed from scratch with cloud platforms in mind. Its architecture (Dageville et al. 2016) is driven directly by various attributes of AWS:

- Object store is the cheapest and most reliable storage, leading to using S3 as the persistent data layer
- S3 has no update capability, leading to using immutable micro-partitions as data storage format
- S3 has low performance, leading to columnar storage, heavy data skipping, and local caching
- For compute layer to easily scale up and down, compute nodes should be stateless
- With data in S3, multiple compute nodes can access it at the same time, as long as someone coordinates their activity.
- S3 is not good for frequent data access and compute nodes are stateless, hence an extra management and metadata entity is needed

- In a multi-tenant system, all the barriers are purely logical, hence sharing data between users is possible

The result multi-cluster shared-data architecture uniquely translates a lot of cloud benefits to the end user, providing high elasticity, scalability and novel features.

C

Other Systems

While four systems discussed in this chapter are highly representative examples, there are many other products in this space, providing additional unique cloud-related approaches and features. That list includes, but is not limited to: Teradata Intellicloud ([Teradata IntelliCloud](#)), Micro-Focus Vertica (including the Eon mode) ([Whats New in Vertica 9.0: Eon Mode Beta](#)), Pivotal Greenplum ([Pivotal Greenplum on Amazon Web Services](#)), IBM DashDB ([IBM dashDB](#)), Oracle Autonomous Data Warehouse ([Oracle Autonomous Data Warehouse Cloud](#)) and Amazon Athena ([Amazone Athena](#)).

Conclusions

It seems clear today that most future data processing needs will be fulfilled by cloud systems. This chapter discussed the challenges and opportunities cloud brings, as well as approaches to addressing them. A short overview of a few example systems demonstrates that databases can take very different architectural approaches to this new platform and still build very successful cloud systems. With cloud adoption growing at a rapid pace, we expect a lot of innovation in this space in the coming years.

Columnar Storage Formats

Avrilia Floratou

Microsoft, Sunnyvale, CA, USA

Definitions

Row Storage: A data layout that contiguously stores the values belonging to the columns that make up the entire row.

Columnar Storage: A data layout that contiguously stores values belonging to the same column for multiple rows.

Overview

Fast analytics over Hadoop data has gained significant traction over the last few years, as multiple enterprises are using Hadoop to store data coming from various sources including operational systems, sensors and mobile devices, and web applications. Various Big Data frameworks have been developed to support fast analytics on top of this data and to provide insights in near real time.

A crucial aspect in delivering high performance in such large-scale environments is the underlying data layout. Most Big Data frameworks are designed to operate on top of data stored in various formats, and they are extensible enough to incorporate new data formats. Over the years, a plethora of open-source data formats have been designed to support the needs of various applications. These formats can be *row* or *column* oriented and can support various forms of serialization and compression. The *columnar* data formats are a popular choice for fast analytics workloads. As opposed to row-oriented storage, columnar storage can significantly reduce the amount of data fetched from disk by allowing access to only the columns that are relevant for the particular query or workload. Moreover, columnar storage combined with efficient encoding and compression techniques can drastically reduce the storage requirements without sacrificing query performance.

Column-oriented storage has been successfully incorporated in both disk-based and memory-based relational databases that target OLAP workloads (Vertica 2017). In the context of Big Data frameworks, the first works on columnar storage for data stored in HDFS (Apache Hadoop HDFS 2017) have appeared around 2011 (He et al. 2011; Floratou et al. 2011). Over the years, multiple proposals have been made to satisfy the needs of various applications and to address the increasing data volume and complexity. These discussions resulted in the creation of two popular columnar formats, namely, the Parquet (Apache Parquet 2017) and ORC (Apache ORC 2017) file formats. These formats are both open-source and are currently supported by multiple proprietary and open-source Big Data frameworks. Apart from columnar organization, the formats provide efficient encoding and compression techniques and incorporate various statistics that enable predicate pushdown which can further improve the performance of analytics workloads.

In this article, we first present the major works in disk-based columnar storage in the context of Big Data systems and Hadoop data. We then provide a detailed description of the Parquet and

ORC file formats which are the most widely adopted columnar formats in current Big Data frameworks. We conclude the article by highlighting the similarities and differences of these two formats.

C

Related Work

The first works on columnar storage in the context of Hadoop, namely, the RCFfile (Row Columnar File) (He et al. 2011) and the CIF (Column Input File format) (Floratou et al. 2011) layouts, were mostly targeting the MapReduce framework (Dean and Ghemawat 2008). These two columnar formats have adopted significantly different designs. The CIF file format stored each column in the data as a separate file, whereas the RCFfile adopted a PAX-like (Ailamaki et al. 2001) data layout where the columns are stored next to each other in the same file.

These design choices led to different trade-offs. The CIF file format was able to provide better performance as it allowed accessing only the files that contain the desired columns but required extra logic in order to colocate the files that contain adjacent columns. Without providing colocation in HDFS, reconstructing a record from multiple files would result in high network I/O. The RCFfile, on the other hand, did not require any such logic to be implemented as all the columns were stored in the same HDFS block. However, the RCFfile layout made it difficult to enable efficient skipping of columns due to file system prefetching. As a result, queries that were accessing a small number of columns would pay a performance overhead (Floratou et al. 2011).

The successor of the RCFfile format, namely, the ORC (Optimized Row Columnar) file format, was developed to overcome the limitations of the RCFfile format. It was originally designed to speed up Hadoop and Hive, but it is currently incorporated in many other frameworks as well. The ORC file format still uses a PAX-like (Ailamaki et al. 2001) layout but can more efficiently skip columns by organizing the data in larger blocks called row groups. A detailed

description of the ORC file format is provided in the following section.

The Parquet (Apache Parquet 2017) file format is another popular, open-source columnar format. The Parquet file format was designed to efficiently support queries over deeply nested data. The format is based on the Dremel distributed system (Melnik et al. 2010) that was developed at Google for interactively querying large datasets. Similar to the ORC format, the parquet format has also adopted a PAX-like layout (Ailamaki et al. 2001). The following section presents Parquet’s layout in detail.

Detailed comparisons of various columnar formats can be found in Huai et al. (2013) and in Floratou et al. (2014). The work by Floratou et al. (2014) compares the ORC and Parquet file formats in the context of Hive (Apache Hive 2017) and Impala (Kornacker et al. 2015) for SQL workloads.

Other related open-source technologies are Apache Arrow (2017) and Apache Kudu (2017). Apache Arrow is a columnar in-memory format that can be used on top of various disk-based storage systems and file formats to provide fast, in-memory analytical processing. Note that as opposed to the file formats discussed above, Arrow is an in-memory representation and not a disk-based file format. Apache Kudu is an open-source storage engine that complements HDFS (Apache Hadoop HDFS 2017) and HBase (Apache Hbase 2017). It provides efficient columnar scans as well as inserts and updates. Kudu provides mutable storage, whereas the file formats described above (e.g., Parquet) are immutable, and thus any data modifications require rewriting the dataset in HDFS.

Columnar File Formats for Big Data Systems

In this section, we describe in more detail two popular, open-source columnar formats that have been incorporated in various Big Data frameworks, namely, the **ORC** and the **Parquet** file formats. Both ORC and Parquet are Apache projects (Apache ORC 2017; Apache

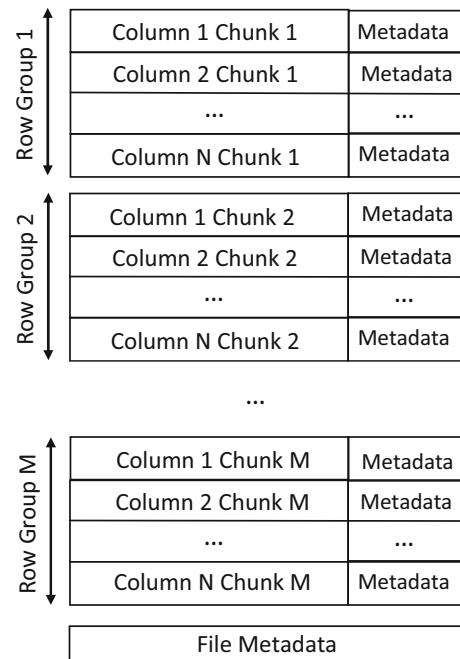

Parquet 2017) and are actively used by multiple organizations when performing analytics over Hadoop data.

The Parquet File Format

The Parquet file format (Apache Parquet 2017) is a self-described columnar data format specifically designed for the Hadoop ecosystem. It is supported by many Big Data frameworks such as Apache Spark (Zaharia et al. 2012) and Apache Impala (Kornacker et al. 2015), among others. The format inherently supports complex nested data types as well as efficient compression and encoding schemes. In the next section, we describe the format layout in more detail.

File Organization

The Parquet format supports both primitive (e.g., integer, Boolean, double, etc.) and complex data types (maps, lists, etc.). The structure of a Parquet file is shown in Fig. 1. The file consists of a set of **row groups** which essentially represent horizontal partitions of the data. A **row group** consists of a set of **column chunks**. Each

Columnar Storage Formats, Fig. 1 The parquet file format

column chunk contains data from a particular data column and it is guaranteed to be contiguous in the file. The column chunk consists of one or more pages which are the unit of compression and encoding. Each page contains a header that describes the compression and encoding method used for the data in the page.

As shown in Fig. 1, the file consists of N columns spread across M row groups. The row groups are typically large (e.g., 1 GB) to allow for large sequential I/Os. Since an entire row group might need to be accessed, the HDFS block size should be large enough to fit the row group. A typical configuration is to have 1 GB HDFS blocks that contain one row group of 1 GB.

Metadata is stored at all the levels in the hierarchy, i.e., file, column chunk, and page. The bottom of the file contains the file metadata which include information about the data schema as well as information about the column chunks in the file. The metadata contains statistics about the data such as the minimum and maximum values in a column chunk or page. Using these statistics, the Parquet file format supports predicate pushdown which allows skipping of pages and reduces the amount of data that needs to be decompressed and parsed. The Parquet readers first fetch the metadata to filter out the column chunks that must be accessed for a particular query and then read each column chunk sequentially.

Compression

As described in the previous section, the unit of compression in the Parquet file format is the page. The format supports common compression codecs such as GZIP and Snappy (Snappy Compression 2017). Moreover, various types of encoding for both simple and nested data types are also supported. The interested reader can find more information about the various encoding techniques in Parquet Encodings (2017).

The ORC File Format

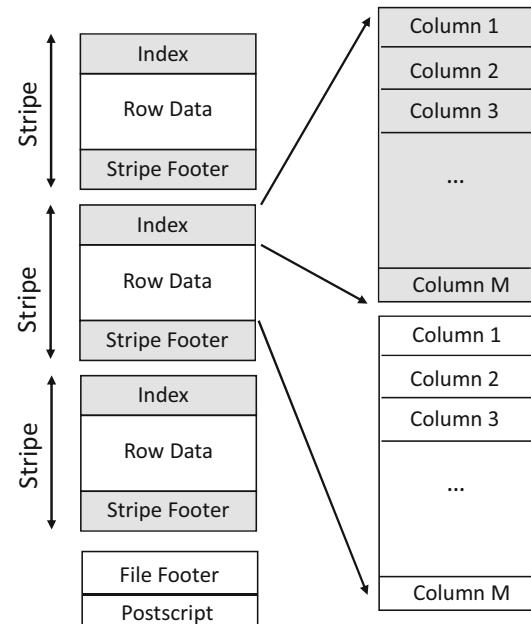

The Optimized Row Columnar (ORC) format (Apache ORC 2017) is a column-oriented storage layout that was created as part of an

initiative to speed up Apache Hive (2017) queries and reduce the storage requirements of data stored in Apache Hadoop (2017). Currently the ORC file format is supported by many Big Data solutions including Apache Hive (2017), Apache Pig (2017), and Apache Spark (Zaharia et al. 2012), among others.

File Organization

The ORC format is an optimized version of the previously used Row Columnar (RC) file format (He et al. 2011). The format is self-describing as it includes the schema and encoding information for all the data in the file. Thus, no external metadata is required in order to interpret the data in the file. The format supports both primitive (e.g., integer, Boolean, etc.) and complex data types (maps, lists, structs, unions). Apart from the columnar organization, the ORC file supports various compression techniques and lightweight indexes.

The structure of an ORC file is shown in Fig. 2. As shown in the figure, the file consists of three major parts: a set of stripes, a file footer, and a postscript. The

Columnar Storage Formats, Fig. 2 The ORC file format

`postscript` part provides all the necessary information to parse the rest of the file such as the compression codec used and the length of the file footer. The `file footer` contains information related to the data stored in the file, such as the number of rows in the file, statistics about the columns, and the data schema. The process of reading the file starts by first reading the tail of the file that consists of the `postscript` and the `file footer` that contain metadata about the main body of the file.

An ORC file stores multiple groups of row data as `stripes`. Each `stripe` has a size of about 250 MB and contains only entire rows so a row cannot span multiple stripes. Internally, each `stripe` is divided into index data, row data, and stripe footer in that order. The data columns are stored next to each other in a PAX-like (Ailamaki et al. 2001) organization. Depending on the query's access pattern, only the necessary columns are decompressed and deserialized. The stripe footer contains the location of the columns in data as well as information about the encoding of each column. The indexes contain statistics about each column in a row group (set of 10,000 rows). For example, in the case of integer columns, the column statistics include the minimum, maximum, and sum values of the column in the given row group. These statistics can be used to skip entire sets of rows that do not satisfy the query predicates. Recently, bloom filters can additionally be used to better prune row groups (ORC Index 2017).

Finally, it is worth noting that column statistics are also stored in the `file footer` at the granularity of `stripes`. These statistics enable skipping entire `stripes` based on a filtering predicate.

Compression

Depending on the user's configuration, an ORC file can be compressed using a generic compression codec (typically zlib (ZLIB Compression 2017) or snappy (Snappy Compression 2017)). The file is compressed in chunks so that entire chunks can be directly skipped without decompressing the data. The default compression chunk size is 256 KB but it is configurable. Having

larger chunks typically results in better compression ratios but requires more memory to be allocated during decompression.

The ORC file makes use of various run-length encoding techniques to further improve compression. The interested reader can find more information about the supported encoding methods in ORC Encodings (2017)

File Format Comparison

The Parquet and ORC file formats have both been created with the goal of providing fast analytics in the Hadoop ecosystem. Both file formats are columnar and they have adopted a PAX-like layout. Instead of storing each column at a separate file, the columns are stored next to each other in the same HDFS block. By having large `row groups` and HDFS blocks, both formats exploit large sequential I/Os and can skip unnecessary columns.

Both formats support various compression codecs at a fine granularity so that the amount of data that is decompressed is minimized. They also support various encoding schemes depending on the data type.

Finally, the file formats incorporate statistics at various levels in order to avoid decompressing and deserializing data that do not satisfy the filtering predicates. Typically, the statistics include the maximum and the minimum values of a column. The ORC file additionally supports bloom filters at the `row group` level, while the Parquet file supports statistics at the page level as well.

Regarding the data types supported, the Parquet file format has been designed to inherently support deeply nested data using the record shredding and assembly algorithm presented in Melnik et al. (2010). The ORC file, on the other hand, flattens the nested data and creates separate columns for each underlying primitive data type.

Conclusions

The increased interest in fast analytics over Hadoop data fueled the development of multiple open-source data file formats. In this work, we

focused on the columnar storage formats that are used to store HDFS data. In particular, we first reviewed the work on disk-based columnar formats for Big Data systems and then presented a detailed description of the open-source ORC and Parquet file formats. These two columnar data formats are currently supported by a plethora of Big Data solutions. Finally, we highlighted the differences and similarities of the two file formats.

Component Benchmark

Klaus-Dieter Lange and David L. Schmidt
Hewlett Packard Enterprise, Houston, TX, USA

Synonyms

[Microbenchmark](#); [Worklet](#)

Overview

Component benchmarks are valuable tools for isolating and analyzing the performance characteristics of specific subsystems within a server

environment. This chapter will provide historical context for component benchmarks, brief descriptions of the most commonly used benchmarks, and a discussion on their uses in the field.

Definitions

Software that utilizes standard applications, or their core routines that focus on a particular access pattern, in order to measure the performance and/or efficiency of one of the primary server and storage components (CPU transactions, memory, and storage/network IO).

Historical Background

From earliest days of digital computer systems, the goal of quantifying, improving, and optimizing computational performance has been a subject great interest. The earliest measures of performance were comparisons of low-level instruction execution times. A mix of several of these execution times would be combined to produce an overall rating that could be compared between systems. The most well-known of these early benchmarks was the Gibson mix, devised by Jack Gibson of IBM (Gibson 1970). As high-level computer languages were developed, more complex applications were created to develop more rigorous methods of measuring a system's performance. Whetstone (Longbottom 2014) and Dhrystone (Weiss 2002) are both early examples of high-level language benchmarks.

As computer systems became more complex, benchmarks were developed to measure the performance of the separate components of the system, such as memory, floating-point arithmetic coprocessors, and data IO. Most of these early benchmarks utilized synthetic workloads and were usually provided to users as source code that needed to be compiled on the system of interest. This allowed such benchmarks to be used on multiple platforms, but there was generally no set standard on how to compile

such benchmarks or how to compare results between different architectures which limited the scope of their use. Industry-standard consortia such as Transaction Processing Performance Council (TPC, <http://www.tpc.org>) and Standard Performance Evaluation Corporation (SPEC, <https://www.spec.org>) were established in the mid-1980s in an effort to provide fair standards for measuring system-level and component-level performance of differing platforms. Several of the benchmarks developed by these consortia are intended to measure component-level performance.

Foundations

Component benchmarks are useful tools to analyze IT equipment and troubleshoot performance bottlenecks. They utilize standard applications, or their core routines that focus on a particular access pattern, in order to measure the performance of one of the primary server and storage components such as CPU transactions, memory access, storage IO, or network IO. By limiting their scope, component benchmarks achieve a deeper analysis of the targeted subsystem. At the same time component benchmarks are often easier to develop than benchmarks that stress the complete server environment and they are typically less expensive to run, because they require fewer equipment and engineering resources.

There can be an overlap in what is considered a component benchmark vs. a microbenchmark. A microbenchmark is typically more limited in scope than a component benchmark, focusing on the performance of a single feature of a component rather than the entire component. Microbenchmarks utilize synthetic workloads rather than actual user applications to measure the performance of their intended resource. Microbenchmarks are further described in a later chapter.

Following is a description of the most common component benchmarks categorized by their target subsystem in a Big Data environment.

Processor subsystem

SPEC CPU2017 (<https://www.spec.org/cpu2017>) is a benchmark package developed by the Standard Performance Evaluation Corporation (SPEC) to provide a comparative measure of compute-intensive performance across the widest practical range of hardware platforms. The benchmark uses workloads developed from programs from a variety of application areas, including artificial intelligence, molecular dynamics, physics, weather-forecasting, imaging, modeling, and computer development. Suites of these workloads are run to measure floating-point (SPECrate2017 Floating Point, SPECspeed2017 Floating Point) and integer (SPECrate2017 Integer, SPECspeed2017 Integer) performance. The suites are further categorized as SPECrate and SPECspeed suites. The SPECrate suites run multiple concurrent copies of each benchmark workload to provide a measure of throughput performance. The SPECspeed suites run a single copy of each benchmark workload to measure processing speed and parallelization performance.

SPEC CPU2006 (<https://www.spec.org/cpu2006>) is the predecessor to SPEC CPU2017 and likewise measures CPU and memory performance utilizing integer and floating-point intensive benchmark suites. There are both rate (SPECint_rate2006, SPECfp_rate2006) and speed (SPECint2006, SPECfp2006) suites to analyze different performance characteristics of the CPU and memory subsystems.

HEP-SPEC06 (Michelotto et al. 2010; HEPiX benchmarking working group) is a benchmark based on the SPEC CPU2006 benchmark suites developed by the HEPiX forum to measure processing performance of applications in a high energy physics environment. HEP-SPEC06 requires the use of the SPEC CPU2006

benchmark tools, but only runs a subset of the component workloads; only the six benchmark modules written in C++ are utilized and are compiled as 32-bit executables. The HEP-SPEC06 run script will then invoke multiple instances of the SPEC CPU2006 run script, each running a single copy of the benchmark workloads. The output results of each SPEC CPU2006 instance are then used to generate a final HEP-SPEC06 score.

Whetstone (Longbottom) was one of the first benchmarks to attempt to standardize the measurement of floating-point performance of CPUs. Developed in 1972, the benchmark workload was a representation of a set of 124 simple Whetstone ALGOL 60 compiler instructions translated into FORTRAN. The benchmark result was measured in thousands of Whetstone instructions per second (kWips), and later in millions of Whetstone instructions per second (MWIPS). The benchmark was updated over the years and ported to C, C++, Basic, and Java. It is frequently included in component benchmark suites.

Dhrystone (Weiss 2002) is a synthetic benchmark program developed in 1984 to measure integer-based processing performance. Developed utilizing metadata from several applications written in different programming languages, Dhrystone was designed to measure system program performance. For many years Dhrystone was considered the representative benchmark for general processor performance. Originally written in Ada, it was translated into C and UNIX and is still often used in component benchmark suites. The name Dhrystone is a pun on the benchmark Whetstone, another benchmark popular at the time of its development.

LINPACK (The LINPACK benchmark programs and reports; Dongarra et al. 2002) is a software library for performing numerical linear algebra on digital com-

puters. The LINPACK benchmark uses the LINPACK software library to solve a set of predetermined set of n by n linear algebra equations in order to measure a system's floating-point computing performance, measured in floating point operations per second (FLOPS). The benchmark workload is almost exclusively floating-point based, so is an excellent stressor of the processors' math and vector instruction sets. There have been several versions of LINPACK benchmarks since their creation in 1979, which include LINPACK 100 ($n = 100$), LINPACK 1000 ($n = 1000$), and HPLinpack (a highly parallelized version that can run across multiple systems). HPL is a portable implementation of the HPLinpack benchmark written in C. Precompiled LINPACK and HPL are available for certain system architectures.

Memory

STREAM (<https://www.cs.virginia.edu/stream>; McCalpin 1995) is a simple synthetic benchmark that measures sustainable memory bandwidth, reported in MB/s. The benchmark is specifically designed to work with dataset much larger than the available processor cache on any given system so that the results are more indicative of the performance of a very large, vector-style application. The benchmark yields four metrics, representing different memory operations: Copy, Add, Scale, and Triad. The benchmark had C and FORTRAN versions available which can run either in a single-threaded or distributed fashion. A precompiled version of this benchmark is often included in component benchmark suites.

Storage IO

SPEC SFS2014 (<https://www.spec.org/sfs2014>) is a benchmark suite which measures file server throughput and response time. The SPEC SFS2014 SP2 benchmark includes five workloads which measure storage performance in different

application areas: database operations, software builds, video data acquisition (VDA), virtual desktop infrastructure (VDI), and electronic design automation (EDA). Each workload is independent of the others and reports the throughput (in MB/s) and overall response time (in msec) for a given number of workload instances. Netmist is the load generator, allowing the benchmark suite can be run over any version of NFS, SMB/CIFS, object-oriented, local, or other POSIX-compatible file system.

Iometer (<http://www.iometer.org>) is a tool which measures the performance and characterization of I/O components for single and clustered systems. It is based on a client-server model where a single client controls one or manager driver which generates I/O using one or more worker threads. Iometer performs asynchronous I/O and can access files or block devices. The tool is very flexible and allows the user to adjust the workload by configuring target disk parameters (e.g., disk size, starting sector, number of outstanding I/Os) and the workload access specifications (e.g., transfer request size, percent random/sequential distribution, percent read/write distribution, aligned I/Os, reply size, TCP/IP status, burstiness). All of the output data is collected into a CSV file for easy manipulation. One of the more commonly utilized output parameter is I/O operations per second (IOPS).

IOzone (http://www.iozone.org/docs/IOzone_msword_98.pdf) is a file system benchmark utility which generates and measures a variety of file operations. These file operations include read, write, re-read, re-write, read backwards, read strided, fread, fwrite, random read/write, pread/pwrite variants, aio_read, aio_write, and mmap. The results can be exported into useful graphs which show performance characteristics and bottlenecks of the disk I/O subsystem. The benchmark is written in C and can be run under many operating systems.

Network IO

Netperf (<https://github.com/HewlettPackard/netperf>) is a software application that provides network bandwidth testing between two hosts on a network. It measures performance of bulk data transfer and request/response network traffic using either TCP or UDP via BSD sockets. There are optional tests that measure performance of DLPI, UnixDomainSockets, the Fore ATM API, and the HP HiPPI LLa interface. Originally developed by Hewlett Packard, it is now available from github. Netperf has been ported to run on numerous distributions of UNIX and Linux, Windows, and VMware.

Component benchmarks are often bundled together into a suite of benchmarks that may or may not also include microbenchmarks to provide a tool that can measure several system features in a single package. Note that these suites are frequently designed for the personal computer or workstation market rather than for the server environment.

Following is a description of the more common component benchmark suites.

SERT (<https://www.spec.org/sert>) is the Server Efficiency Rating Tool developed by SPEC to evaluate the energy efficiency of servers. The SERT suite is a suite of 12 “worklet” modules that stress different system components and measure performance as well as the power consumption of the system. These worklets stress the CPU, memory, and disk I/O subsystem at various target load levels well, as well as one hybrid worklet that stress a series of complex CPU and memory access pattern. The SERT suite utilizes the Chauffeur (<https://www.spec.org/chauffeur-wdk>) harness and is configurable so individual worklets or categories of worklets can be run.

LMBench (<http://lmbench.sourceforge.net>) is a suite of simple benchmarks that measure bandwidth and latency performance for a variety of system components, including memory, caches, disk I/O, and network I/O.

LMBench is written in C and can be used on most distributions of UNIX and Linux.

SiSoftware Sandra (<http://www.sisoftware.eu>) is suite of modules that provide information about a system’s hardware and software, including performance measurements on the CPU, memory, disk I/O, and graphics. Only available on Windows, the primary target of the suite is PC and workstation systems. There are many versions available from the free Lite version to the Enterprise version.

3DMark (<https://www.3dmark.com>) is a benchmarking tool that measures performance of CPU and graphics utilizing modules based off different versions of DirectX. Only available on Windows, Android, and iOS, 3DMark is intended for analyzing PCs used by gaming enthusiasts.

PCMark (<https://www.futuremark.com/benchmarks/pcmark>) is a benchmarking tool similar to 3DMark which measures the performance of different components of PCs, such as CPU, memory, disk I/O, and graphics. Only available on Windows, PCMark is intended for home use.

Key Applications

Single component benchmarks generally are not directly useful for the analysis of Big Data environments, as they measure only one or a few specific aspects of one primary server or storage components. A suite of component benchmarks like the SERT suite can be a key method to measure the behaviors of the primary server and storage components. Nonetheless, they are not measuring the interaction and possible performance bottlenecks between those components. The real usefulness of component benchmarks is their role in the simplification of the performance analysis and the pinpointing of the actual performance bottlenecks within a component.

The major key application of component benchmarks is their usage during server development and the design/deployment phases of new Big Data environments. In general, the first step is to run one of the component suites (or

a series of hand-picked component benchmarks) in order to determine if one subsystem exhibits lower-than-expected performance. Next, an analysis of the subsystem is conducted to further pinpoint the root causes. For example, the performance results from the SERT suite determine lower-than-expected CPU subsystem performance. The next step would include running the SPEC CPU2017 benchmark suite to further close in on the root cause. Finally, after a possible resolution of the issues is implemented, the original component suite should be run again in order to verify that the resolution satisfactorily fixed the bottleneck. Please note that it is the nature of performance bottlenecks that they switch from one component to another, once the root cause of the original bottleneck is resolved.

In order to maintain their usefulness, component benchmarks need a continuous development cycle to keep up with emerging technologies. For example, in order to accurately measure the performance gain of a new microarchitecture, a compiled version of the benchmark code (including its libraries if applicable), which supports this new microarchitecture, should be utilized. A 0.5–3.0% performance gain from such a microarchitecture optimization is quite common.

Compressed Indexes for Repetitive Textual Datasets

Travis Gagie¹ and Gonzalo Navarro²

¹EIT, Diego Portales University, Santiago, Chile

²Department of Computer Science, University of Chile, Santiago, Chile

Definitions

Given a text or collection of texts containing long repeated substrings, we are asked to build an index that takes space bounded in terms of the size of a well-compressed encoding of the text or texts and that, given an arbitrary pattern, can quickly report the occurrences of that pattern in the dataset.

Overview

Humanity now stores as much data in a year as we did in our whole history until the turn of the millennium. Most applications that use this data need to query it efficiently, and one of the most important kinds of queries is pattern matching in texts. It is usually impractical to scan massive textual datasets every time we want to count or find the occurrences of a pattern, so we must index them. Until fairly recently, indexing a text often took much more memory than simply storing the dataset. In 2000, however, Ferragina and Manzini (2000, 2005) showed how to simultaneously compress and index a text, with the index itself supporting access to the text and thus replacing it. Also in 2000, Grossi and Vitter (2000, 2005) and Sadakane (2000, 2003) proposed an alternative data structure with essentially the same query functionality but with a space bound proportional to the size of the uncompressed text; it was then improved to occupy compressed space. Ferragina and Manzini's and Grossi and Vitter's data structures, the FM-index and compressed suffix array (CSA), have

had a dramatic impact on several fields such as bioinformatics, where FM-indexes are central to many important DNA aligners such as Bowtie (Langmead et al. 2009) and BWA (Li and Durbin 2009). We note that, in contrast to inverted lists, CSAs and FM-indexes can index any kind of text and allow any pattern to be sought, without regard for word boundaries. This is important not only for applications involving DNA but also to index source code repositories, multimedia sequences, and even tokenized word sequences in order to perform phrase searches.

CSAs and FM-indexes use space comparable to the sizes of encodings produced by the best statistical compressors, which achieve bounds in terms of higher-order entropies, but massive texts are often repetitive and are thus much more compressible using dictionary-based compressors such as LZ77 (Ziv and Lempel 1977). For example, humans are genetically almost identical, so a good dictionary-based compressor can compress a database of a thousand human genomes to about 1% of its size, as reported by the 1000 Genomes Project (<http://www.internationalgenome.org>). Naturally, researchers have tried to adapt CSAs and FM-indexes to take better advantage of repetitions or to find alternatives to them that do so. Their efforts can be broadly classified into four groups: run-length compressed FM-indexes, indexes based on Lempel-Ziv compression or context-free grammars, compressed directed acyclic word graphs (CDAWGs), and, most recently, graph-based indexes. We briefly survey the history of each approach, mentioning its strengths and weaknesses and giving pointers to practical implementations where they are available.

Key Research Findings

Run-Length Compressed CSAs and FM-Indexes

Consider a repetitive text (or the concatenation of the texts in a repetitive collection) $T[1..n]$. The suffix array of T , $A[1..n]$, points to the starting

positions of all the suffixes of T in lexicographic order. Assume a long string $S[1..k]$ appears s times in T . Then the s suffixes starting with $S[1..k]$ appear in a contiguous range $A[p_1..p_1 + s - 1]$. It is likely that the suffixes starting with $S[2..k]$ also appear together in another range $A[p_2..p_2 + s - 2]$, in the same order as those in $A[p_1..p_1 + s - 1]$. The same is likely to occur for any $S[k'..k]$ as long as $k - k'$ is sufficiently large. Such a regularity shows up in the Ψ function of CSAs, $\Psi[i] = A^{-1}[A[i] + 1]$, since the values in $\Psi[p_1..p_1 + s - 1]$ will point to $[p_2..p_2 + s - 2]$, and so on, thereby inducing runs of 1s in $\Psi'[i] = \Psi[i] - \Psi[i - 1]$, which is the main component of CSAs. It also shows up in the Burrows-Wheeler Transform (BWT) of T , $\text{BWT}[i] = T[A[i] - 1]$, which is the main component of the FM-index: $\text{BWT}[p_2..p_2 + s - 1]$ will be a run of copies of $S[1]$ and so on.

Mäkinen et al. (2010) took the first step toward adapting CSAs and FM-indexes to handle repetitive texts better, by run-length compressing the runs of 1s in Ψ' or the runs of the same letters in the BWT. The number of runs in Ψ' is almost the same as the number r of runs in the BWT. Their run-length compressed CSA and FM-index then use $O(r)$ space, often much less than a standard CSA or FM-index while still counting patterns' occurrences quickly.

Until very recently it was not known how to compress similarly the suffix-array sample with which we can locate patterns' occurrences in T , without making those locating queries extremely slow. However, Gagie et al. (2018) have now introduced a new sampling scheme that takes $O(r)$ space and lets us locate each occurrence with essentially only a predecessor query. Specifically, they can count the number of occurrences of a pattern of length m in $O(m \log \log n)$ time and then locate each occurrence in $O(\log \log n)$ time.

Lempel-Ziv and Grammar-Based Indexes

Kärkkäinen and Ukkonen (1996) showed how to store an $O(z)$ -space data structure in addition to the text T , where z is the number of phrases in the LZ77 parse of T , such that locating all the occurrences of a pattern of length m takes $O(m^2 + m \log z + \sqrt{mz \log m})$ time plus $O(\log z)$ time per occurrence. They divided the

occurrences into two types, called primary and secondary: the former start in one phrase and end in another (or at the next phrase boundary), and the latter are completely contained within single phrases. Their idea was to store a pair of Patricia trees, one for the reversed phrases in the parse and the other for the suffixes starting at phrase boundaries. By dividing a pattern every possible way into a nonempty prefix and a (possibly empty) suffix and searching for the reversed prefix in the first tree and the suffix in the second, they obtain a pair of Patricia tree nodes or, equivalently, a pair of ranges in the lexicographically sorted reversed prefixes and suffixes. Using an $O(z)$ -space data structure for four-sided two-dimensional range reporting, they obtain all the primary occurrences. They use access to the text to verify the occurrences. Using another $O(z)$ -space data structure that represents the structure of the LZ77 parse, they can then obtain all the secondary occurrences from the primary ones.

Researchers are still following Kärkkäinen and Ukkonen's basic design. The major alterations have aimed at a compressed representation of the text, which is essential in the repetitive scenario. Compressed representations, which must offer direct access in order to support searches, have been built on the LZ77 parse or a variant of it (Kreft and Navarro 2013; Do et al. 2014; Navarro 2017), a context-free grammar (Claude and Navarro 2011, 2012; Gagie et al. 2012, 2014; Bille et al. 2017), a run-length compressed FM-index without samples (which also replaces the Patricia trees) (Belazzougui et al. 2015, 2017), and CDAWGs (Belazzougui et al. 2015, 2017). Another improvement has been to substitute z-fast tries for the Patricia trees, which allows removing the quadratic dependence on m in the query time (Gagie et al. 2014; Bille et al. 2017).

There are also indexes based on edit-sensitive parsing (Maruyama et al. 2013; Takabatake et al. 2014, 2016) and locally consistent parsing (Nishimoto et al. 2016), although the former has poor worst-case query time and seems practical only for long patterns, and the latter is complicated and competitive in theory only when the text is dynamic.

No structure using $O(z)$ space offers good worst-case query times, because it is not known how to support fast access to the text within this space. The most recent theoretical bounds are due to Bille et al. (2017), who showed how we can store an $O(z \log(n/z) \log \log z)$ -space data structure such that later we can locate all the occurrences of a pattern of length m in $O(m)$ time plus $O(\log \log z)$ time per occurrence. The implementation of Kreft and Navarro (2013) uses $O(z)$ space and offers the best compression with query times that are competitive in practice (despite their $O(m^2 z)$ worst-case bound).

Several authors (Schneeberger et al. 2009; Wandelt et al. 2013; Ferrada et al. 2014; Procházka and Holub 2014; Rahn et al. 2014) have independently proposed ideas essentially equivalent to finding the primary occurrences using an FM-index built on the substrings of length 2ℓ centered around phrase boundaries, where ℓ is a parameter. Gagie and Puglisi (2015) surveyed early work in this direction, and others (Danek et al. 2014; Wandelt and Leser 2015; Valenzuela 2016; Valenzuela and Mäkinen 2017; Ferrada et al. 2018) have given new implementations. These indexes are practical, though they have good worst-case query times only for patterns of length $m \leq \ell$. Increasing ℓ at construction worsens compression, whereas searching for patterns longer than ℓ requires the use of heuristics.

CDAWGs

A string $S[1..k]$ appearing s times in T tends to induce large isomorphic subtrees in the suffix tree of T , namely, the subtrees (with s leaves) of the suffix tree nodes representing the strings $S[1..k]$, $S[2..k]$, and so on. By regarding the suffix tree as a deterministic automaton, identifying all of its leaves with a single final state, and minimizing it, one obtains the CDAWG of T (Blumer et al. 1987). The minimization gets rid of the isomorphic subtrees, so the CDAWG benefits from repetitiveness as well.

The CDAWG can be represented using $O(e)$ space, where e is the number of right extensions of maximal repeats in T . With it, we can locate all the occurrences of a pattern of length m in

$O(m \log \log n)$ time plus $O(1)$ time per occurrence (Belazzougui et al. 2015). Its disadvantage is that e is always larger than r and z , by a wide margin in practice, and hence CDAWGs tend to be much larger than the structures described above. The fastest variant (Belazzougui and Cunial 2017) uses $O(e + \bar{e})$ space (where \bar{e} is the e measure of the reversed text) and answers locating queries in optimal time: $O(m)$ and then $O(1)$ per occurrence.

An advantage of CDAWGs is that they can be augmented to support suffix tree functionality (Belazzougui and Cunial 2017; Takagi et al. 2017), which is more powerful than just counting and locating pattern occurrences and of interest in bioinformatics applications. The CDAWG implements a number of suffix tree navigation operations in $O(\log n)$ time. Other compressed suffix trees for repetitive collections (Abeliuk et al. 2013; Navarro and Ordóñez 2016) build on a run-length encoded CSA or FM-index and apply grammar compression to the extra suffix tree components: the suffix tree's topology and the longest common prefix array. Like the CDAWG, they profit from repetitiveness but are significantly larger than their underlying compressed suffix array. The only compressed suffix tree of this kind offering good space guarantees (Gagie et al. 2017b), uses $O(r \log(n/r))$ space, and implements the suffix tree operations in time $O(\log(n/r))$.

Graph-Based Indexes

Graph-based indexes are the newest approach to compressed indexing of repetitive textual datasets so far focused on genomics (Eggertsson et al. 2017; Novak et al. 2017b). Most are generalizations of FM-indexes; Na et al.'s suffix tree of an alignment (Na et al. 2013a) and suffix array of an alignment (Na et al. 2013b) have now been superseded by their FM-index of an alignment (Na et al. 2016; Na et al. 2018). Work in this direction began with Ferragina et al. (2009) extending FM-indexes to labelled trees, followed by Bowe et al. (2012) extending them to de Bruijn graphs and Sirén et al. (2011, 2014) and Sirén (2017) extending them to labelled directed acyclic graphs (DAGs). Gagie

et al. (2017a) recently introduced a framework unifying these results.

Sirén et al.’s indexes are meant for pan-genomics and work essentially by embedding and indexing the DAGs in a kind of de Bruijn graph, allowing matches in recombinations of the input genomes. On the other hand, Na et al. index only the input genomes, essentially by embedding and indexing them in a kind of colored de Bruijn graph.

Both techniques depend on the presence of long, perfectly conserved regions to obtain better compression than run-length compressed FM-indexes, so it is not clear whether they will retain a significant advantage when compressing databases of tens of thousands of genomes in which low-frequency variations are included, how they compare to reference-free alignment methods, and to what extent they have applications outside bioinformatics.

Implementations

The run-length compressed FM-index of Mäkinen et al. (2010) is available at <http://jltsiren.kapsi.fi/rindex>. There are several implementations specifically for genomics (e.g., BGT, BWT-merge, MSBWT, RopeBWT2, SGA), many of which are available on GitHub. The index of Gagie et al. (2018) is implemented at <https://github.com/nicolaprezza/r-index>. The best implementation of the index of Kreft and Navarro (2013) is by Claude et al. (2016), currently available at <https://github.com/migumar2/uiHRDC/tree/master/self-indexes/LZ>.

Valenzuela (2016) and Valenzuela and Mäkinen (2017) give a good general-purpose hybrid index and a good pan-genomic aligner based on a hybrid index, available at <https://www.cs.helsinki.fi/u/dvalenzu/software>.

The DAG-based implementation of Sirén et al. is available at <https://github.com/jltsiren/gcsa2>. There are also several implementations of graph indexes specifically for genomics (Dilthey et al. 2015; Maciuca et al. 2016; Novak et al. 2017a; Paten et al. 2017), some of which are available at <https://github.com/vgteam/vg>.

Example Application

The main applications of indexing repetitive texts have been in bioinformatics, such as indexing genomic databases to support fast alignments. We may be given a database of a thousand human genomes, for example, and asked to preprocess it such that later, given a pattern and an integer k , we can quickly report which genomes contain substrings within edit distance k of that pattern. There are several techniques for implementing such approximate pattern matching using indexes for exact matching (Navarro and Raffinot 2002; Ohlebusch 2013; Mäkinen et al. 2015).

Future Directions for Research

There are several important open problems in the area. An immediate one is to explore the practical impact of the new run-length compressed FM-index of Gagie et al. (2018). In the longer term, combining run-length compressed FM-indexes with graph-based indexes and finding new applications for such indexes seem promising. Another challenge is to upgrade suffix arrays to suffix trees for repetitive collections; suffix trees require access to arbitrary suffix array cells, which is not known to be possible within $O(r)$ space, where r is again the number of runs in the BWT. Obtaining better search performance within space close to $O(z)$ in Lempel-Ziv- and grammar-based indexes is also important, where z is again the number of phrases in the LZ77 parse, because z is in practice significantly smaller than r , even if in theory they are incomparable. String attractors (Kempa and Prezza 2017) were introduced as a generalization of these two and many other measures of repetitiveness, so indexes based on them could be good with respect to all these measures simultaneously.

Computer Architecture for Big Data

Behrooz Parhami

Department of Electrical and Computer Engineering, University of California, Santa Barbara, CA, USA

Synonyms

Big data hardware acceleration; Hardware considerations for big data

Definitions

How features of general-purpose computer architecture impact big-data applications and, conversely, how requirements of big data lead to the emergence of new hardware and architectural support.

Overview

Computer architecture (Parhami 2005) is a sub-discipline of computer science and engineering that is concerned with designing computing structures to meet application requirements

effectively, economically, reliably, and within prevailing technological constraints. In this entry, we discuss how features of general-purpose computer architecture impacts big-data applications and, conversely, how requirements of big data lead to the emergence of new hardware and architectural support.

Historical Trends in Computer Architecture

The von Neumann architecture for stored-program computers, with its single or unified memory, sometimes referred to as the Princeton architecture, emerged in 1945 (von Neumann 1945; von Neumann et al. 1947) and went virtually unchallenged for decades. It dominated the alternative Harvard architecture with separate program and data memories (Aiken and Hopper 1946) from the outset as the more efficient and versatile way of implementing digital computers.

As the workload for general-purpose computers began to change, adjustments in, and alternatives to, von Neumann architecture were proposed. Examples include de-emphasizing arithmetic operations in favor of data movement primitives, as seen in input/output and stream processors (Rixner 2001); introducing hardware aids for frequently used operations, as in graphic processing units or GPUs (Owens et al. 2008; Singer 2013); and adding special instructions for improved performance on multimedia workloads (Lee 1995; Yoon et al. 2001).

Recently, data-intensive applications necessitated another reassessment of the match between prevalent architectures and application requirements. The performance penalty of data having to be brought into the processor and sent back to memory through relatively narrow transfer channels was variously dubbed the “von Neumann bottleneck” (Markgraf 2007) and the “memory wall” (McKee 2004; Wulf and McKee 1995). Memory data transfer rates are measured in GB/s in modern machines, whereas the processing rates can be three or more decimal orders of magnitude higher.

The term “non-von” (Shaw 1982) was coined to characterize a large category of machines that relaxed one or more of the defining features of the von Neumann architecture, so as to alleviate some of the perceived problems. Use of cache memories (Smith 1982), often in multiple levels, eased the von Neumann bottleneck for a while, but the bottleneck reemerged, as the higher cache data transfer bandwidth became inadequate and applications that lacked or had relatively limited locality of reference emerged. Memory interleaving and memory-access pipelining, pioneered by IBM (Smotherman 2010) and later used extensively in Cray supercomputers, was the next logical step.

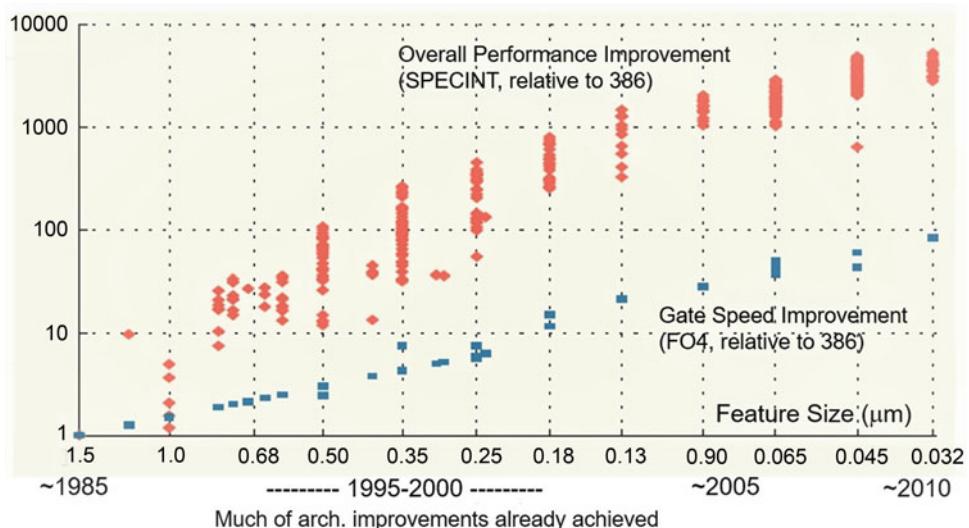

Extrapolating a bit from Fig. 1 (which covers the period 1985–2010), and using round numbers, the total effect of architectural innovations has been a 100-fold gain in performance, on top of another factor-of-100 improvement due to faster gates and circuits (Danowitz et al. 2012). Both growth rates in Fig. 1 show signs of slowing down, so that future gains to support the rising processing need of big data will have to come, at least in part, from other sources. In the technology arena, use of emerging technologies will provide some boost for specific applications. An intriguing option is resurrecting hybrid

digital/analog computing, which was sidelined long ago in favor of all-digital systems. Architecturally, specialization is one possible avenue for maintaining the performance growth rate, as are massively parallel and in-memory or near-memory computing.

How Big Data Affects Computer Architecture

The current age of big data (Chen and Zhang 2014; Hu et al. 2014) has once again exposed the von Neumann bottleneck, forcing computer architects to seek new solutions to the age-old problem, which has become much more serious. Processing speed continues to rise exponentially, while memory bandwidth increases at a much slower pace.

It is by now understood that big data is different from “lots of data.” It is sometimes defined in terms of the attributes of volume, variety, velocity, and veracity, known as the “4Vs” (or “5 Vs,” if we also include value). Dealing with big data requires big storage, big-data processing capability, and big communication bandwidth. The first two (storage and data processing) directly affect the architecture of the nodes holding

Computer Architecture for Big Data, Fig. 1 Technology advances and architectural innovations each contributed a factor of ~ 100 improvement in processor performance over three decades. (Danowitz et al. 2012)

and processing the data. The part of communication that is internode is separately considered in this encyclopedia. However, there is also the issue of intranode communication represented in buses and networks-on-chip that belong to our architectural discussion here.

In addition to data volume, the type of data to be handled is also changing from structured data, as reflected, for example, in relational databases, to semi-structured and unstructured data. While this change has some negative effects in terms of making traditional and well-understood database technologies obsolete, it also opens up the possibility of using scalable processing platforms made of commodity hardware as part of the cloud-computing infrastructure. Massive unstructured data sets can be stored in distributed file systems, such as the ones designed in connection with Hadoop (Shafer et al. 2010) or SQL/noSQL (Cattell 2011).

In addition to the challenges associated with rising storage requirements and data access bandwidth, the processing load grows with data volume because of various needs. These are:

- Encryption and decryption
- Compression and decompression
- Sampling and summarization
- Visualization and graphing
- Sorting and searching
- Indexing and query processing
- Classification and data mining
- Deduction and learning

The first four items above, which are different forms of data translation, are discussed in the next section. The other items, viz., data transformations, will be discussed subsequently.

Architectural Aids to Data Translations

Many important data translations are handled by endowing a general-purpose architecture with suitable accelerator units deployed as coprocessors. Such accelerators are ideally custom integrated circuits, whose designs are fully optimized

for their intended functions. However, in view of rapid advances in capabilities, performance, and energy efficiency of field-programmable gate arrays (Kuon et al. 2008), a vast majority of modern accelerators reported in the literature are built on FPGA circuits.

Accelerators for encryption and decryption algorithms have a long history (Bossuet et al. 2013). The binary choice of custom-designed VLSI or general-purpose processing for cryptographic computations has expanded to include a variety of intermediate solutions which include the use of FPGAs and GPUs. The best solution for an application domain depends not only on the required data rates and the crypto scheme, but also on power, area, and reliability requirements.

Data compression (Storer 1988) allows us to trade processing time and resources for savings in storage requirements. While any type of data can be compressed (e.g., text compression), massive sizes of video files make them a prime target for compression. With the emergence of video compression standards (Le Gall 1991), much effort has been expended to implement the standards on special-purpose hardware (Pirsch et al. 1995), offering orders of magnitude speed improvement over general-purpose programmed implementations.

Both sampling and summarization aim to reduce data volume while still allowing the operations of interest to be performed with reasonable precision. An alternative to post-collection reduction of data volume is to apply compression during data collection, an approach that in the case of sensor data collection is known as compressive sensing (Baraniuk 2007). Compressive sensing, when applicable, not only saves on processing time but also reduces transmission bandwidth and storage requirements. There are some mathematical underpinnings common to compressive sensing techniques, but at the implementation level, the methods and algorithms are by and large application-dependent.

Data visualization (Ward et al. 2010) refers to the production of graphical representation of data for better understanding of hidden structures and relationships. It may provide the only reasonable hope for understanding massive amounts of data,

although machine learning is a complementary and competing method of late. Several visualization accelerators were implemented in the late 1990s (e.g., Scott et al. 1998), but the modern trend is to use FPGA and cluster-based methods.

Architectural Aids to Data Transformations

Sorting is an extremely important primitive that is time-consuming for large data sets. It is used in a wide array of contexts, which includes facilitating subsequent searching operations. It can be accelerated in a variety of ways, from building more efficient data paths and memory access schemes, in order to make conventional sorting algorithms run faster, to the extreme of using hardware sorting networks (Mueller et al. 2012; Parhami 1999).

Indexing is one of the most important operations for large data sets, such as those maintained and processed by Google. Indexing and query processing have been targeted for acceleration within large-scale database implementations (Casper and Olukotun 2014; Govindaraju et al. 2004). Given the dominance of relational databases in numerous application contexts, a variety of acceleration methods have been proposed for operations on such databases (e.g., Bandi et al. 2004). Hardware components used in realizing such accelerators include both FPGAs and GPUs.

Hardware aids for classification are as diverse as classification algorithms and their underlying applications. A prime example in Internet routing is packet classification (Taylor 2005), which is needed when various kinds of packets, arriving at extremely high rates, must be separated for appropriate handling. Modern hardware aids for packet classification use custom arrays for pipelined network processing, content-addressable memories (Liu et al. 2010), GPUs (Owens et al. 2008), or tensor processing units (Sato et al. 2017). Data mining, the process of generating new information by examining large data sets, has also been targeted for acceleration (Sklyarov et al. 2015), and it can benefit from similar highly parallel processing approaches.

Also falling under such acceleration schemes are aids and accelerators for processing large graphs (Lee et al. 2017).

The earliest form of deduction engines were theorem provers. An important application of automatic deduction and proof is in hardware verification (Cyrluk et al. 1995). In recent years, machine learning has emerged as an important tool for improving the performance of conventional systems and for developing novel methods of tackling conceptually difficult problems. Game-playing systems (Chen 2016) constitute important testbeds for evaluating various approaches to machine learning and their associated hardware acceleration mechanisms. This is a field that has just started its meteoric rise and bears watching for future applications.

Memory, Processing, and Interconnects

In both general-purpose and special-purpose systems interacting with big data, the three interconnected challenges of providing adequate memory capacity, supplying the requisite processing power, and enabling high-bandwidth data movements between the various data-handling nodes must be tackled (Hilbert and Lopez 2011).

The memory problem can be approached using a combination of established and novel technologies, including nonvolatile RAM, 3D stacking of memory cells, processing in memory, content-addressable memory, and a variety of novel (nanoelectronics or biologically inspired) technologies. We won't dwell on the memory architecture in this entry, because the memory challenge is addressed in other articles (see the Cross-References).

Many established methods exist for increasing the data-handling capability of a processing node. The architectural nomenclature includes superscalar and VLIW organizations, collectively known as instruction-level parallelism (Rau and Fisher 1993), hardware multithreading (Eggers et al. 1997), multicore parallelism (Gepner and Kowalik 2006), domain-specific hardware accelerators (examples cited earlier in this entry),

transactional memory (Herlihy and Moss 1993), and SIMD/vector architectural or instruction-set extensions (Lee 1995; Yoon et al. 2001). A complete discussion of all these methods is beyond the scope of this entry, but much pertinent information can be found elsewhere in this encyclopedia.

Intranode communication is achieved through high-bandwidth bus systems (Hall et al. 2000) and, increasingly, for multicore processors and systems-on-chip, by means of on-chip networks (Benini and De Micheli 2002). Interconnection bandwidth and latency rank high, along with memory bandwidth, among hardware capabilities needed for effective handling of big-data applications, which are increasingly implemented using parallel and distributed processing. Considerations in this domain are discussed in the entry “Parallel Processing for Big Data.”

Future Directions

The field of computer architecture has advanced for several decades along the mainstream line of analyzing general applications and making hardware faster and more efficient in handling the common case while being less concerned with rare cases which have limited impact on performance. Big data both validates and challenges this assumption. It validates it in the sense that certain data-handling primitives arise in all contexts, regardless of the nature of the data or its volume. It challenges the assumption by virtue of the von-Neumann bottleneck or memory-wall notions discussed earlier. The age of big data will speed up the process of trickling down of architectural innovations from supercomputers, which have always led the way, into servers or even personal computers, which now benefit from parallel processing and, in some cases, massive parallelism.

Several studies have been performed about the direction of computer architecture in view of new application domains and technological developments in the twenty-first century (e.g., Ceze et al. 2016; Stanford 2012). Since much of the processing schemes for big data will be provided through

the cloud, directions of cloud computing and associated hardware acceleration mechanisms become relevant to our discussion here (Caulfield et al. 2016). Advanced graphics processors (e.g., Nvidia 2016) will continue to play a key role in providing the needed computational capabilities for data-intensive applications requiring heavy numerical calculations. Application-specific accelerators for machine learning (Sato et al. 2017), and, more generally, various forms of specialization, constitute another important avenue of architectural advances for the big-data universe.

Definitions

Compression mechanisms reduce the storage cost of retained data. In the extreme case of data that must be retained indefinitely, the initial cost of performing the compression transformation can be amortized down to zero, since the savings in storage space continue to accrue without limit, albeit at decreasing rates as time goes by and disk storage becomes cheaper. A more typical scenario arises when a fixed data retention period must be supported, after which the stored data is no longer required; and when a certain level of access operations to the stored data can be expected, as part of a regulatory or compliance environment. In this second scenario, the *total cost of retention* (TCR) is a function of multiple competing factors, and the compression regime that provides the most compact storage might not be the one that provides the smallest TCR. This entry summarizes recent work in the area of cost models for data retention.

Overview

Data compression techniques have received extensive study over more than six decades. Entropy coding mechanisms such as Huffman, arithmetic, and asymmetric numeral system (ANS) coding have been used to support a range of modeling approaches, including those based on implicit and explicit dictionaries, those based on statistical prediction, those based on grammar identification, and those based on the Burrows-Wheeler transform. Witten et al. (1999) and Moffat and Turpin (2002) provide details of many such combinations; the ANS mechanism is more recent (Duda 2009, 2013; Moffat and Petri 2017). Each possible arrangement of model and coder represents another option for use by practitioners, with a wide range of trade-offs possible. Compression systems are typically compared in two quite different ways, based on the size of the compressed data (the *effectiveness* of the approach) and based on the computational and memory resources required to attain the encoding

and decoding transformation (the *efficiency* of the approach). Moreover, it is often the case that effectiveness and efficiency are in tension – that the most effective techniques are also the ones that are least efficient and vice versa. For example, software implementations of compression tools often include an optional parameter (in several cases, “-1” to “-9”) to indicate the effort that should be used during encoding, with better compression resulting from greater effort; and principled trade-off mechanisms have also been proposed (Farruggia et al. 2014).

Hence, if a choice must be made between competing alternatives (compression programs or option settings) for use in some particular application or situation, a joint overall cost must be developed based on all relevant factors and used to measure the *total cost of retention*. This entry summarizes recent work by Liao et al. (2017) that describes such a cost model as a response to a *service-level agreement* and provides a synopsis of their key findings.

Data Storage and Retention

An archiving service stores different kinds of objects such as files, log entries, or variable-size data blobs. Adding objects to the storage system is generally referred to as a PUT request; and to retrieve objects, a GET request specifying one or more objects is issued to the storage system.

The objects stored by the archiving system can be viewed as a stream of bytes arriving at a constant rate when averaged over time. Liao et al. (2017) consider the case of data that arrives at an ingest rate of λ GiB/day, is subject to some obligatory minimum retention period of L_D days, and while retained must be available to GET requests assumed to occur at the rate of q queries per stored GiB per day. Each GET request for an object that was ingested during some particular day less than L_D days in the past is translated to a byte location within that day’s data, and a request for the corresponding object (some number of bytes or kibibytes) is then issued, so that the object can be retrieved and delivered. For example, log data or transac-

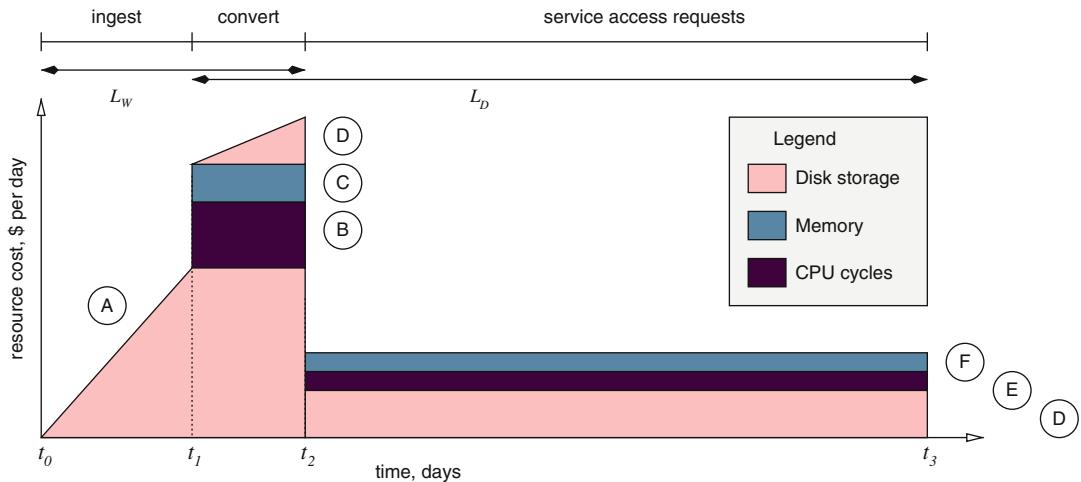

tion data might accumulate through some business process and be required to be retained for some minimum compliance period as part of a regulatory framework; and small fragments of that data might be required to be available on demand for audit or verification purposes. Such data retention regimes would typically be the subject of a *service-level agreement*, or SLA, including requirements in regard to the maximum delay L_W between ingest of any data and when it becomes available for querying operations, in regard to the maximum latency L_R permissible for any access operations, and in regard to other such performance and reliability requirements.

A cloud provider offering a data storage service naturally seeks to *minimize* the overall cost of providing the service within the constraints of the SLA. Compression is a key technology in this regard, since for long retention periods, the flag-fall cost of compressing the data can almost certainly be recouped via decreased storage costs – provided, that is, the required GET operations can also be supported within the constraints imposed by the SLA.

Cost Model for Data Retention

Liao et al. (2017) propose that the total cost of a storage system be subdivided into four categories broadly aligned with the components measured by most cloud system providers: (a) permanent storage, (b) working memory, (c) compute cycles, and (d) I/O operations. Each of these categories is then measured and billed over a specific time period, with the units of each category converted into a common currency of dollars. For example, consuming 50 GiB of permanent storage for 12 months might be billed at \$0.30 per GiB-month for a total storage cost of \$180; and the compute cycles necessary to support GET operations on that data might cost a further \$50 over the course of the year.

The service provider can be assumed to form data *bales* at daily or sub-daily intervals during the ingestion period, each bale assembled from multiple PUT operations. Once accumulated, the bale is then processed as a sequence of inde-

Computing the Cost of Compressed Data, Fig. 1 The bale-based data retention regime described by Liao et al. (2017) (Figure 2 of that paper, with copyright held by the original four authors). The six marked zones are: (A) cost of disk space for incoming data; (B) cost of CPU for index

construction, if applicable; (C) cost of memory space for index construction, if applicable; (D) cost of disk space for retained data; (E) cost of CPU for decoding and access operations during retention period; (F) cost of memory space during retention period, if applicable

pendently retrievable *blocks*, with the bale as a whole following the life cycle shown in Fig. 1. A generic compression algorithm, such as gzip, or a domain specific algorithm, such as MPEG, might be applied to each block, to reduce the amount of permanent storage required while that block is held through the retention period. Ideally a compression scheme which minimizes the overall balance between storage cost and resource expenditure should be chosen, subject to the constraints set by the SLA parameters. For example, the maximum write delay L_W and the maximum read latency L_R set constraints on the encoding and decoding speed of the compression algorithm and/or the size of the blocks that can be allowed. Similarly, the choice of permanent storage has implications on the types of compression algorithms which can comply with the SLA and also on the cost involved. For example, high-latency permanent storage devices will require a compression algorithm with fast decompression speed, in order to handle GET request within L_R .

That is, each possible algorithm requires a certain amount of compute and memory resources (zones (B) and (C) in Fig. 1) to convert incoming bales. After the bale is converted, it resides on secondary storage, incurring a constant storage

cost (D) for the remaining lifetime of the bale. To service GET requests arriving at an average rate of q queries per day per GiB of stored data, the system consumes additional compute and memory resources (E), (F) in order to decompress blocks. Additional IO costs may arise when transferring data to/from permanent storage and to/from the storage system itself.

Implications of the Cost Model

Liao et al. measure encoding and decoding speeds for compression mechanisms in four broad groups:

- No compression at all (denoted as method none);
- Fast encoding and decoding, based on an adaptive model and modest resource consumption, and with reasonably good compression effectiveness achieved at even relatively short block lengths (taking zlib, <https://github.com/madler/zlib>, as an exemplar);
- Excellent compression effectiveness when long blocks can be permitted, at the cost of more expensive encoding and decoding

- (taking `xz`, <http://tukaani.org/xz/>, as an exemplar); and
- RLZ, a semi-static mechanism designed for fast decoding and good compression regardless of block size but requiring a per-bale memory-resident dictionary throughout each bale’s retention period (Hoobin et al. 2011; Petri et al. 2015) (taking <https://github.com/mpetri/rlz-store> as an exemplar).

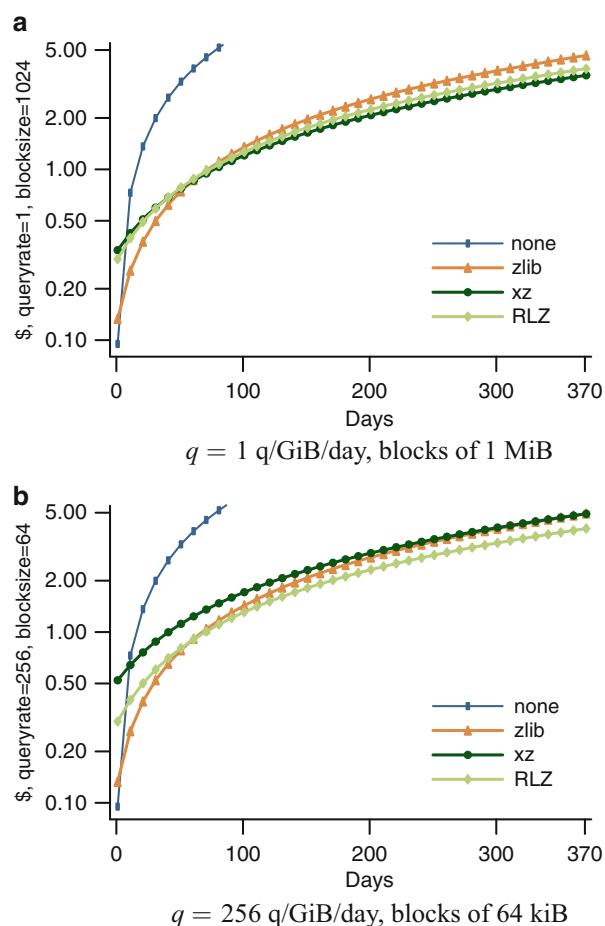

Liao et al. also provide compression effectiveness rates achieved for typical web data using a range of block sizes, highlighting the fact that for the adaptive zlib and xz approaches, compression effectiveness diminishes as blocks are made smaller.

Figure 2 takes that data and applies it to two different scenarios. In both graphs the total

retention cost (TRC, in dollars per 64 GiB bale) is plotted on the vertical axis as a function of cumulative retention time, shown on the horizontal axis, for durations from 1 day to a little over 1 year. In the first pane, a low query rate $q = 1$ query per day per stored GiB is assumed. In this arrangement, relatively large blocks of 1 MiB can be employed as the encoding unit, and as a result `xz` achieves excellent compression rates, close to those of the semi-static RLZ mechanism. Moreover, the 8 MiB allocation of memory required by RLZ (to be precise, 8 MiB in the configuration plotted; dictionary size is another dimension that affects the comparison) is a cost drain that is not recouped even though RLZ decoding is faster. Hence, for all but short retention durations, where the encoding speed of `zlib` is an advantage, `xz` provides the smallest TRC.

Computing the Cost of Compressed Data, Fig. 2

Total retention cost for two different scenarios: (a) a low daily access rate allows large blocks to be used, favoring the “very good but somewhat slow” compression regime `xz`; (b) a high query rate requires small blocks, favoring the semi-static RLZ mechanism. For short retention periods, `zlib` is the cheapest option in both scenarios; and storing the data uncompressed (method `none`) is never an attractive option

In the lower pane, the query rate is considerably increased, to $q = 256$ GET requests per stored GiB per day, and the block sizes need to shorten (the value $b = 64$ kB is used in the plot) so that decoding time doesn't swamp the other costs. Assuming that each GET request is to a different block, that query rate and block size mean that around 1.5% of the bale is decoded each day, and decoding throughput becomes a determining factor. Now RLZ's dictionary memory pays for itself, and it provides the best TRC, a combination of fast decoding and excellent compression effectiveness.

Based on the data they collected (including, as is also used in Figure 2, cost information from mid-2016 for a major cloud services provider), Liao et al. draw broad conclusions in regard to the efficacy of the various options:

- if the retention period is short, then zlib is the most economical choice, using a block size that decreases as the query rate increases;
- if the query rate is low, and if memory is expensive relative to secondary storage, then xz should be preferred; and
- if the query rate is high, and/or if the memory-to-disk cost ratio is more moderate, then RLZ-style approaches should be employed.

More generally, Liao et al. note that “thinking TRC” provides a framework in which compression improvements can be accurately measured and present one such approach that reduces RLZ-based retention costs by amortizing dictionary costs over a small number of consecutive bales.

Definitions

A conflict-free replicated data type (CRDT) is an abstract data type, with a well-defined interface, designed to be replicated at multiple pro-

cesses and exhibiting the following properties: (i) any replica can be modified without coordinating with other replicas and (ii) when any two replicas have received the same set of updates, they reach the same state, deterministically, by adopting mathematically sound rules to guarantee state convergence.

Overview

Internet-scale distributed systems often replicate data at multiple geographic locations to provide low latency and high availability, despite outages and network failures. To this end, these systems must accept updates at any replica and propagate these updates asynchronously to the other replicas. This approach allows replicas to temporarily diverge and requires a mechanism for merging concurrent updates into a common state. CRDTs provide a principled approach to address this issue.

As any abstract data type, a CRDT implements some given functionality and exposes a well-defined interface. Applications interact with the CRDT only through this interface. As CRDTs are designed to be replicated and to allow uncoordinated updates, a key aspect of a CRDT is its semantics in the presence of concurrency. The concurrency semantics defines what is the behavior of the object in the presence of concurrent updates, defining the state of the object for any given set of received updates.

An application developer uses the CRDT interface and concurrency semantics to reason about the behavior of her application in the presence of concurrent updates. A system developer creating a system that provides CRDTs needs to focus on another aspect of CRDTs: the synchronization model. The synchronization model defines the requirements that the system must meet so that CRDTs work correctly. We now detail each of these aspects independently.

Concurrency Semantics

The operations defined in a data type may intrinsically commute or not. Consider, for instance, a counter data type, a shared integer that supports

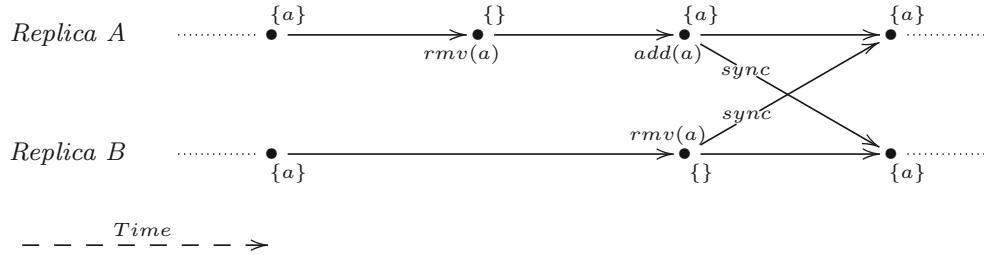

increment and decrement operations. As these operations commute (i.e., executing them in any order yields the same result), the counter data type naturally converges toward the expected result and reflects all executed operations reflects all executed operations.

Unfortunately, for most data types, this is not the case, and several concurrency semantics are reasonable, with different semantics being suitable for different applications. For instance, consider a shared memory cell supporting the assignment operation. If the initial value is 0, the correct outcome for concurrently assigning 1 and 2 is not well defined.

When defining the concurrency semantics, an important concept that is often used is that of the *happens-before* relation (Lamport 1978). In a distributed system, an event e_1 *happened-before* an event e_2 , $e_1 \prec e_2$, iff (i) e_1 occurred before e_2 in the same process; or (ii) e_1 is the event of sending message m , and e_2 is the event of receiving that message; or (iii) there exists an event e such that $e_1 \prec e$ and $e \prec e_2$. When applied to CRDTs, we can say that an update u_1 *happened-before* an update u_2 iff the effects of u_1 had been applied in the replica where u_2 was initially submitted.

As an example, if an event was *Alice reserved the meeting room*, it is relevant to know if that was known when *Bob reserved the meeting room* to determine if Alice should be given priority or if the two users concurrently tried to reserve the same room.

For instance, let us use *happened-before* to define the semantics of the *add-wins* set (also known as observed-remove set, OR-set (Shapiro et al. 2011)). Intuitively, in the *add-wins* semantics, in the presence of two operations that do not commute, a concurrent add and remove of the same element, the add wins leading to a state where the element belongs to the set. More formally, the set interface has two update operations: (i) $\text{add}(e)$, for adding element e to the set, and (ii) $\text{rmv}(e)$, for removing element e from the set. Given a set of update operations O that are related by the happens-before partial order \prec , the state of the set is defined as $\{e \mid \text{add}(e) \in O \wedge \exists \text{rmv}(e) \in O \cdot \text{add}(e) \prec \text{rmv}(e)\}$.

Conflict-Free Replicated Data Types CRDTs, Fig. 1 Run with an add-wins set

Figure 1 shows a run where an add-wins set is replicated in two replicas, with initial state $\{a\}$. In this example, in replica A, a is first removed and later added again to the set. In replica B, a is removed from the set. After receiving the updates from the other replica, both replicas end up with the element a in the set. The reason for this is that there is no $\text{rmv}(a)$ that happened after the $\text{add}(a)$ executed in replica A.

An alternative semantics based on the happens-before relation is *remove-wins*. Intuitively, in *remove-wins* semantics, in the presence of a concurrent add and remove of the same element, the remove wins leading to a state where the element is not in the set. More formally, given a set of update operations O , the state of the set is defined as: $\{e \mid \text{add}(e) \in O \wedge \forall \text{rmv}(e) \in O \cdot \text{rmv}(e) \prec \text{add}(e)\}$. In the previous example, after receiving the updates from the other replica, the state of both replicas would be the empty set, because there is no $\text{add}(a)$ that happened after the $\text{rmv}(a)$ in replica B.

Another relation that can be useful for defining the concurrency semantics is that of a total order among updates and particularly a total order that approximates wall-clock time. In distributed systems, it is common to maintain nodes with their physical clocks loosely synchronized. When combining the clock time with a site identifier, we have unique timestamps that are totally ordered. Due to the clock skew among multiple nodes, although these timestamps approximate an ideal global physical time, they do not necessarily respect the happens-before relation. This can be achieved by combining physical and logical clocks, as shown by Hybrid Logical Clocks (Kulkarni et al. 2014), or by only arbitrating

a wall-clock total order for the events that are concurrent under causality (Zawirski et al. 2016).

This relation allows to define the *last-writer-wins* semantics, where the value written by the last writer wins over the values written previously, according to the defined total order. More formally, with the set O of operations now totally ordered by $<$, the state of a *last-writer-wins* set would be defined as: $\{e \mid \text{add}(e) \in O \wedge \forall \text{rmv}(e) \in O \cdot \text{rmv}(e) < \text{add}(e)\}$. Returning to our previous example, the state of the replicas after the synchronization would include a if, according to the total order defined among the operations, the $\text{rmv}(a)$ of replica B is smaller than the $\text{add}(a)$ of replica A. Otherwise, the state would be the empty set.

We now briefly introduce the concurrency semantics proposed for several CRDTs.

Set

For a set CRDT, we have shown the difference between three possible concurrency semantics: *add-wins*, *remove-wins*, and *last-writer-wins*.

Register

A register CRDT maintains an opaque value and provides a single update operation that writes an arbitrary value: $\text{wr}(value)$. Two concurrency semantics have been proposed leading to two different CRDTs: the *multi-value* register and the *last-writer-wins* register. In the *multi-value* register, all concurrently written values are kept. In this case, the read operation returns the set of concurrently written values. Formally, the state of a multi-value register is defined as the multi-set: $\{v \mid \text{wr}(v) \in O \wedge \exists \text{wr}(u) \in O \cdot \text{wr}(v) \prec \text{wr}(u)\}$.

In the *last-writer-wins* register, only the value of the last write is kept, if any. Formally, the state of a last-writer-wins register can be defined as a set that is either empty or holds a single value: $\{v \mid \text{wr}(v) \in O \wedge \exists \text{wr}(u) \in O \cdot \text{wr}(v) < \text{wr}(u)\}$, assuming some initial write.

Counter

A counter CRDT maintains an integer and can be modified by update operations `inc` and `dec`, to increase and decrease by one unit its value, respectively (this can easily generalize to arbitrary amounts). As mentioned previously, as operations intrinsically commute, the natural concurrency semantics is to have a final state that reflects the effects of all registered operations. Thus, the result state is obtained by counting the number of increments and subtracting the number of decrements: $|\{\text{inc} \mid \text{inc} \in O\}| - |\{\text{dec} \mid \text{dec} \in O\}|$.

Now consider that we want to add a write operation $\text{wr}(n)$, to update the value of the counter to a given value. This opens two questions related with the concurrency semantics. First, what should be the final state when two concurrent write operations are executed? In this case, the last-writer-wins semantics would be simple (as maintaining multiple values, as in the multi-value register, is overly complex).

Second, what is the result when concurrent writes and `inc/dec` operations are executed? In this case, by building on the happens-before relation, we can define several concurrency semantics. One possibility is a *write-wins* semantics, where `inc/dec` operations have no effect when executed concurrently with the last write. Formally, for a given set O of updates that include at least a write operation, let v be the value in the last write, i.e., $\text{wr}(v) \in O \wedge \exists \text{wr}(u) \in O \cdot \text{wr}(v) < \text{wr}(u)$. The value of the counter would be $v + o$, with $o = |\{\text{inc} \mid \text{inc} \in O \wedge \text{wr}(v) < \text{inc}\}| - |\{\text{dec} \mid \text{dec} \in O \wedge \text{wr}(v) < \text{dec}\}|$ representing `inc/dec` operations that happened after the last write.

Other CRDTs

A number of other CRDTs have been proposed in the literature, including CRDTs for elementary

data structures, such as lists (Preguiça et al. 2009; Weiss et al. 2009; Roh et al. 2011), maps (Brown et al. 2014; Almeida et al. 2018), graphs (Shapiro et al. 2011), and more complex structures, such as JSON documents (Kleppmann and Beresford 2017). For each of these CRDTs, the developers have defined and implemented a type-specific concurrency semantics.

Synchronization Model

A replicated system needs to synchronize its replicas, by propagating and applying updates in every replica. There are two main approaches to propagate updates: state-based and operation-based replication.

In state-based replication, replicas synchronize by establishing bi-directional (or unidirectional) synchronization sessions, where both (one, resp.) replicas send their state to a peer replica. When a replica receives the state of a peer, it merges the received state with its local state. As long as the synchronization graph is connected, every update will eventually propagate to all replicas.

CRDTs designed for state-based replication define a merge function to integrate the state of a remote replica. It has been shown (Shapiro et al. 2011) that all replicas of a CRDT converge if (i) the states of the CRDT are partially ordered according to \leq forming a join semilattice; (ii) an operation modifies the state s of a replica by an inflation, producing a new state that is larger or equal to the original state according to \leq , i.e., for any operation m , $s \leq m(s)$; and (iii) the merge function computes the join (least upper bound) of two states, i.e., for states s, u , it computes $s \sqcup u$.

In operation-based replication, replicas converge by propagating operations to every other replica. When an operation is received in a replica, it is applied to the local replica state. Besides requiring that every operation is reliably delivered to all replicas, e.g., by using some reliable multicast communication subsystem, some systems may require operations to be delivered according to some specific order, with causal order being the most common.

CRDTs designed for operation-based replication must define, for each operation, a generator

and an effector function. The generator function executes in the replica where the operation is submitted, the source replica, it has no side effects and generates an effector that encodes the side effects of the operation. In other words, the effector is a closure created by the generator depending on the state of the origin replica. The effector operation must be reliably executed in all replicas, where it updates the replica state. Shapiro et al. (2011) have shown that if effector operations are delivered in causal order, replicas will converge to the same state if concurrent effector operations commute. If effector operations may be delivered without respecting causal order, then all effector operations must commute. Most operation-based CRDT designs require causal delivery.

Alternative models: When operations modify only part of the state, propagating the complete state for synchronization to a remote replica is inefficient, as the remote replica already knows most of the state. Delta-state CRDTs (Almeida et al. 2018) address this issue by propagating only delta mutators, which encode the changes that have been made to a replica since the last communication. The first time a replica communicates with some other replica, the full state needs to be propagated. This can be improved by using a state summary (e.g., version vector) for computing and sending only the deltas in the first communication also, as shown in big delta-state CRDTs (van der Linde et al. 2016), typically at the cost of storing more metadata in the CRDT state. Another improvement is to compute digests that help determine which parts of a remote state are needed, avoiding shipping full states (Enes 2017).

In the context of operation-based replication, effector operations should be applied immediately to the source replica. However, propagation to other replicas can be deferred for some period and effectors stored in an outbound log, presenting an opportunity to compress the log by rewriting some operations – e.g., two `add(1)` operations in a counter can be converted in a `add(2)` operation. This mechanism has been used by Cabrita and Preguiça (2017). Delta mutators can also be seen as a compressed representation of a log of operations.

Operation-based CRDTs require executing a generator function against the replica state to compute an effector operation. In some scenarios, this may introduce an unacceptable delay for propagating an operation. Pure operation-based CRDTs (Baquero et al. 2014) address this issue by allowing the original operations to be propagated to all replicas, typically at the cost of more complex operations and of having to store more metadata in the CRDT state.

C

Key Research Findings

Preservation of Sequential Semantics

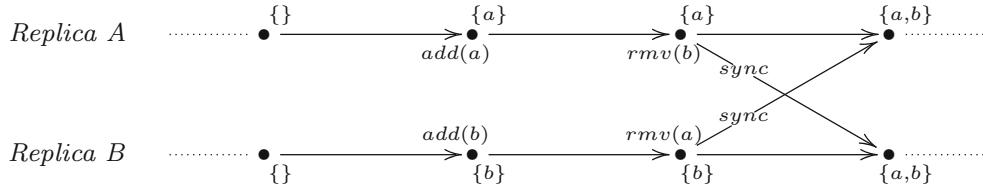

When modeling an abstract data type that has an established semantics under sequential execution, CRDTs should preserve that semantics. For instance, CRDT sets should ensure that if the last operation in a sequence of operations to a set added a given element, then a query operation immediately after that one will show the element to be present on the set. Conversely, if the last operation removed an element, then a subsequent query should not show its presence.

Sequential execution can occur even in distributed settings if synchronization is frequent. An instance can be updated in replica A, merged into another replica B and updated there, and merged back into replica A before A tries to update it again. In this case, we have a sequential execution, even though updates have been executed in different replicas.

Historically, not all CRDT designs have met this property. The *two-phase-set* CRDT (2PSet) does not allow re-adding an element that was removed, and thus it breaks the common sequential semantics. Later CRDT set designs, such as *add-wins* and *remove-wins* sets, do preserve the original sequential semantics while providing different concurrency semantics.

Extended Behavior Under Concurrency

Some CRDT designs handle concurrent operations by arbitrating a given sequential ordering to accommodate concurrent execution. For example, the state of a *last-writer-wins* set replica can be explained by a sequential execution of the op-

Conflict-Free Replicated Data Types CRDTs, Fig. 2 Add-wins set run showing that there might be no sequential execution of operations that explains CRDT behavior

erations according to the LWW total order used. When operations commute, such as in counters, there might even be several sequential executions that explain a given state.

Not all CRDTs need or can be explained by sequential executions. The add-wins set is an example of a CRDT where there might be no sequential execution of operations to explain the state observed, as Fig. 2 shows. In this example, the state of the set after all updates propagate to all replicas includes a and b , but in any sequential extension of the causal order, a remove operation would always be the last operation, and consequently the removed element could not belong to the set.

Some other CRDTs can exhibit states that are only reached when concurrency does occur. An example is the *multi-value register*. If used sequentially, sequential semantics is preserved, and a read will show the outcome of the most recent write in the sequence. However, if two or more values are written concurrently, the subsequent read will show all those values (as the *multi-value* name implies), and there is no sequential execution that can explain this result. We also note that a follow-up write can overwrite both a single value and multiple values.

Guarantees and Limitations

An important property of CRDTs is that an operation can always be accepted at any given replica and updates are propagated asynchronously to other replicas. In the CAP theorem framework (Brewer 2010; Gilbert and Lynch 2002), the CRDT conflict-free approach favors availability over consistency when facing communication disruptions. This leads to resilience to network failure and disconnection,

since no prior coordination with other replicas is necessary before accepting an operation. Furthermore, operations can be accepted with minimal user perceived latency since they only require local durability. By eschewing global coordination, replicas evolve independently, and reads will not reflect operations accepted in remote replicas that have not yet been propagated to the local replica.

In the absence of global coordination, session guarantees (Terry et al. 1994) specify what the user applications can expect from their interaction with the system's interface. Both state-based CRDTs and operation-based CRDTs when supported by reliable causal delivery provide per-object causal consistency. Thus, in the context of a given replicated object, the traditional session guarantees are met. CRDT-based systems that lack transactional support can enforce system-wide causal consistency, by integrating multiple objects in a single map/directory object (Almeida et al. 2018). Another alternative is to use mergeable transactions to read from a causally consistent database snapshot and to provide write atomicity (Preguiça et al. 2014).

Some operations cannot be expressed in a conflict-free framework and will require global agreement. As an example, in an auction system, bids can be collected under causal consistency, and a new bid will only have to increase the offer with respect to bids that are known to causally precede it. However, closing the auction and selecting a single winning bid will require global agreement. It is possible to design a system that integrates operations with different coordination requirements and only resorts to global agreement when necessary (Li et al. 2012; Sovran et al. 2011).

Some global invariants, which usually are enforced with global coordination, can be enforced in a conflict-free manner by using escrow techniques (O’Neil 1986) that split the available resources among the different replicas. For instance, the Bounded Counter CRDT (Balegas et al. 2015b) defines a counter that never goes negative, among assigning to each replica a reserve of allowed decrements under the condition that the sum of all allowed decrements does not exceed the value of the counter. As long as its reserve is not exhausted, a replica can accept decrements without coordinating with other replicas. After a replica exhausts its reserve, a new decrement will either fail or require synchronizing with some replica that still can decrement. This technique uses point-to-point coordination and can be generalized to enforce other system-wide invariants (Balegas et al. 2015a)

Examples of Applications

CRDTs have been used in a large number of distributed systems and applications that adopt weak consistency models. The adoption of CRDTs simplifies the development of these systems and applications, as CRDTs guarantee that replicas converge to the same state when all updates are propagated to all replicas. We can group the systems and applications that use CRDTs into two groups: storage systems that provide CRDTs as their data model and applications that embed CRDTs to maintain their internal data.

CRDTs have been integrated in several storage systems that make them available to applications. An application uses these CRDTs to store its data, being the responsibility of the storage systems to synchronize the multiple replicas. The following commercial systems use CRDTs: Riak (Developing with Riak KV Data Types <http://docs.basho.com/riak/kv/2.2.3/developing/data-types/>), Redis (Biyikoglu 2017), and Akka (Akka Distributed Data: <https://doc.akka.io/docs/akka/2.5.4/scala/distributed-data.html>).

A number of research prototypes have also used CRDTs, including Walter (Sovran et al. 2011),

SwiftCloud (Preguiça et al. 2014), and Antidote (Antidote: <http://antidotedb.org>) (Akkoorath et al. 2016).

CRDTs have also been embedded in multiple applications. In this case, developers either used one of the available CRDT libraries, implemented themselves some previously proposed design, or designed new CRDTs to meet their specific requirements. An example of this latter use is Roshi (Roshi is a large-scale CRDT set implementation for timestamped events <https://github.com/soundcloud/rosi>.), a LWW-element-set CRDT used for maintaining an index in SoundCloud stream.

C

Future Directions of Research

Scalability

In order to track concurrency and causal predecessors, CRDT implementations often store metadata that grows linearly with the number of replicas (Charron-Bost 1991). While global agreement suffers from greater scalability limitations since replicas must coordinate to accept each operation, the metadata cost from causality tracking can limit the scalability of CRDTs when aiming for more than a few hundred replicas. A large metadata footprint can also impact the computation time of local operations and will certainly impact the required storage and communication.

Possible solutions can be sought in more compact causality representations when multiple replicas are synchronized among the same nodes (Malkhi and Terry 2007; Preguiça et al. 2014; Gonçalves et al. 2017) or by hierarchical approaches that restrict all to all synchronization and enable more compact mechanisms (Almeida and Baquero 2013).

Reversible Computation

Nontrivial Internet services require the composition of multiple subsystems, to provide storage, data dissemination, event notification, monitoring, and other needed components. When composing subsystems, which can fail independently or simply reject some operations, it is useful

to provide a CRDT interface that undoes previously accepted operations. Another scenario that would benefit from undo is collaborative editing of shared documents, where undo is typically a feature available to users.

Undoing an increment on a counter CRDT can be achieved by a decrement. Logoot-Undo (Weiss et al. 2010) proposes a solution for undoing (and redoing) operations for a sequence CRDT used for collaborative editing. However, providing a uniform approach to undoing, reversing, operations over the whole CRDT catalog is still an open research direction. The support of undo is also likely to limit the level of compression that can be applied to CRDT metadata.

Security

While access to a CRDT-based interface can be restricted by adding authentication, any accessing client has the potential to issue operations that can interfere with the other replicas. For instance, delete operations can remove all existing state. In state-based CRDTs, replicas have access to state that holds a compressed representation of past operations and metadata. By manipulation of this state and synchronizing to other replicas, it is possible to introduce significant attacks to the system operation and even its future evolution.

Applications that store state on third-party entities, such as in cloud storage providers, might not trust the provider and choose end-to-end encryption of the exchanged state. This, however, would require all processing to be done at the edge, under the application control. A research direction would be to allow some limited form of computation, such as merging state, over information whose content is subject to encryption. Potential techniques, such as homomorphic encryption, are likely to pose significant computational costs. An alternative is to execute operations on encrypted data without disclosing it, relying on specific hardware support, such as Intel SGX and ARM TrustZone.

Nonuniform Replicas

The replication of CRDTs typically assumes that eventually all replicas will reach the same state, storing exactly the same data. However, depend-

ing on the read operations available in the CRDT interface, it might not be necessary to maintain the same state in all replicas. For example, an object that has a single read operation returning the top-K elements added to the object only needs to maintain those top-K elements in every replica. The remaining elements are necessary if a remove operation is available, as one of the elements not in the top needs to be promoted when a top element is removed. Thus, each replica can maintain only the top-K elements and the elements added locally.

This replication model is named nonuniform replication (Cabrita and Preguiça 2017) and can be used to design CRDTs that exhibit important storage and bandwidth savings when compared with alternatives that keep all data in all replicas. Although it is clear that this model cannot be used for all data types, several useful CRDT designs have been proposed, including top-K, top-Sum, and histogram. To understand what data types can adopt this model and how to explore it in practice is an open research question.

Verification

An important aspect related with the development of distributed systems that use CRDTs is the verification of the correctness of the system. This involves not only verifying the correctness of CRDT designs but also the correctness of the system that uses CRDTs. A number of works have addressed these issues.

Regarding the verification of the correctness of CRDTs, several approaches have been taken. The most commonly used approach is to have proofs when designs are proposed or to use some verification tools for the specific data type, such as TLA (Lamport 1994) or Isabelle (Isabelle: <http://isabelle.in.tum.de/>). There have also been some works that proposed general techniques for the verification of CRDTs (Burckhardt et al. 2014; Zeller et al. 2014; Gomes et al. 2017), which can be used by CRDT developers to verify the correctness of their designs. Some of these works (Zeller et al. 2014; Gomes et al. 2017) include specific frameworks that help the developer in the verification process.

A number of other works have proposed techniques to verify the correctness of distributed systems that use CRDTs (Gotsman et al. 2016; Zeller 2017; Balegas et al. 2015a). These works typically require the developer to specify the properties that the distributed system must maintain and a specification of the operations in the system (that is independent of the actual code of the system). Despite these works, the verification of the correctness of CRDT designs and of systems that use CRDTs, how these verification techniques can be made available to programmers, and how to verify the correctness of implementations remain an open research problem.

[Business process conformance checking](#)

Definitions

Given an event log and a process model from the same process, conformance checking compares the recorded event data with the model to

identify commonalities and discrepancies. The conformance between a log and model can be quantified with respect to different quality dimensions: *fitness*, *precision*, and *generalization*.

Overview

Conformance checking compares an event log with a process model of the same process (Munoz-Gama 2016). An event log is composed of a series of log traces where each log trace relates to the sequence of observed events of a process instance, i.e., a case. An event can be related to a particular activity in the process but can also record many other process information such as time stamp, resource, and cost. In a real-life context, event logs can be extracted from Process-Aware Information Systems (PAIS) such as workflow management (WFM) systems, business process management (BPM) systems, or typical relational databases, such as SAP database. Similarly, process models can often be extracted from the organization's information systems. These can be normative models that the organization uses to manage their process, or descriptive, created by hand or automatically discovered to gain insight into their processes (van der Aalst 2013).

Depending on the nature of the model, discrepancies between the log and model can have different interpretations (van der Aalst 2016). For a normative model, deviations indicate violations of imposed constraints. For example, a banking process may require the processing and approval of a loan to be done by different employees to avoid the risk of misconduct (four-eyes principle). Clearly, conformance checking between an event log of the handled loan applications and the process model can be applied to assess compliance. On the other hand, for a descriptive model, deviations indicate that the model is not fully capturing all the observed behavior in the log. For example, process analysts might perform conformance checking on the models discovered by different process discovery algorithms before selecting the ones that are of sufficient quality for further analysis.

To illustrate conformance checking, a simple process is introduced. Figure 1 shows a doctoral scholarship application process in an informal modeling notation. This process consists of eight activities: *Start Processing*, *Evaluate Project*, *Evaluate Academic Record*, *Evaluate Advisor CV*, *Final Evaluation*, *Accept*, *Reject*, and *Notify Results*. To begin the process, an applicant has to submit their academic record, their advisor's CV, and a description of their proposed project. Once the required documents are received, the committee would begin by evaluating the submitted documents. As shown by the AND gateway, the committee can choose to evaluate the three documents in any order. Following the preliminary evaluation, a final evaluation is done to consolidate the previous results. This leads to either the acceptance or rejection of the application. Finally, the applicant is notified of the result. An example of log trace corresponding to an accepted application could be $\langle \text{Start Processing}, \text{Evaluate Project}, \text{Evaluate Academic Record}, \text{Evaluate Advisor CV}, \text{Final Evaluation}, \text{Accept}, \text{Notify Results} \rangle$.

Dimensions of Conformance

Through conformance checking, commonalities and discrepancies between a log and model are quantified. One simple idea would be to consider that a log and model are conforming with each other if the observed behavior in the log is captured by the model. This means that a log and model are perfectly conforming if all the log traces can be *fitted* to the model. However, this can be easily achieved with a model that allows any behavior. Such models do not provide much information to the data analyst about the process. This shows that there is a need to consider conformance with respect to different dimensions.

Currently, conformance is generally considered with respect to three dimensions – *fitness*, *precision*, and *generalization*.

Fitness relates to how well a model and log fit each other. A log trace perfectly *fits* the model if it can be replayed onto the model and corresponds to a complete model trace. For example, $\langle \text{Start Processing}, \text{Evaluate Project}, \text{Evaluate Academic Record} \rangle$

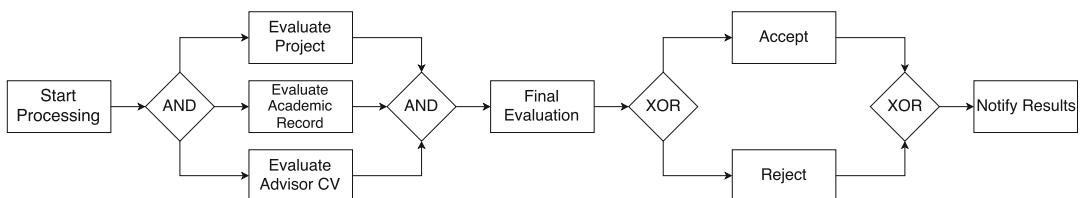

Record, Evaluate Advisor CV, Final Evaluation, Accept, Notify Results} perfectly fits the model in Fig. 1 since each of the observed steps can be sequentially replayed at the model, and the trace corresponds to a particular possible way to execute the process model. However, the trace *(Start Processing, Evaluate Project, Evaluate Academic Record, Final Evaluation, Reject, Notify Results)* does not fit the model because the advisor's CV (*Evaluate Advisor CV*) is never evaluated. This suggests that the corresponding application has been rejected without proper evaluation.

Precision relates to a model's ability to capture the observed behavior without allowing unseen behavior. It is not enough to have a model that is perfectly fitting with the log since this can be easily achieved with a model that permits any behavior. Consider the "flower" model in Fig. 2; it consists of all the transitions attached to a state that corresponds to both the start and end state. This means any sequence involving the connected transitions is permissible by the model. Though perfectly fitting with the log, such underfitting model does not convey much useful information to the user. In contrary, the process

model illustrated in Fig. 3 is much more precise than the flower model.

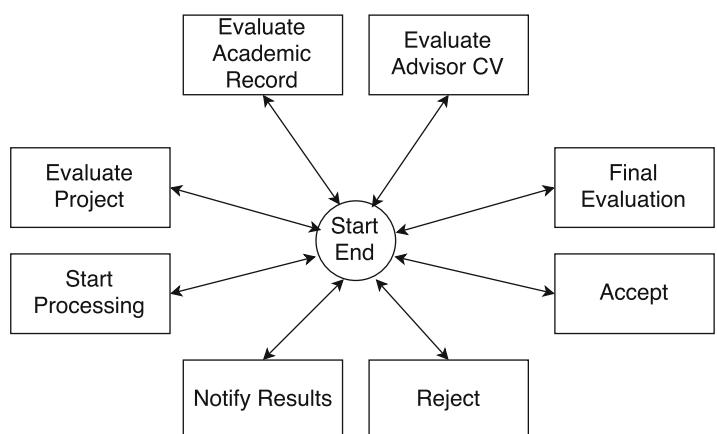

Generalization relates to a model's ability to account for yet to be observed behavior. Typically, an event log only represents a small fraction of the possible behavior in the process. As such, a good model must be generalizing enough so that unobserved but possible behavior is described. For example, if the model in Fig. 4 was discovered from an event log that contains only the trace *(Start Processing, Evaluate Project, Evaluate Academic Record, Evaluate Advisor CV, Final Evaluation, Accept, Notify Results)*, then the model would be both perfectly fitting and precise since all observed behaviors are captured by the model and that it does not allow any unseen behavior. Clearly, there is much unseen behavior that is very likely to occur in the future, e.g., the rejection of an application. This shows that, while it is important to have precise models, it is also important to avoid overfitting the observed behavior.

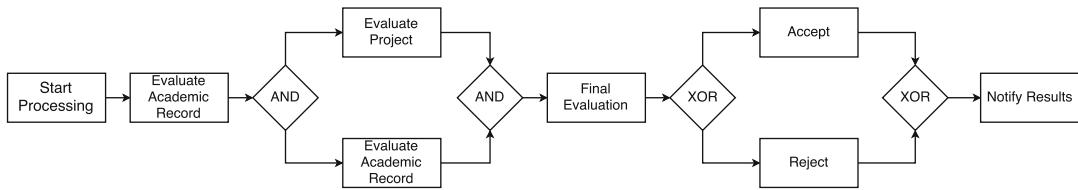

Some authors consider a fourth dimension called *simplicity*, relating to the model complexity, i.e., simple models should be preferred over

Conformance Checking, Fig. 1 Informal process model of a university scholarship process

Conformance Checking, Fig. 4 Model that overfits one particular possible execution of the doctoral scholarship process

Conformance Checking, Fig. 5 Three main types of conformance checking approaches

complex models if both describe the same behavior. However this quality dimension relates only to the model and therefore is not normally measured by conformance checking techniques. This dimension is covered in the *Automated Process Discovery* entry of this encyclopedia.

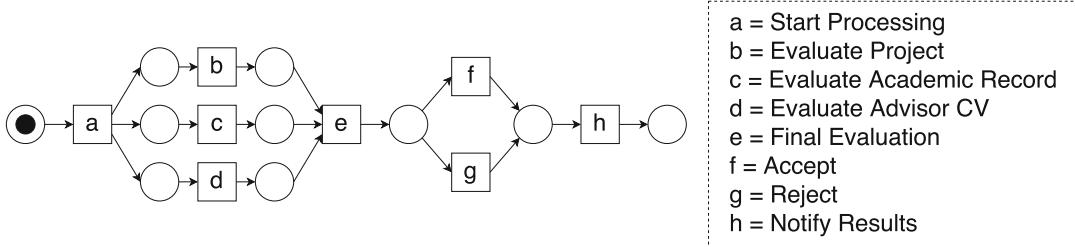

Overall, while the three quality dimensions are orthogonal to each other, in a real-life context, one is unlikely to find a pair of log and model that are in perfect conformance (i.e., perfectly fitting, precise, and generalizing). Often times, different scenarios may require different conformance levels and prioritization of the quality dimensions. For example, to analyze the well-established execution paths of a process, an analyst might prioritize fitness over the other dimensions. On the other hand, if an event log only contains a small number of cases, generalization would

likely to be prioritized over the other dimensions to account for possible future behavior.

Types of Conformance

Conformance checking techniques can be applied to understand and quantify these relationships between a log and model. There is a large collection of approaches and metrics that are based on different ways to compare a log and model.

Figure 5 shows that there are three main groups of conformance checking approaches – *replay*, *comparison*, and *alignment*. Replay-based approaches replay log traces onto the model and record information about the conformance during the replay. Process models can be denoted in different modeling notations, e.g., Business Process Modeling Notation (BPMN), Petri nets, and process trees, and each

Conformance Checking, Fig. 6 Model M_1 of the university doctoral scholarship process denoted in Petri net notation

representation bias has distinct characteristics, e.g., formalism and determinism. However, a proper process model is typically executable so that log traces can be re-executed stepwise by the model. Comparison-based approaches convert both the log and model into a common representation so that the log and model are directly comparable. Last but not least, alignment-based approaches seek to explain observed behavior in terms of modeled behavior by aligning log traces with the model. This brings conformance checking to the level of events and can offer detailed diagnosis on conformance issues.

Key Research Findings

In this section, two conformance checking approaches and three conformance metrics are presented.

Token Replay

Token replay is a replay-based conformance checking approach that measures the fitness between a log and model by replaying log traces onto process models denoted in the Petri net notation (Rozinat and van der Aalst 2008).

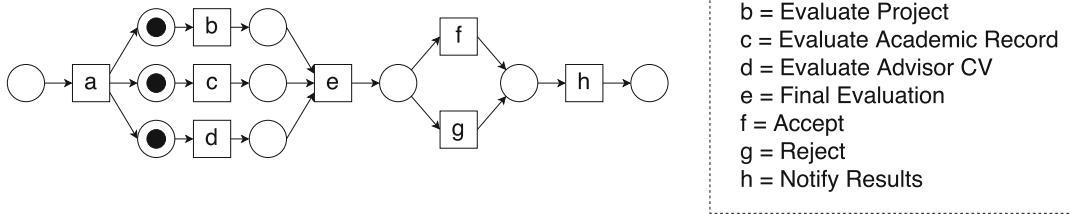

Consider model M_1 in Fig. 6 and log L_1 in Fig. 7. Model M_1 is denoted in Petri net notation so that the squares correspond to the activities in the process, filled circles correspond to tokens that mark the state of a process instance as activities get executed, and empty circles correspond to places that hold tokens. To execute an activity, all its input places (i.e., all the places connected by an incoming arrow to the activity) must have at least one token. This means that the activity

$$\begin{aligned}L_1 &= [t_1 = \langle a, b, c, d, e, f, h \rangle, \\&t_2 = \langle a, c, b, e, f, h \rangle, \\&t_3 = \langle a, b, d, c, g, e, h \rangle]\end{aligned}$$

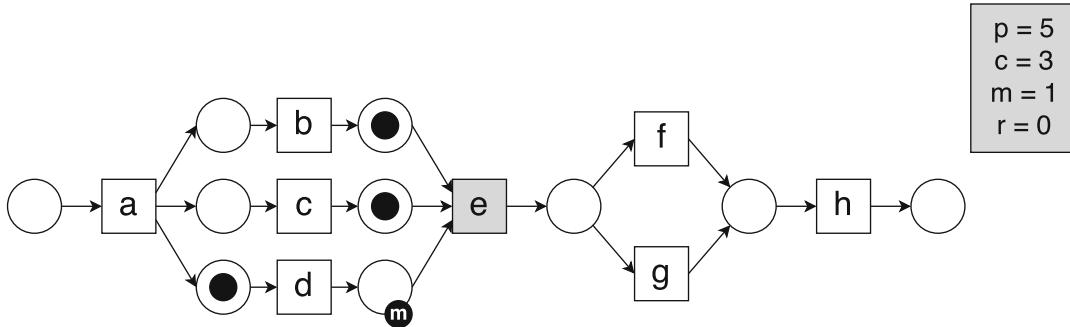

Conformance Checking, Fig. 7 Running example: event log L_1

is *enabled* and can be *fired*. When an activity is fired, the activity *consumes* a token from each of its input places before *producing* one token at each of its output places (i.e., all the places connected by an outgoing arrow from the activity). For example, activity a in model M_1 in Fig. 6 is currently enabled. If the activity is fired, it would consume the token of its input place and produce three tokens at each of its three output places as illustrated in Fig. 8. As such, an instance of the process can be recorded by successively firing enabled activities until no activities are enabled. For a valid Petri net model, an instance is initiated by having a token at each of the source places (i.e., places without any incoming arrows) and is deemed to be completed by firing activities until there is only one token at each of the sink places (i.e., places without any outgoing arrows) and none at any other places. The sequence of fired activities corresponds to a complete model trace, i.e., a possible execution of the model.

Log traces can be replayed onto the model by successively firing the activities related to each event in the log trace at an initiated Petri net model. If the log trace is perfectly fitting with the model, there should not be any problem with the replay since the log trace corresponds to a complete model trace. However, for deviating traces, replay would not be successful due to missing or

Conformance Checking, Fig. 8 Model M_1 after firing activity a

Conformance Checking, Fig. 9 Missing token to fire activity e in token replay of trace $t_2 = \langle a, c, b, e, f, h \rangle$

redundant tokens. An activity might be marked to be fired in the log trace but is not enabled in the model due to missing tokens at its input places. Consider the replay of trace t_2 in L_1 . Starting from the initial state of model M_1 as shown in Fig. 6, the firing of activity a, b, and c would consume three tokens and produce five tokens in the process. Figure 9 shows the state of model M_1 after the firing of the first three activities and records the number of consumed and produced tokens. According to trace t_2 , the next activity to be fired is activity e. However, this is not possible since one of the input places of activity e does not have any token, i.e., activity e is not enabled. To continue the replay, the missing token is artificially added into the empty input place, and the number of missing token is incremented. The rest of trace t_2 (activity f and g) can be replayed successively. Figure 10 shows that, after firing activity h, there is a remaining token in the input place of activity d since this activity was not fired in the replay of trace t_2 . As recalled, a process instance is only completed when there is only one token at each of the sink places and none at any other places. To complete the replay, the

remaining token is removed artificially, and the number of remaining tokens is incremented.

Based on the count of each token types consumed, produced, missing, and remaining ($p = 8$, $c = 8$, $m = 1$, $r = 1$), the fitness between model M_1 and trace t_2 can be computed as:

$$\begin{aligned} \text{fitness}(t_2, M) &= \frac{1}{2}(1 - \frac{m}{c}) + \frac{1}{2}(1 - \frac{r}{p}) \\ &= \frac{1}{2}(1 - \frac{1}{5}) + \frac{1}{2}(1 - \frac{1}{5}) = 0.8 \end{aligned}$$

This fitness metric can be extended to the log level by considering the number of produced, consumed, missing, and remaining tokens from the token replay of all log traces.

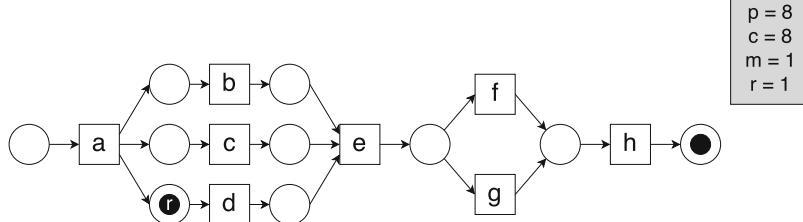

Cost-Based Alignment

The token replay approach can easily identify deviating traces in an event log. Moreover, the deviation severity can be compared using a fitness metric computed from the number of produced, consumed, missing, and remaining tokens. However, the token replay approach is prone to creat-

ing too many tokens for highly deviating traces so that any behavior is allowed. This can lead to an overestimation of the fitness. The approach is also specific to the Petri net notation. More importantly, in the case of a deviating trace, the approach does not provide a model explanation of the log trace. For example, the deviations in trace $t_2 = \langle a, c, b, e, f, h \rangle$ can be explained if it was considered with respect to the complete model trace $\langle a, c, b, d, e, f, h \rangle$. From this mapping, it is clear that the log trace is missing the execution of activity d (Evaluate Advisor CV). These mappings from log traces to model traces were introduced as *alignments* to address this limitation (van der Aalst et al. 2012).

Alignments are tables of two rows where the top row corresponds to the observed behavior (i.e., log projection) and the bottom row corresponds to the modeled behavior (i.e., model projection). Each column is therefore a move in the alignment where the observed behavior is aligned with the modeled behavior. Consider alignment γ_1 in Fig. 11. This alignment aligns

trace $t_3 = \langle a, b, d, c, g, e, h \rangle$ in L_1 and model M_1 in Fig. 6. The top row (ignoring \gg) yields the trace $t_3 = \langle a, b, d, c, g, e, h \rangle$, and the bottom row (ignoring \gg) yields a complete model trace $\langle a, b, d, c, e, g, h \rangle$. For each move in alignment γ_1 , the top row matches the bottom row if the step in the log trace matches the step in the model trace. This is called a *synchronous move*. In the case of deviations, a no-move symbol \gg is placed in the bottom row if there is a step in the log trace that cannot be mimicked by the model trace. For example, activity g is executed before activity e in trace t_3 , but model M_1 requires activity e to be fired before activity g. Hence, a *log move* is put where the top row has activity g and the bottom row has a no-move \gg . Similarly, a no-move symbol \gg is placed in the top row if there is a step in the model trace that cannot be mimicked by the log trace. For example, activity g is executed after activity e in the model trace according to model M_1 . Therefore, a *model move* is added where the top row has a no-move \gg and the bottom row has activity g. It is also possible

Conformance Checking, Fig. 10 Remaining token in token replay of trace $t_2 = \langle a, c, b, e, f, h \rangle$

$$\gamma_1 = \begin{array}{|c|c|c|c|c|c|c|c|} \hline a & b & d & c & g & e & \gg & h \\ \hline a & b & d & c & \gg & e & g & h \\ \hline \end{array} \quad \gamma_2 = \begin{array}{|c|c|c|c|c|c|c|c|} \hline a & b & d & c & \gg & g & e & \gg & h \\ \hline a & b & \gg & c & d & \gg & e & g & h \\ \hline \end{array}$$

$$\gamma_3 = \begin{array}{|c|c|c|c|c|c|c|c|} \hline a & b & d & c & \gg & g & e & h \\ \hline a & b & d & c & e & g & \gg & h \\ \hline \end{array}$$

Conformance Checking, Fig. 11 Possible alignments between trace $t_3 = \langle a, b, d, c, g, e, h \rangle$ in L_1 and model M_1 in Fig. 6

$$\gamma_4 = \begin{array}{|c|c|c|c|c|c|c|c|c|c|c|c|c|c|c|c|} \hline a & b & d & c & g & e & h & \gg \\ \hline \gg & a & b & d & c & e & g & h \\ \hline \end{array}$$

Conformance Checking, Fig. 12 Default alignment between trace t_3 in log L_1 and model M_1 in Fig. 6

that there are invisible transitions in the model which are not observable in the log. Similar to a model move, there would be a no-move in the top row and an invisible transition label in the bottom row. In total, there are four types of *legal moves* in an alignment: synchronous move, log move, model move, and invisible move.

For a particular log trace and model, there could be many possible alignments where each represents a different explanation of the observed behavior in terms of modeled behavior. For example, Fig. 11 shows three possible alignments between trace t_3 and model M_1 in Fig. 6. Clearly, alignment γ_1 and γ_3 are better alignments of trace t_3 and model M_1 than alignment γ_2 since they provide closer explanations with less log moves and model moves. The quality of an alignment can be quantified by assigning costs to moves. In general, model moves and log moves are assigned higher costs than synchronous moves because they represent deviations between modeled behavior and observed behavior. A standard cost assignment could be that all model moves and log moves are assigned a cost of 1 and synchronous moves and invisible moves are assigned a cost of 0. Invisible moves are normally assigned zero costs as they are related to invisible routing transitions in the model that are not observable in the log. Under the standard cost assignment, the costs of the alignments in Fig. 11 can be computed as follows:

$$\text{cost}(\gamma_1) = 0 + 0 + 0 + 0 + 1 + 0 + 1 + 0 = 2$$

$$\text{cost}(\gamma_2) = 0 + 0 + 1 + 0 + 1 + 1 + 0 + 1 + 0 = 4$$

$$\text{cost}(\gamma_3) = 0 + 0 + 0 + 0 + 1 + 0 + 1 + 0 = 2$$

This confirms the previous intuition that alignment γ_1 and γ_3 are better alignments than alignment γ_2 . Alignments with the minimal costs correspond to *optimal alignments* that give the clos-

est explanations of log traces in terms of modeled behavior. Note that there could be multiple optimal alignments for a particular log trace. For example, alignment γ_1 and γ_3 are both optimal alignments of trace t_3 under the standard cost assignment. Furthermore, optimal alignments are only optimal with respect to the given cost assignment. For example, alignment γ_1 would cease to be the optimal alignment if model moves and log moves of activity g are assigned a cost of 2 (i.e., $\text{cost}(\gamma_1) = 4$) to reflect that having deviations at the decision part of the process is quite severe. In practice, optimal alignments can be automatically found by finding the cheapest complete model trace in the synchronous product of the log trace and model using heuristic algorithms with proven optimality guarantees, e.g., the A* algorithm (van der Aalst et al. 2012).

Alignments can also be used to compute conformance metrics with respect to the different quality dimensions.

Cost-Based Fitness Metric

The fitness of a log trace and a model can be quantified by comparing the cost of an optimal alignment with the worst case scenario cost (Adriansyah 2014). In the worst scenario, the log trace is completely unfitting with the model. A default alignment between the two can be computed by assigning all the steps in the log trace as log moves and all the steps in the complete model trace as model moves. Since the optimal alignment minimizes the total alignment cost, the least costly complete model trace is used. Figure 12 shows the default alignment between trace t_3 and model M_1 under the standard cost assignment. The top row (ignoring \gg) yields trace t_3 , and the bottom row (ignoring \gg) yields a complete model trace $\langle a, b, d, c, e, g, h \rangle$. The cost-based fitness of trace t_3 can be computed as:

$$\begin{aligned} \text{fitness}(t_3, M) &= 1 - \frac{\text{cost}(\text{align}(t_3, M))}{\text{cost}(\text{align}_{\text{default}}(t_3, M))} \\ &= 1 - \frac{0 + 0 + 0 + 0 + 1 + 0 + 1 + 0}{1 + 1 + 1 + 1 + 1 + 1 + 1 + 1 + 1 + 1 + 1 + 1 + 1} \\ &= 1 - \frac{2}{14} = 0.857 \end{aligned}$$

where a fitness value of 1.0 means that the model and log trace are perfectly fitting.

Escaping Arc Precision

Precision based on escaping arcs can also be computed using alignments (Adriansyah et al. 2012). As previously mentioned, an imprecise model allows unobserved behavior, i.e., underfitting. For example, consider the Petri net model M_1 in Fig. 6 and the optimal alignments (under the standard cost assignment) between model M_1 and log L_1 in Fig. 13. Clearly, model M_1 is not perfectly precise as it allows for behavior that is not observed in log L_1 . According to model M_1 , activity b, c, and d can be executed in parallel following the execution of activity a. However, none of the log traces execute activity d after activity a. This imprecision in the model can be quantified by constructing a prefix automaton using the model projection of the alignments, i.e., the bottom row of the alignments. As previously presented, model projections of alignments explain potentially unfitting log traces in terms of modeled behavior so that they can be replayed on the process model. Figure 14 illustrates the constructed prefix automaton \mathcal{A}_1 for the alignments between log L_1 and model M_1 (ignoring the circles highlighted in red for now). Each prefix of the model projections of the alignments identifies a state (represented as circles), and the number in

the states corresponds to the weight. For example, the state $\langle a \rangle$ has a weight of 3 because it appears three times in the model projections (all three alignments start with activity a). On the other hand, the state $\langle a, c, b \rangle$ is only present in alignment γ_6 and therefore has a weight of 1. The states of automaton \mathcal{A}_1 represent states reached by the model during the execution of the log. For any particular state in automaton \mathcal{A}_1 , there might be activities that are enabled by the model but are not observed in the log execution. These activities indicate imprecisions of the model and are called *escaping arcs* of the model. Escaping arc states (represented as circles highlighted in red) are added to automaton \mathcal{A}_1 by replaying the automaton onto the model and checking for enabled activities at each state. For example, at state $\langle a \rangle$ (i.e., after firing activity a), activity b, c, and d are enabled as shown in Fig. 8. However, the prefix $\langle a, d \rangle$ was not observed in the construction of automaton \mathcal{A}_1 using log L_1 . This means that there is an escaping arc from state $\langle a \rangle$ to state $\langle a, d \rangle$, and this is added to the automaton by the state highlighted in red. The rest of the escaping arcs can be added in a similar way.

With the constructed prefix automaton, escaping arc precision can be computed by comparing the number of escaping arcs with the number of allowed arcs for all states:

$$\begin{aligned} precision(\mathcal{A}_1) &= 1 - \frac{\sum_{s \in S} \omega(s) \cdot |esc(s)|}{\sum_{s \in S} \omega(s) \cdot |mod(s)|} \\ &= 1 - \frac{3 \cdot 0 + 3 \cdot 1 + 2 \cdot 0 + \dots + 1 \cdot 1 + 1 \cdot 0 + 1 \cdot 0}{3 \cdot 1 + 3 \cdot 3 + 2 \cdot 2 + \dots + 1 \cdot 2 + 1 \cdot 1 + 1 \cdot 1} \\ &= 1 - \frac{6}{36} = 0.833 \end{aligned}$$

where S is the set of states in automaton \mathcal{A}_1 , $\omega(\cdot)$ maps a state $s \in S$ to its weight, $esc(\cdot)$ maps a state $s \in S$ to its set of escaping arc states, and $mod(\cdot)$ maps a state $s \in S$ to its set of allowed states. A precision value of 1.0 indicates perfect precision, i.e., the model only allows observed behavior and nothing else.

Artificial Negative Events

Another approach to measure precision is through artificial negative events. Artificial negative events are induced by observing events that did not occur in the event log. These unobserved events (i.e., negative events) give information about things that are not allowed to

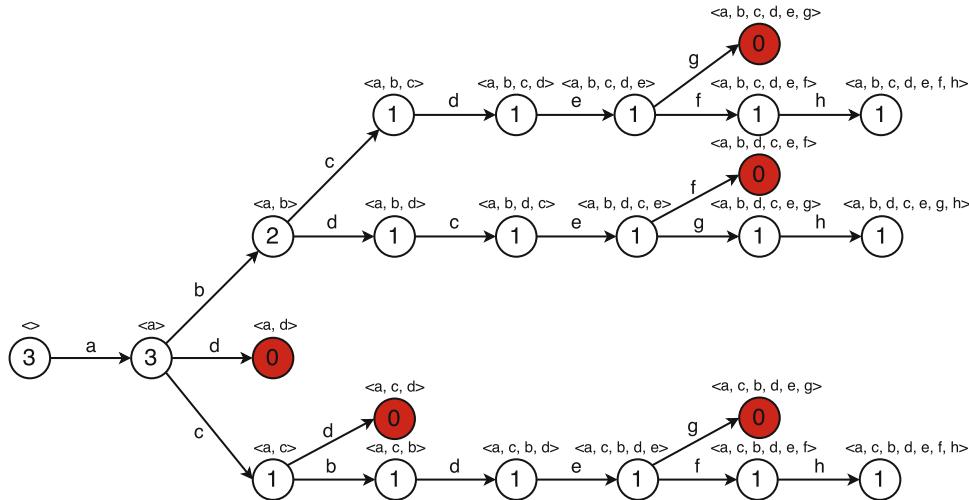

Conformance Checking,

Fig. 13 Optimal alignments between trace t_1, t_2, t_3 in $\log L_1$ and model M_1 in Fig. 6

$$\gamma_5 = \begin{vmatrix} a & b & c & d & e & f & h \\ a & b & c & d & e & f & h \end{vmatrix} \quad \gamma_6 = \begin{vmatrix} a & c & b & \gg & e & f & h \\ a & c & b & d & e & f & h \end{vmatrix}$$

$$\gamma_7 = \begin{array}{|c|c|c|c|c|c|c|c|c|} \hline & a & b & d & c & \gg & g & e & h \\ \hline a & b & d & c & e & g & \gg & h \\ \hline \end{array}$$

C

Conformance Checking, Fig. 14 Prefix automaton \mathcal{A}_1 of alignments between log L_1 and model M_1 enhanced with model behavior

occur in the process. Assuming that the event log gives a complete view of the process (i.e., a log completeness assumption), the precision of the process model can be computed using artificial negative events and the concepts of precision and recall in data mining.

Artificial negative events can be induced by grouping similar traces and then observing the events that did not occur for every event in the traces. Under the log completeness assumption, this means that these unobserved events are negative events that are not allowed to happen by the process (Goedertier et al. 2009).

The process model can then be compared with the log by treating the model as a predictive model. For a given incomplete event sequence (i.e., an unfinished process instance), activities that are permitted by the model and observed in the log are classified as true positives (TP). Activities that are permitted by the model but

are induced as negative events from the log are classified as false positive (FP). Activities that are not permitted by the model but observed in the log are classified as false negative (FN). Finally, activities that are not permitted by the model and are induced as negative events from the log are classified as true negative (TN). As shown in Fig. 15, precision and recall can be computed using a confusion matrix. Specifically, the precision of the positive class can be computed as:

$$precision = \frac{TP}{TP + FP}$$

The computed precision value corresponds to the precision of the three quality dimensions in process mining since it refers to the proportion of modeled behavior that is observed in the log.

The use of artificial negative events can also be extended to quantify generalization and to com-

	Actual Positive	Actual Negative
Predicted Positive	True Positive (TP)	False Positive (FP)
Predicted Negative	False Negative (FN)	True Negative (TN)

Conformance Checking, Fig. 15 Confusion matrix

pute a precision metric that is more robust against less complete event logs. This is achieved by extending the artificial negative event induction strategy to assign weights to the induced negative events (vanden Broucke et al. 2014).

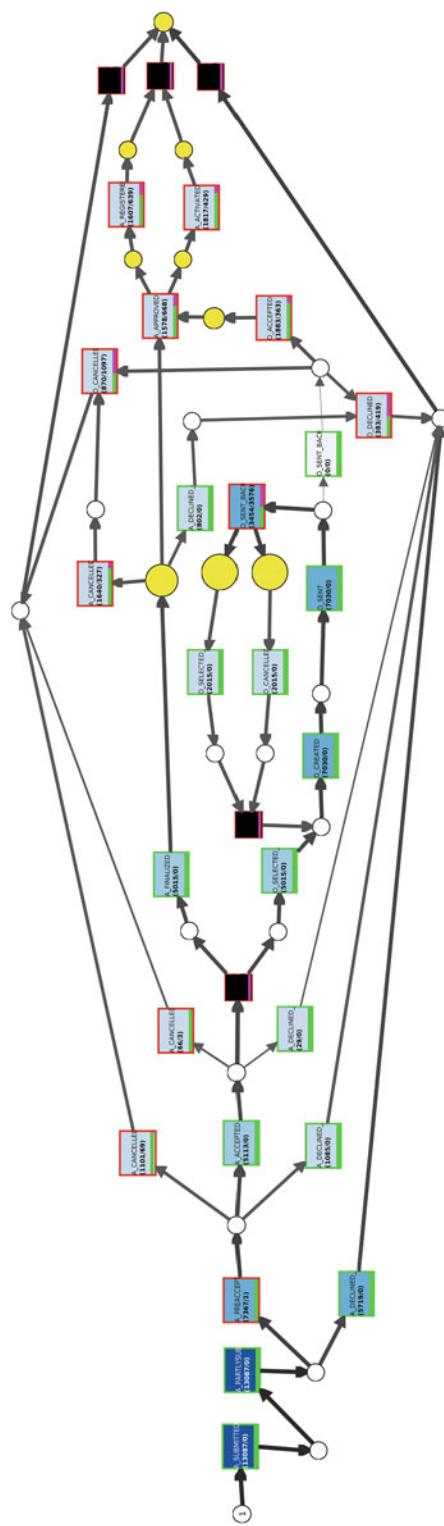

Examples of Application

All of the conformance checking techniques presented in the previous section have been implemented and are applicable to most real-life scenarios. In the following, the A* cost-based alignment technique is applied to a real-life dataset to illustrate how conformance checking can be applied to gain insights about a process. This example utilizes the data presented in the “Conformance Checking: What does your process do when you are not watching?” tutorial by de Leoni, van Dongen, and Munoz-Gama at the “15th International Conference on Business Process Management (BPM17).”

As previously presented, a process model and an event log are required to perform conformance checking. The real-life event log is taken from a Dutch financial institute and is of an application process for a personal loan or overdraft within a global financial organization (van Dongen 2012). This means that each case in the log records the occurred events of a particular loan application. The log contains some 262,200 events in

13,087 cases. Apart from some anonymization, the data is presented as it is recorded in the financial institute. The log is merged from three intertwined subprocesses so that the originating subprocess of each event can be identified by the first letter of the activity recorded by the event. In this example, the log is filtered so that it only contains events from two of the subprocesses: the process which records the state of the application (identifiable by “A_”) and the process which records the state of an offer communicated to the applicant (identifiable by “O_”). The model has been created with the help of domain experts and can be assumed to be a realistic representation of the underlying process.

Figure 16 shows the process model projected with the computed alignment results to allow a visual diagnosis of the conformance results. For each transition, there is an error bar to show the distribution of synchronous moves (green) and model moves (pink) for the transition. For example, there are 383 synchronous moves and 419 model moves related to transition *O_DECLINED*. The occurrence and amount of log moves are indicated by highlighting places in yellow and the size of the highlighted places. Observing the model, one can note that transition *O_SENT_BACK* is associated with a large amount of model moves. This transition is quite an important part of the process as it corresponds to the event where the financial institute receives a reply from the applicant after a loan offer is made. A model move of *O_SENT_BACK* in a log trace means that the system did not register a reply from the applicant regarding a made offer as required by the process for the corresponding loan application. Investigation of cases with a model move in *O_SENT_BACK* (e.g., the case with caseId 174036) would show that there are cases for which an offer was created, sent, and accepted without having received a reply from the corresponding applicant. Whether it was due to a system error, an employee’s mistake, or at worst a fraudulent case, clearly it is in the financial institute’s best interest to investigate the root cause of this conformance issue.

Conformance Checking, Fig. 16 Process model projected with alignment results

Future Directions for Research

While there have been significant advances in the research of conformance checking over the recent years, there are still many open challenges and research opportunities. Some of them include:

Conformance Dimensions

The proposed three quality dimensions (fitness, precision, and generalization) have been widely accepted, but there is still a need for further understanding on how to interpret and quantify them through metrics. Furthermore, conformance can be extended beyond the current three dimensions, e.g., log completeness to quantify whether if the observed event data gives the full picture of the underlying process (Janssenswillen et al. 2017).

Big Data and Real Time

Process mining techniques and tools are getting applied to larger and more complex processes. This means that they have to be scalable to handle the increased size and complexity. In fact, much of the recent research efforts in conformance checking have been focused on this issue. Related research lines include decomposed conformance checking (Munoz-Gama 2016) and online conformance checking for event streams (Burattin 2015).

Conformance Diagnosis and Process

Model Repair

It is not enough to just identify conformance issues; good diagnostic and visualization tools are crucial in helping the analyst identify and understand the root causes of the conformance issues. While there has been work done in this aspect of conformance checking, e.g., Buijs and Reijers (2014) and Munoz-Gama et al. (2014), there is much more to be done to provide better conformance diagnosis technology, e.g., new techniques and user study. Finally, once the differences between the model and the log have been diagnosed, the user may wish to repair the model in order to fix such differences and achieve a model that better describes the real process

executed. This topic is extensively covered in the *Process Model Repair* entry of this encyclopedia.

Continuous Queries

Martin Hirzel

IBM Research AI, Yorktown Heights, NY, USA

C

Synonyms

Streaming SQL queries; Stream-relational queries; StreamSQL queries

Definitions

A continuous query in an SQL-like language is a declarative query on data streams expressed in a query language for streams derived from the SQL for databases.

Overview

Just like data that is stored in a relational database can be queried with SQL, data that travels in a stream can be queried with an SQL-like query language. For databases, the relational model and its language, SQL, have been successful because the relational model is a foundation for clean and rigorous mathematical semantics and because SQL is declarative, specifying what the desired result is without specifying how to compute it (Garcia-Molina et al. 2008). However, the classic relational model assumes that data resides in relations in a database. When data travels in a stream, such as for communications, sensors, automated trading, etc., there is a need for continuous queries. SQL dialects for continuous queries fill this need and inherit the advantages of SQL and the relational model. Furthermore, SQL-like streaming languages capitalize on the familiarity of SQL for developers and of implementation techniques from relational databases.

There are various different SQL-like streaming languages. This article illustrates concepts using CQL (the continuous query language, Arasu et al. (2006)) as a representative example, because it has clean semantics and addresses the interplay between streams and relations.

Section “[Findings](#)” explores other SQL-like streaming languages beyond CQL.

SQL-Like Syntax

The surface syntax for streaming SQL dialects borrows familiar SQL clauses (such as select,

from, and where) and augments them with streaming constructs (which turn streams into relations and vice versa). Consider the following CQL (Arasu et al. 2006) query with extensions adapted from Soulé et al. (2016):

```

1 Quotes : { ticker : string, ask : int } stream;
2 History : { ticker : string, low : int } relation;
3 Bargains : { ticker : string, ask : int, low : int } stream
4   = select istream(*)
5     from Quotes[now], History
6     where Quotes.ticker == History.ticker and Quotes.ask <= History.low;
```

Line 1 declares *Quotes* as a stream of {*ticker*, *ask*} tuples, and Line 2 declares *History* as a relation of {*ticker*, *low*} tuples. Neither *Quotes* nor *History* is defined with a query in the example. Lines 3–6 declare *Bargains* and define it with a query. Line 3 declares *Bargains* as a stream of {*ticker*, *ask*, *low*} tuples. Line 4 specifies the output using the **istream** operator, which creates a stream from the insertions to a relation, using * to pick up all available tuple attributes. Line 5 joins two relations, *Quotes[now]* and *History*, where *Quotes[now]* creates a relation from the

current contents of stream *Quotes*. Finally, Line 6 selects only tuples satisfying the given predicate, whereas any tuples for which the predicate is false are dropped.

The above example illustrates the core features of CQL, viz.: using operators such as **now** to turn streams into relations, using SQL to query relations, and using operators such as **istream** to turn relations into streams. For more detail, the following paragraphs explain the CQL grammar, starting with the top-level syntax:

```

program ::= decl+
decl   ::= ID `:` tupleType declKind (‘=’query)? `;`
tupleType ::= ‘{’(ID `:` TYPE)+, ‘}’
declKind ::= ‘relation’ | ‘stream’
query   ::= select from where? groupBy?
```

A program consists of one or more declarations. Each declaration has an identifier (*ID*), a tuple type (one or more attributes specified by their identifiers and types), a declaration kind (either **relation** or **stream**), and an optional query. The grammar meta-notation contains superscripts

for optional items (*X?*), repetition (*X⁺*), and repetition separated by commas (*X⁺,*). Finally, a query consists of mandatory select and from clauses and optional where and group-by clauses. Next, we look at the grammar for the select clause, which specifies the query output:

```

select      ::= ‘select’ outputList | ‘select’ relToStream ‘(’ outputList ‘)’
relToStream ::= ‘istream’ | ‘dstream’ | ‘rstream’
outputList  ::= ‘*’ | projectItem+, | aggrItem+,
projectItem ::= expr (‘as’ ID)?
aggrItem   ::= AGGR ‘(’ ID*, ‘)’(‘as’ ID)?
```

A select clause either specifies an output list directly or wraps an output list in a relation-to-stream operator. In the first case, the query output is a relation, while in the second case, the query output is a stream. There are three relation-to-stream operators: **istream** captures insertions, **dstream** captures deletions, and **rstream** captures the entire relation at any given point in time.

Here, a relation at a given point in time is a bag of tuples (i.e., an unordered collection of tuples that can contain duplicates). A stream is an unbounded bag of timestamped tuples (pairs of $\langle \text{timestamp}, \text{tuple} \rangle$). The grammar for *outputList* is borrowed from SQL. Next, we look at the grammar for the *from* clause, which specifies the query input:

```

from      ::= 'from' inputItem+,
inputItem ::= ID ('[' streamToRel ']')? ('as' ID)?
streamToRel ::= 'now' | 'unbounded' | timeWindow | countWindow
timeWindow ::= partitionBy? 'range' TIME ('slide' TIME)?
countWindow ::= partitionBy? 'rows' NAT ('slide' NAT)?
partitionBy ::= 'partition' 'by' ID+

```

An input item either identifies a relation directly or applies a stream-to-relation operator to a stream identifier. Stream-to-relation operators are written postfix in square brackets, reminiscent of indexing or slicing syntax in other programming languages. There are four such operators: **now** (tuples with the current timestamp), **unbounded** (tuples up to the current timestamp), **range** (time-based sliding window), and **rows** (count-based sliding window). Sliding windows can optionally be partitioned, in which case their size is determined separately and independently for each unique combination of the specified partitioning attributes. Sliding windows can optionally specify a slide granularity. Finally, we look at the grammar for *where* and *groupBy* as examples of other classic SQL clauses:

```

where    ::= 'where' expr
groupBy ::= 'group' 'by' ID+

```

The *where* clause selects tuples using a predicate expression, and the *group-by* clause specifies the scope for aggregation queries. These clauses in CQL are borrowed unchanged from SQL. For brevity, we omitted other classic SQL constructs, such as *distinct*, *union*, *having*, or other types of joins, which streaming SQL dialects such as CQL can borrow from SQL as is.

Typically, before execution, queries in SQL or its derivatives are first translated into a logical query plan of operators, which is the subject of the next section.

Stream-Relational Algebra

Whereas the SQL-like syntax of the previous section is designed to be authored by humans, this section describes an algebra designed to be optimized and executed by stream-query engines. The algebra is stream-relational because it augments with stream operators the relational algebra from databases. Relational algebra has well-understood semantics (Garcia-Molina et al. 2008), and the CQL authors rigorously defined the formal semantics for the additional streaming operators (Arasu and Widom 2004). The following paragraphs provide only an informal overview of the operators; interested readers can consult the literature for formal treatments. The notation for operator signatures is:

$$\text{operator}_{\langle \text{configuration} \rangle}(\text{input}) \rightarrow \text{output}$$

The configuration of an operator specializes its behavior. The input to an operator consists of one or multiple relations or a stream. And the output of an operator consists of either a relation or a stream. Relational algebra is compositional, since the output of one operator can be plugged

into the input of another operator, modulo compatible kind and type. For instance, the stream-relational algebra for stream *Bargains* in the CQL

$$\text{istream}\left(\sigma_{\langle \text{ask} \leq \text{low} \rangle} \left(\bowtie_{\langle \text{Quotes.ticker} = \text{History.ticker} \rangle} (\text{now}(\text{Quotes}), \text{History}) \right) \right)$$

Classic relational algebra has operators from relations to relations (Garcia-Molina et al. 2008):

- $\pi_{\langle \text{assignments} \rangle}(\text{relation}) \rightarrow \text{relation}$
Project each input tuple using assignments to create a tuple in the output relation.
- $\sigma_{\langle \text{predicate} \rangle}(\text{relation}) \rightarrow \text{relation}$
Select tuples for which the predicate is true, and filter out tuples for which it is false.
- $\bowtie_{\langle \text{predicate} \rangle}(\text{relation}^+) \rightarrow \text{relation}$
Join tuples from input relations as if with a cross product followed by $\sigma_{\langle \text{predicate} \rangle}$.
- $\gamma_{\langle \text{groupBy}, \text{assignments} \rangle}(\text{relation}) \rightarrow \text{relation}$
Group tuples and then aggregate within each group, using the given assignments.

For brevity, we omitted other classic relational operators, but they could be added trivially, thanks to the compositionality of the algebra. CQL can use the well-defined semantics of classic relational algebra operators by applying them on snapshots of relations at a point in time. Some operators, such as π and σ , process each tuple in isolation, without carrying any state from one tuple to another (Xu et al. 2013). These operators could be easily lifted to work on streams, and indeed, some streaming SQL dialects do just that. But the same is not true for stateful operators such as \bowtie and γ . To use these on streams, CQL first converts streams to relations, using window operators:

- **now(stream) \rightarrow relation**
At each time instant t , all tuples from the input stream with timestamp exactly t .
- **unbounded(stream) \rightarrow relation**
At each time instant t , all tuples from the input stream with timestamp at most t .

example from the start of section “[SQL-Like Syntax](#)” is:

- **range_{(partitionBy, size, slide)?}(stream) \rightarrow relation**
Use a time-based sliding window on the input stream as the output relation.
- **rows_{(partitionBy, size, slide)?}(stream) \rightarrow relation**
Use a count-based sliding window on the input stream as the output relation.

These window operators correspond directly to the corresponding surface syntax discussed in section “[SQL-Like Syntax](#)”. Gedik surveyed these and more window constructs and their implementation (Gedik 2013). A final set of operators turns relations back into streams:

- **istream(relation) \rightarrow stream**
Watch input relation for insertions, and send those as tuples on the output stream.
- **dstream(relation) \rightarrow stream**
Watch input relation for deletions, and send those as tuples on the output stream.
- **rstream(relation) \rightarrow stream**
At each time instant, send all tuples currently in input relation on output stream.

This article illustrated continuous queries in SQL-like languages using CQL as the concrete example, because it is clean and well studied. The original CQL work contains more details and a denotational semantics (Arasu et al. 2006; Arasu and Widom 2004). Soulé et al. furnish CQL with a static type system and formalize translations from CQL via stream-relational algebra to a calculus with an operational semantics (Soulé et al. 2016).

Findings

CQL was not the first dialect of SQL for streaming. TelegraphCQ reused the front-end of PostgreSQL as the basis for its surface language (Chandrasekaran et al. 2003). Rather than focusing on surface language innovation, TelegraphCQ focused on a stream-relational algebra back-end that pioneered new techniques for dynamic optimization and query sharing. Gigascope had its own dialect of SQL called GSQL (Cranor et al. 2003). Unlike CQL, GSQL used an algebra where all operators work directly on streams. As discussed earlier, this is straightforward for π and σ , but not for \bowtie and γ . Therefore, GSQL required \bowtie and γ to be configured with constraints over ordering attributes that effectively function as windows. Aurora used a graphical interface for surface-level programming, but we still consider it an SQL-like system, because it used a stream-relational algebra (Abadi et al. 2003). Aurora’s Stream Query Algebra (SQuAl) contained the usual operators π , σ , \bowtie , and γ , as well as union, sort, and a resample operator that interpolates missing values.

CQL took a more language-centric approach than its predecessors. It also inspired work probing semantic subtleties in SQL-like streaming languages. Jain et al. precisely define the semantics for the corner case of StreamSQL behavior where multiple tuples have the same timestamp (Jain et al. 2008). In that case, there is no inherent order among these tuples, so tuple-based windows must choose arbitrarily, leading to undefined results. Furthermore, if actions are triggered on a per-tuple basis, there can be multiple actions at a single timestamp, leading to spurious intermediate results that some would consider a glitch. The SECRET paper is also concerned with problems of time-based sliding windows (Botan et al. 2010). SECRET stands for ScopE (which timestamps belong to a window), Contents (which tuples belong to a window), REport (when to output results), and Tick (when to trigger computation). Finally, Zou et al. explored turning repeated SQL queries into con-

tinuous CQL queries by turning parameters that change between successive invocations into an input stream (Zou et al. 2010).

Today, there is still much active research on big-data streaming systems, but the focus has shifted from SQL dialects to embedded domain-specific languages (EDSLs, Hudak 1998). An EDSL for streaming is a library in a host language that offers abstractions for continuous queries. In practice, most EDSLs lack the rigorous semantics of stand-alone languages such as CQL but have the advantage of posing a lower barrier to entry for developers who are already proficient in the host language, being easier to extend with user-defined operators, and not requiring a separate language tool-chain (compiler, debugger, integrated development environment, etc.).

C

Examples

The beginnings of sections “[SQL-Like Syntax](#)” and “[Stream-Relational Algebra](#)” show a concrete example of the same query in CQL and in stream-relational algebra, respectively. The most famous example of a set of continuous queries written in an SQL-like language is the Linear Road benchmark. The benchmark consists of computing variable-rate tolling for congestion pricing on highways. A simplified version of Linear Road serves to motivate and illustrate CQL (Arasu et al. 2006). The full version of Linear Road is presented in a paper of its own (Arasu et al. 2004). Both the simplified version and the full version of the benchmark continue to be popular, and not just for SQL-inspired streaming systems and languages (Grover et al. 2016; Hirzel et al. 2016; Jain et al. 2006; Soulé et al. 2016).

Future Directions for Research

Stream processing is an active area of research, and new papers often use a streaming SQL foundation to present their results. One challenging issue for streaming systems is how to handle
